JOSEPH WENESER	L. I. SCHIFF	P. J. PRICE

Manuscripts for publication should be submitted to S. PASTERNACK, Editor, *The Physical Review,* Brookhaven National Laboratory, Upton, New York 11973. The authors' institutions are requested to pay a publication charge of $60 per page which, if honored, entitles them to 100 free reprints. An additional $10 will be requested for prepublication of the abstract in *Physics Abstracts.* Instructions will be sent with galley proofs.

Proof and all correspondence concerning papers in the process of publication should be addressed to the Supervisor, Editorial Department, American Institute of Physics, 335 East 45 Street, New York, New York 10017. Reference must be made to title, author, journal, and scheduled date of publication.

Subscription Price

	U.S.A., Canada, and Mexico	Elsewhere
Members of The American Physical Society	$15.00	$17.00
Nonmembers	40.00	43.00

Back Numbers

Yearly back-number rate when complete year is available:

Prior to 1929, and 1942 to 1946, inclusive	**$30.00**
1929 to 1963 except 1942 to 1946, inclusive	**$45.00**
1964 and thereafter	**$50.00**

Single copies: $3.00 each. *Index issue* (1964 and thereafter): $2.00 each.

General index, 1921–1950: Paper binding, **$10** (Members); **$14** (Nonmembers)
Cloth binding, **$12** (Members); **$16** (Nonmembers)

Author index, 1956–1960: Paper binding, **$ 2** (Members); **$ 3** (Nonmembers)

Subscriptions, renewals, orders for back numbers, and changes of address should be addressed to the Circulation Department, American Institute of Physics, 335 East 45 Street, New York, New York 10017. For change of address, allow at least six weeks' advance notice; send both old and new addresses and, if possible, please include an address stencil imprint from the mailing envelope of a recent issue.

Permission is granted to quote from this journal in scientific articles, with the customary acknowledgment of the source. Reproduction of figures and tables is permitted provided that the author's consent is obtained and that the editorial office is notified. Reproduction of whole articles for commercial purposes requires written permission of both Editor and author.

The Physical Review is published weekly at Prince and Lemon Streets, Lancaster, Pennsylvania 17604.

Second-class postage paid at Lancaster, Pa.

THE PHYSICAL REVIEW

A journal of experimental and theoretical physics established by E. L. Nichols in 1893

SECOND SERIES, VOL. 134, No. 4A 18 MAY 1964

Resonant Frequencies of an Electromagnetic Cavity in an Accelerated System of Reference*

C. V. HEER
Department of Physics, Ohio State University, Columbus, Ohio
(Received 27 December 1963)

The resonant frequencies of an electromagnetic cavity in a nonpermanent gravitational field such as that provided by rotation is considered. The constitutive equations for accelerated macroscopic matter are developed and it is shown that the electromagnetic-field tensors are related by $H_{xt}=K_eF_{xt}$ and, $K_mH^{xy}=F^{xy}$, etc. For the special case of angular rotation about the z axis the constitutive equations are given in terms of noncovariant field vectors **B**, **H**, **D**, **E**. Using these constitutive equations Maxwell's equations are solved, and it is shown that the degeneracy between the axially degenerate modes, i.e., clockwise and counterclockwise traveling waves, is removed by the rotation. In vacuum due to the similarity between energy flux and momentum a shift in frequency of $\boldsymbol{\Omega}\cdot\mathbf{J}/\hbar$ or a splitting between traveling wave modes of $2\boldsymbol{\Omega}\cdot\mathbf{J}/\hbar$ is predicted. This led to a suggestion of the "Coriolis-Zeeman" effect for photons. Using either the above development or the energy density it is shown that the effect depends on the moment of the energy flux and is only proportional to the angular momentum. In the geometrical-optics region an index of refraction valid for accelerated macroscopic matter is developed and is applied to the square Fabry-Perot cavity rate gyroscope to yield the same result as either of the above methods. An experiment to show the validity of Minkowski's decomposition of the energy-momentum tensor is discussed.

INTRODUCTION

THE effect of acceleration on the resonant frequencies of an electromagnetic resonant structure or cavity is considered in this paper. Interference of light rays in a rotating system was suggested by Michelson as early as 1904 on the basis of the ether.[1] The observations of subsequent workers[2] confirmed the measurement of rotation by the interference technique and Michelson and Gale succeeded in measuring the angular rotation of the earth.[3] With the advent of the general theory of relativity it was shown that problems related to light transmission in accelerated frames of reference were more properly treated within the framework of general relativity. Adopting this viewpoint the author suggested that in rotating resonant-electromagnetic structures the degeneracy of the traveling wave modes about the axis of rotation would be removed by rotation and a beat frequency between the two modes of $2m\Omega$ would be observed.[4] This work was extended to optical masers[5] and confirmed by the experiments of Macek and Davis,[6] and Cheo and Heer.[7] It is the purpose of this paper to extend this earlier work.

In order to pursue the subject in a systematic manner the general principle of relativity that all systems of reference are equivalent with respect to the fundamental laws of physics is invoked. This requirement that the laws of nature be expressible in the form of equations which are form invariant or covariant is made possible by incorporating the metric $g_{\alpha\beta}$ into the physical laws. The $g_{\alpha\beta}$ are defined by the quadratic form

$$ds^2=g_{\alpha\beta}dx^\alpha dx^\beta. \quad (1)$$

For a system which is rotating with angular velocity Ω about the z axis and described by coordinates $x^1=x$, $x^2=y$, $x^3=z$, $x^4=ct$, the symmetric tensor $g_{\alpha\beta}$ has

the following nonzero covariant and contravariant components.

$$\begin{aligned} &g_{xx}=g_{yy}=g_{zz}=1; && g_{xt}=g^{xt}=(-\Omega y/c);\\ &g_{yt}=g^{yt}=(\Omega x/c); && g^{xx}=(1-\Omega^2y^2/c^2);\\ &g^{yy}=(1-\Omega^2x^2/c^2); && g^{zz}=1; \qquad (2)\\ &g^{xy}=(\Omega^2xy/c); && g_{tt}=-[1-\Omega^2(x^2+y^2)/c^2];\\ &g^{tt}=-1; && \det g\equiv g=-1. \end{aligned}$$

Of the simple systems, i.e., constant linear velocity, linear acceleration, and angular rotation, only angular rotation does not permit the introduction of an instantaneous rest frame for the entire system and the metric cannot be placed in diagonal form. This aspect of the metric is considered in some detail by Möller.[8] It is also for this reason that effects of the order of v/c are observed in the rotating system. Thus, the experiment of Michelson can be explained by regarding the trajectory of a light ray as given by $ds^2=0$.

Maxwell's Equations

Following the procedure suggested in the Introduction, Maxwell's equations are written in a covariant form in an instantaneous rest frame, and by the rules of tensor algebra, remain valid in an arbitrary frame. For macroscopic matter Maxwell's equations in covariant form are

$$\frac{\partial F_{\alpha\beta}}{\partial x^\gamma}+\frac{\partial F_{\beta\gamma}}{\partial x^\alpha}+\frac{\partial F_{\gamma\alpha}}{\partial x^\beta}=0,$$

and

$$(-g)^{-1/2}\frac{\partial}{\partial x^\beta}[(-g)^{1/2}H^{\alpha\beta}]=j^\alpha. \qquad (3)$$

In the subsequent discussion $g_{\alpha\beta}$ remains dimensionless, $F_{\alpha\beta}$ and $H^{\alpha\beta}$ have the dimensions of (energy)$^{1/2}$, and the m.k.s. system of units is used. Although $F_{\alpha\beta}$ and $H^{\alpha\beta}$ can be written in terms of a polar vector and an axial vector in a covariant manner, a noncovariant notation[9] is found more convenient and consistent with conventional techniques. Nonconvariant vectors are defined as

$$\begin{aligned} &\epsilon_0^{1/2}E_x=F_{xt}; && \mu_0^{-1/2}B_x=\tfrac{1}{2}\delta_{xyz}F_{yz}; && \mu_0^{1/2}J_x=j^x;\\ &\epsilon_0^{-1/2}D_x=H^{tx}; && \mu_0^{1/2}H_x=\tfrac{1}{2}\delta_{xyz}H^{yz}; && \epsilon_0^{-1/2}\rho=j^t; \end{aligned} \qquad (4)$$

where δ_{xyz} is the three-dimensional Levi-Cevita symbol. Maxwell's equations take on their conventional appearance in this notation,

$$\begin{aligned} &\mathrm{curl}\mathbf{E}+\partial\mathbf{B}/\partial t=0, && \mathrm{div}\mathbf{B}=0,\\ &\mathrm{curl}\mathbf{H}-\partial\mathbf{D}/\partial t=\mathbf{J}, && \mathrm{div}\mathbf{D}=\rho, \end{aligned} \qquad (5)$$

but the operations curl and div are defined only for Cartesian ordering of the differentiation.

[8] C. Möller, *The Theory of Relativity* (Oxford University Press, London, 1957).
[9] J. Plebanski, Phys. Rev. 118, 1396 (1960).

Instantaneous Rest Frame

Using the rules of tensor algebra for two systems of coordinates which are related by

$$\begin{aligned} &dX^\Phi=\bar{A}^\Phi{}_\alpha dx^\alpha, && dx^\alpha=A^\alpha{}_\Phi dX^\Phi,\\ &\bar{A}^\Phi{}_\alpha A^\alpha{}_\Psi=\delta^\Phi{}_\Psi, && A^\alpha{}_\Psi\bar{A}^\Psi{}_\beta=\delta^\alpha{}_\beta, \end{aligned} \qquad (6)$$

the covariant and contravariant components of a tensor transform as

$$T_{\alpha\beta}=\bar{A}^\Phi{}_\alpha\bar{A}^\Psi{}_\beta T_{\Phi\Psi}, \quad \text{and} \quad T^{\alpha\beta}=A^\alpha{}_\Phi A^\beta{}_\Psi T^{\Phi\Psi}. \qquad (7)$$

Following the procedure discussed by Möller[8] an instantaneous rest frame is regarded as a system of inertia for which $G_{XX}=G_{YY}=G_{ZZ}=1$ and $G_{TT}=-1$. If (x,y,z,ct) and (X,Y,Z,cT) are regarded as instantaneously at rest with respect to each other, then

$$A^x{}_T=\bar{A}^X{}_t=0. \qquad (8)$$

Since $g_{\alpha\beta}$ is a tensor, the components of the metric $g_{\alpha\beta}$ are related to those in the instantaneous rest frame by

$$g_{\alpha\beta}=\bar{A}^\Phi{}_\alpha\bar{A}^\Psi{}_\beta G_{\Phi\Psi}. \qquad (9)$$

For subsequent reference,

$$g_{tx}=-\bar{A}^T{}_t\bar{A}^T{}_x, \quad \text{and} \quad g_{tt}=-\bar{A}^T{}_t\bar{A}^T{}_t. \qquad (10)$$

Also in the remainder of this paper capital Greek or Latin indices refer to the instantaneous rest frame, small indices refer to the frame under consideration, and repeated Greek letters are summed over the four indices. Repeated Latin letters are summed over only the space indices.

CONSTITUTIVE EQUATIONS

For vacuum $H^{\alpha\beta}=F^{\alpha\beta}$, and the relationship between **B**, **H**, **E** and **D** follow immediately from the transformation $F^{\alpha\beta}=g^{\alpha\mu}g^{\beta\gamma}F_{\mu\gamma}$. Macroscopic matter requires further elaboration. A procedure similar to that used by Minkowski for introducing the constitutive equations in special relativity is used to find the constitutive equations in a nonpermanent gravitational field. For isotropic dielectric and paramagnetic substances the constitutive equations in an instantaneous rest frame have their usual form

$$D_X=K_e\epsilon_0E_X, \quad B_X=K_m\mu_0H_X; \quad J_X=\sigma E_X \qquad (11)$$

in noncovariant notation. K_e is the dielectric constant, K_m the magnetic constant, and σ the electrical conductivity. In the instantaneous rest frame there is no distinction between covariant and contravariant components and these constitutive equations may be written as

$$\begin{aligned} &H_{XT}=K_eF_{XT}; \quad F_{YZ}=K_mH_{YZ};\\ &j_X=(\mu_0/\epsilon_0)^{1/2}\sigma F_{XT}; \quad j^T=\epsilon_0^{-1/2}\rho_I. \end{aligned} \qquad (12)$$

In any other frame of reference the components follow from the rules given by Eqs. (7) and (8). Thus

$$F_{xt}=\bar{A}^X{}_x\bar{A}^T{}_tF_{XT} \quad (\text{sum } X \text{ only}), \qquad (13a)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and similar expressions follow for H_{xt}. A simple relationship between H_{xt} and F_{xt} follows, i.e.,

$$H_{xt}=\bar{A}^{X}{}_{x}\bar{A}^{T}{}_{t}H_{XT}=K_{e}\bar{A}^{X}{}_{x}\bar{A}^{T}{}_{t}F_{XT}=K_{e}F_{xt}. \quad (13b)$$

Following a similar procedure for F^{xy} and H^{xy}, the first two constitutive equations may be written in the simple form as

$$H_{xt}=K_{e}F_{xt} \quad \text{and} \quad K_{m}H^{xy}=F^{xy}. \quad (14a)$$

Noncovariant notation may be introduced by relating the covariant and contravariant components;

$$K_{m}H^{xy}=F^{xy}=g^{x\alpha}g^{y\beta}F_{\alpha\beta}, \quad \text{and} \quad K_{e}F_{xt}=H_{xt}=g_{x\alpha}g_{t\beta}H^{\alpha\beta}.$$

For the special example of rotation along the z axis, the introduction of the metric given by Eqs. (2) and the noncovariant field vectors yields the following constitutive equations. With $\boldsymbol{\Omega}=\Omega\mathbf{a}_z$ these expressions reduce to

$$\mathbf{B}+\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\times\left[\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\times\mathbf{B}\right]=K_{m}\mu_{0}\mathbf{H}+c^{-1}\left[\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\times\mathbf{E}\right],$$
$$\mathbf{D}+\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\times\left[\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\times\mathbf{D}\right]=K_{e}\epsilon_{0}\mathbf{E}-c^{-1}\left[\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\times\mathbf{H}\right]. \quad (14b)$$

For vacuum, $K_e=1=K_m$, these equations may be rearranged to read

$$\mathbf{B}=\mu_{0}\mathbf{H}+(\mu_{0}/\epsilon_{0})^{1/2}[(\boldsymbol{\Omega}x\mathbf{r}/c)\times\mathbf{D}],$$
$$\mathbf{D}=\epsilon_{0}\mathbf{E}-(\epsilon_{0}/\mu_{0})^{1/2}[(\boldsymbol{\Omega}x\mathbf{r}/c)\times\mathbf{B}]. \quad (14c)$$

Rotation has the effect of making even the vacuum appear anisotropic. This effect occurs in first order of Ω and corresponds to the type term introduced by Michelson for the description in terms of the "aether."

The source equation transforms as a four vector, and by the rules of tensor algebra

$$j_{x}=\bar{A}^{X}{}_{x}j_{X}+\bar{A}^{T}{}_{x}j_{T}, \quad \text{and} \quad j_{t}=\bar{A}^{T}{}_{t}j_{T}. \quad (15)$$

For macroscopic matter the constitutive equations in the instantaneous rest system are given by Eqs. (12). Substituting for j_X and j_t yields

$$j_{x}=(-g_{tt})^{-1/2}(\mu_{0}/\epsilon_{0})^{1/2}\sigma F_{xt}-g_{tx}(-g_{tt})^{-1}j_{t}. \quad (16a)$$

Again using the metric to determine the components of j^x, the current and charge in the rotating system may be written as

$$\mathbf{J}=\sigma\left\{\mathbf{E}-\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\left[\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\cdot\mathbf{E}\right]\right\}\times[1-\Omega^{2}(x^{2}+y^{2})/c^{2}]^{-1/2},$$
$$\rho=\left\{\sigma c^{-1}\left(\frac{\boldsymbol{\Omega}x\mathbf{r}}{c}\right)\cdot\mathbf{E}+\rho_{I}\right\}[1-\Omega^{2}(x^{2}+y^{2})/c^{2}]^{-1/2}. \quad (16b)$$

Matter with a finite conductivity in the presence of an oscillating electric field will appear to have an induced oscillating current and charge. It is often desireable to separate the property of matter from the vacuum field. In the notation used in the paper this is expressed by

$$H^{\alpha\beta}=F^{\alpha\beta}-M^{\alpha\beta}$$

and noncovariant vectors $\mathbf{M}$ and $\mathbf{P}$ for the magnetization and polarization are defined as

$$\mu_{0}^{1/2}M_{x}=\tfrac{1}{2}\delta_{xyz}M^{xy}, \quad \text{and} \quad \epsilon_{0}^{-1/2}P_{x}=M^{xt}. \quad (17)$$

With these definitions, Maxwell's equations may be written in terms of $\mathbf{B}$ and $\mathbf{E}$ if $\mathbf{J}$ is replaced by

$$\mathbf{J}\rightarrow\mathbf{J}+\text{curl}\mathbf{M}+\partial\mathbf{P}/\partial t. \quad (18)$$

RESONANT FREQUENCY OF A ROTATING CAVITY

The approximate frequency of oscillation of a resonant electromagnetic cavity or structure is found by a method used by Slater[10] for microwave cavities. His method is modified to include traveling waves and it is necessary to use complex wave functions. A set of orthonormal functions $\mathbf{E}_a$ and $\mathbf{H}_a$ which are solutions of the vector Helmholtz equation and which satisfy the boundary conditions $\mathbf{n}\times\mathbf{E}_a=0$ and $\mathbf{n}\cdot\mathbf{H}_a=0$ on a perfectly conducting surface S and $\mathbf{n}\times\mathbf{H}_a=0$ and $\mathbf{n}\cdot\mathbf{E}_a=0$ on an insulating surface S' are introduced. These vectors are related by $-ik_a\mathbf{H}_a=\text{curl}\mathbf{E}_a$ and $ik_a\mathbf{E}_a=\text{curl}\mathbf{H}_a$. $k_a\mathbf{F}_a=\text{grad}\psi_a$ for the scalar potential. Orthogonality is chosen such that $\int dv\mathbf{E}_a\cdot\mathbf{E}_b^*=\delta(a=b)$, etc., and an arbitrary vector may be expanded in terms of this basic set, i.e.,

$$\mathbf{E}(\mathbf{r},t(=\sum_{a}\mathbf{E}_{a}\int dv\mathbf{E}\cdot\mathbf{E}_{a}^{*}+\sum_{\beta}\mathbf{F}_{\beta}\int dv\mathbf{E}\cdot\mathbf{F}_{\beta}^{*}, \quad (19)$$

where the volume integrals are the time-dependent coefficients. Expanding Maxwell's equations in this manner yields

$$-ik_{a}\int dv\mathbf{E}\cdot\mathbf{E}_{a}^{*}+\frac{d}{dt}\int dv\mathbf{B}\cdot\mathbf{H}_{a}^{*}=-\int_{S}dA(\mathbf{n}\times\mathbf{E})\cdot\mathbf{H}_{a}^{*}, \quad (20a)$$

$$+ik_{a}\int dv\mathbf{H}\cdot\mathbf{H}_{a}^{*}-\frac{d}{dt}\int dv\mathbf{D}\cdot\mathbf{E}_{a}^{*}=\int dv\mathbf{J}\cdot\mathbf{E}_{a}^{*}-\int_{S'}dA(\mathbf{n}\times\mathbf{H})\cdot\mathbf{E}_{a}^{*}, \quad (20b)$$

$$\int dv\mathbf{D}\cdot\text{grad}\psi_{a}^{*}+\int dv\rho\psi_{a}^{*}=0. \quad (20c)$$

This expansion in normal modes implies that the element

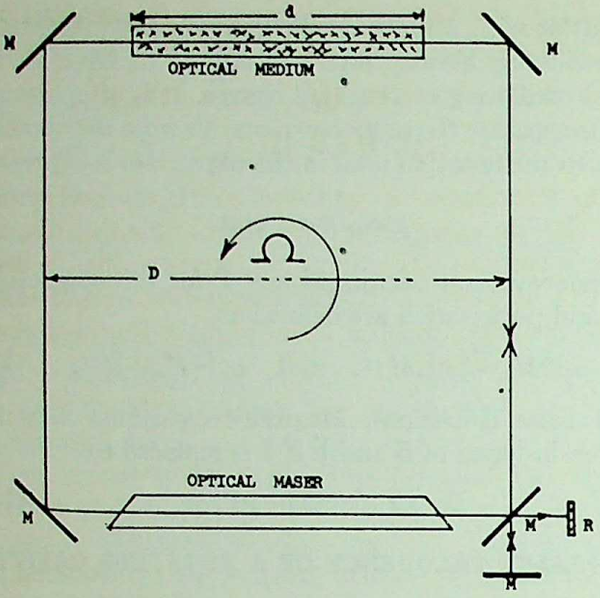

FIG. 1. Four mirrors M form the square Fabry-Perot cavity with diameter D. Optical media of length d and index of refraction $(K_eK_m)^{1/2}$ shifts the splitting in resonant frequency of the axially degenerate modes which is caused by the angular rotation Ω from the vacuum value given by Eq. (25) to that given by Eq. (26). Beats are observed with the photodetector R.

of volume is $dxdydz$ and the surface elements $dxdy$, etc. This is not true in the rotating system and a correction of the $\mathcal{O}(\Omega^2)$ is implied in the wave functions. The above equations are correct to $\mathcal{O}(\Omega^2)$ and should yield the resonant frequency to $\mathcal{O}(\Omega^2)$. Omitting the source terms on the right and using the constitutive equations to eliminate $\mathbf{B}$ and $\mathbf{D}$, the remaining equations may be solved to yield the resonant frequency. If $\nu_a{}^0$ is the resonant frequency, and $\mathbf{E}_a$ and $\mathbf{H}_a$ the normal modes for $\Omega=0$, the resonant frequency correct to $\mathcal{O}(\Omega)$ becomes

$$\nu_a=\nu_a{}^0\Big\{1+\tfrac{1}{2}(K_eK_mc^2)^{-1/2}\Omega \cdot\int dv[\mathbf{r}x(\mathbf{E}_a{}^*\times\mathbf{H}_a+\mathbf{E}_a\times\mathbf{H}_a{}^*)]\Big\}, \quad (21)$$

where as emphasized earlier $\boldsymbol{\Omega}$ is along the z axis. If two modes a and a' are axially degenerate for $\Omega=0$, then the frequency splitting between the two modes is given by

$$\Delta\nu/\nu_a=(K_eK_mc^2)^{-1/2}\Omega \cdot\int dv[\mathbf{r}x(\mathbf{E}_a\times\mathbf{H}_a{}^*+\mathbf{E}_a{}^*\times\mathbf{H}_a)]+\mathcal{O}(\Omega^2). \quad (22)$$

The cylindrical microwave cavity with rotation Ω along the z or symmetry axis provides an excellent example. In the TE_{mnp} mode the zero-order wave functions are of the form

$$\mathbf{E}_a=A_a\{\hat{a}_z\times\text{grad}[e^{im\varphi}Z_m(\alpha_{mn}\rho)]\}\sin\pi pz/z_0. \quad (23)$$

A direct evaluation of the integral for vacuum yields

$$\Delta\omega=2\pi\Delta\nu=2m\Omega, \quad (24)$$

and the rotation removes the twofold degeneracy of the axial mode.

A system of interest as a sensitive rate gyroscope[5–7] is the square Fabry-Perot cavity with confocal or flat mirrors. If $\mathbf{E}_a$ is an almost plane wave with a finite cross section, and if the perpendicular axis of the cavity makes angle γ with the z axis of rotation, integration over the beam volume yields a frequency splitting of

$$\Delta\nu/\nu_a=(\Omega D/c)\cos\gamma \quad (25)$$

for vacuum, D is the diameter of the square. Other configurations may be treated in a similar manner. If for convenience $\gamma=0$ and one arm of the Fabry-Perot contains matter as shown in Fig. 1 with an index of refraction $(K_eK_m)^{1/2}$ and of length d, then

$$\Delta\nu/\nu_a=(\Omega D/c)\{1-(d/4D)[1-(K_eK_m)^{-1/2}]\} \quad (26)$$

is the required correction for the matter.

Plane Waves

In the limit of short wavelengths or of the validity of geometrical optics the invariance of the phase $d\varphi=k_\alpha dx^\alpha$ and the invariance of the scalar $k_\alpha k^\alpha$ can be used to determine the index of refraction as measured by an observer in a nonpermanent gravitational field. Fermat's principle can be applied to determine the path. Using the transformation between k_t and k_T, the scalar invariant becomes

$$k_\Phi k^\Phi=k_\alpha k^\alpha=(\omega/c)^2(K_eK_m-1)(-g_{tt})^{-1}, \quad (27)$$

and is of course the usual null vector for vacuum. If $d\sigma$ is a line element along the path of the ray and n^a is the contravariant component of the ray direction, then

$$n^a=dx^a/d\sigma=k^ac\omega^{-1}(-g_{tt}/K_eK_m)^{1/2} \quad (28)$$

follows from Eq. (27) and the various relationships for the $g_{\alpha\beta}$.[11] Further manipulation yields for the phase

$$d\varphi=k_\alpha dx^\alpha=\omega c^{-1}\{[(-K_eK_m/g_{tt})^{1/2}-g_{at}n^a/g_{tt}]d\sigma-cdt\}. \quad (29)$$

If the quantity inside the square brackets is regarded as the index of refraction μ,

$$\mu=(-K_eK_m/g_{tt})^{1/2}-g_{at}n^a/g_{tt}, \quad (30)$$

then the path follows the variation

$$\delta\int\mu d\sigma=0. \quad (31)$$

Equation (31) is quite general and is Fermat's principle applicable for macroscopic matter and nonpermanent gravitational fields. If the principle of equivalence is invoked and for the $g_{at}=0$, the bending of a light ray in a macroscopic medium and in a permanent gravita-

[11] See L. Landau and E. Lifshitz, *The Classical Theory of Fields* (Addison-Wesley Publishing Company, Inc., Reading, Massachusetts, 1951), p. 280, for a similar development for vacuum.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tional field described by g_{tt} is readily obtained. ($-g_{tt}=1+2\chi/c^2$ where χ is the gravitational potential.) It is interesting to note that the bending by a gravitational field is not separable from that bending by matter. For the special example a system rotating about the z axis and described by the metric given by Eq. (2), μ becomes

$$\mu=(K_eK_m)^{1/2}+c^{-1}(\boldsymbol{\Omega}\times\mathbf{r})\cdot\hat{n}+\mathcal{O}(\Omega^2), \tag{32}$$

where $\hat{n}$ is a unit normal in the direction of the ray. Macroscopic matter does not effect the term depending on g_{at} and the term of $\mathcal{O}(\Omega)$ in the index of refraction depends on the vacuum properties only. If this index of refraction is used for the square Fabry-Perot cavity, or cavities in which geometrical optics may be used with some validity, the shift in resonant frequency is the same as indicated by Eqs. (25) and (26).[12]

CORIOLIS-ZEEMAN EFFECT FOR PHOTONS

The removal of the twofold degeneracy of the axial mode of the cylindrical cavity discussed earlier yields an angular frequency of

$$\omega_{mnp}=\omega_{mnp}{}^0\pm m\Omega \quad (m=0,\ 1,\ 2,\ \cdots). \tag{33}$$

If the photon concept is used and $\mathbf{J}$ is the orbital angular momentum of the photon, the above equation may be written as

$$\hbar\omega=\hbar\omega^0+J_z\Omega, \tag{34}$$

and the correction is proportional to $\boldsymbol{\Omega}\cdot\mathbf{J}$. For vacuum, Eq. (22) is consistent with the concept of angular momentum. In fact, Eq. (25) is readily obtained by noting that

$$\Delta\nu/\nu=2\boldsymbol{\Omega}\cdot\mathbf{J}/h\nu=(\Omega D/c)\cos\gamma, \tag{35}$$

where $J_z=(h\nu/c)(D/2)\cos\gamma$ is the projection of the orbital angular momentum $\mathbf{J}$ along the z axis. The observer in the rotating system would find the resonant frequency dependent on the angular momentum of the photon and would regard the level splitting as a "Coriolis-Zeeman" effect for the photon. This concept is valid only for vacuum. The right side of Eq. (22) is the expression for the moment of energy flux rather than angular momentum. This distinction between energy flux and momentum is apparent only in the presence of matter or in $\mathcal{O}(\Omega^2)$.

If the energy-momentum tensor is defined as

$$S_\alpha{}^\beta=F_{\alpha\mu}H^{\beta\mu}-\tfrac{1}{4}\delta_\alpha{}^\beta F_{\mu\nu}H^{\mu\nu}, \tag{36}$$

whose covariant divergence yields the four-force $f_\alpha=F_{\alpha\beta}j^\beta$, the various components in the noncovariant notation are

$$\begin{aligned} &S_t{}^x=-c^{-1}(\mathbf{E}\times\mathbf{H})_x, \quad S_x{}^t=c(\mathbf{D}\times\mathbf{B})_x, \\ &S_t{}^t=-\tfrac{1}{2}(\mathbf{E}\cdot\mathbf{D}+\mathbf{B}\cdot\mathbf{H}). \end{aligned} \tag{37}$$

In the instantaneous rest frame $S_T{}^T$ is the energy density, $S_T{}^X$ the energy flux, and $S_X{}^T$ the momentum, and these quantities have the same interpretation in other systems of coordinates. The energy-momentum tensor in the instantaneous rest frame and the frame of observation are related by

$$S_\Phi{}^\Psi=A^\alpha{}_\Phi\bar{A}^\Psi{}_\beta S_\alpha{}^\beta, \tag{38}$$

and the energy density may be written as

$$S_T{}^T=S_t{}^t+(g_{tx}/g_{tt})S_t{}^x. \tag{39}$$

For the stationary system which is being considered the $g_{\alpha\beta}$ do not depend on the local time variable t and for short periods of time in which losses may be ignored, solutions of Maxwell's equations which are independent of the time variable may be obtained. The observer in the moving system interprets the integral of $S_t{}^t$ over the volume of the cavity or radiation field at time t as a constant of motion for the system. If a single photon is present the photon frequency is measured as

$$\nu=h^{-1}\int dv\, S_t{}^t=h^{-1}\int dv[S_T{}^T-(g_{tx}/g_{tt})S_t{}^x]. \tag{40}$$

Considered as a traveling wave the integral over $S_T{}^T$ is independent of the sense of rotation and the beat frequency caused by the interference of clockwise (c.w.) and counter-clockwise (c.c.w.) photons at a detector attached to the moving system is

$$\begin{aligned} \Delta\nu&=2h^{-1}\int dv[g_{tx}/g_{tt}]S_t{}^x \\ &=2h^{-1}c^{-2}\boldsymbol{\Omega}\cdot\int dv[\mathbf{r}x(\mathbf{E}\times\mathbf{H})]+\mathcal{O}(\Omega^2). \end{aligned} \tag{41}$$

This is the same as the earlier expression given by Eq. (22) when $\mathbf{E}$ and $\mathbf{H}$ are replaced by zero-order orthonormal $\mathbf{E}_a$ and $\mathbf{H}_a$ wave functions. The dependence on the projection of the moment of the energy flux rather than the angular momentum is immediately apparent.

MINKOWSKI'S ENERGY-MOMENTUM TENSOR

The lack of symmetry in the Minkowski energy-momentum tensor between the energy flux $S_T{}^\Phi$ and the momentum $S_\Phi{}^T$ in the presence of macroscopic matter has been discussed frequently in the literature.[13]

The energy-momentum tensor is symmetric in an inertia frame in the absence of matter and becomes

[12] Although an experiment with matter waves does not seem possible at this time, it is interesting to note that using the same formalism with the Klein-Gordon equation a phase difference between the c.w. and c.c.w. paths is obtained in which the Compton wavelength $\lambda=h/mc$ replaces the optical wavelength. The phase shift is $8\pi D^2\Omega/\lambda c$ in an experiment similar to that used by Michelson (Ref. 3). Interference depends on the Compton rather than the de Broglie wavelength (Ref. 4).

[13] See Ref. 8, p. 204 for a discussion and references to related discussions.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

nonsymmetric in the presence of matter or nonpermanent gravitational fields. A first-order nonsymmetry appears in the presence of rotation. Minkowski's theory requires that transparent matter not exchange energy with the electromagnetic field. It is shown in the earlier developments in this paper that the frequency shift in first order of Ω depends on the moment of the energy flux and also that the change in index of refraction in the geometrical optic region is independent of the presence of matter to $\mathcal{O}(\Omega)$. These same results follow with the Minkowski energy-momentum tensor given by Eq. (36). Thus an observation of the beat frequency in accord with Eq. (26) in the presence of matter would support the Minkowski formulation. This effect should be observable in the square Fabry-Perot cavity with flat mirrors for which the mode of operation is simple. Since the presence of the maser material allows the cavity to oscillate at both frequencies and the beat frequency is sensitive to rotation only, the shift in the beat frequency is measureable. Combining Eqs. (25) and (26) for ν_a coinciding with a maser line, the fractional shift is

$$(\Delta\nu_M/\Delta\nu_0)=1-(d/4D)[1-(K_eK_m)^{-1/2}], \quad (42)$$

where $\Delta\nu_M$ is the beat frequency with matter and $\Delta\nu_0$ with vacuum. If a large portion of the maser is filled with matter an effect as large as 30% can be expected. Unfortunately terms of $\mathcal{O}(\Omega^2)$ cannot be tested by present experimental apparatus. Applying the principle of equivalence it is the terms of $\mathcal{O}(\Omega^2)$ which are equivalent to the effects of a permanent gravitational field. Although not emphasized in the development, the equations developed in this paper may be applied in a permanent gravitational field by invoking the principle of equivalence.

EXCITATION OF CAVITY MODES

Using the form invariance of the fundamental laws of physics and the concept of the instantaneous rest frame, the constitutive equations for macroscopic matter in an accelerated system have been developed and used with Maxwell's equations to discuss the resonant frequencies of electromagnetic cavities. The deformation of matter by the acceleration forces has been neglected. Since the deformation of matter by the acceleration would change the shape of the cavity and the physical constants of enclosed matter, the small shifts suggested would be difficult to observe. For axially degenerate modes the deformations affect both c.w. and c.c.w. traveling waves in the same manner and the splitting between modes given by Eq. (22) is almost independent of the deformations. The splitting between modes given by Eq. (22) is valid over the entire region of the electromagnetic spectrum for which cavity modes may be defined. Thus, in the microwave region a reasonable size cavity would have a value of $m\sim10$, while in the optical region a value of $m>10^6$ is possible. For a closed microwave cavity the normal modes may be determined in a standard manner and wall losses introduced by discussing the decay of stored energy in terms of the Q. Since the beat frequency would be of the order of cycles per second for a rotation rate of 1 rad per sec, a Q of the order of 10^9 would be required to resolve the splitting between the c.w. and c.c.w. modes. Such a Q is almost possible with superconducting cavity walls. In the optical region the Fabry-Perot cavity shown in Fig. 1 may be discussed in a similar manner. A system with dimensions of the order of 1 m has the Q limited to 10^8 by diffraction[14] and reflection losses and a beat note of the order of kilocycles is not resolved.

In order to enhance the apparent Q of the system a maser material in the appropriate frequency range may be used.[5–7] The volume source or sink term on the right-hand side of Eq. (20b) may be due to either the polarization, magnetization, or conductivity as shown by Eq. (18). If the maser media has a narrow linewidth described by $\epsilon''(\nu)$ or $\chi''(\nu)$,[15] either property may be discussed in terms of a generalized negative resistance $\sigma(\nu)$ which is proportional to it. In this linear approximation the response of the c.w. mode depends on the value of $\sigma(\nu)$ at the frequency of the c.w. mode. A similar argument follows for the c.c.w. mode, and both modes will be excited for a maser linewidth greater than the splitting. Oscillation will occur for both modes in the linear approximation. If the polarization depends on the electric field in a nonlinear manner, the question of coupling between these closely spaced modes needs further consideration.[16] It may be possible to study these nonlinearities by using the square Fabry-Perot cavity as a precision spectrometer system.

AND

LUDWIG TEWORDT†
Bell Telephone Laboratories, Murray Hill, New Jersey

(Received 7 October 1963; revised manuscript received 13 January 1964)

The electronic thermal conductivity of superconductors is discussed without recourse to the quasiparticle approximation. The Kubo formula for the thermal conductivity is used as the starting point. This is first examined in the Hartree-Fock approximation in the Nambu space. It is shown that in the Eliashberg approximation of neglecting the momentum dependence of the electronic self-energy, the calculation of the thermal conductivity is reduced to a quadrature, involving however the complex energy gap and renormalization functions which are solutions of the Eliashberg gap equations at finite temperatures. These equations are given in an Appendix. The problem is also considered in the ladder approximation in the Nambu space, and a generalized Boltzmann equation is derived which includes corrections to the Hartree-Fock approximation corresponding to the replacement of the scattering by the transport cross section. It is shown that the standard Boltzmann equation for superconducting quasiparticles is obtained in the weak-coupling limit. No numerical calculations are performed in this paper, but a clear scheme for such calculations is outlined. Reasons for believing that such calculations will explain the anomalous drop in the electronic thermal conductivity of superconducting lead are given.

I. INTRODUCTION

EXPERIMENTS on the strong elemental superconductors lead and mercury show that the electronic thermal conductivity of these materials differs markedly from that of typical weak superconductors like tin or indium. For lead and mercury[1] the ratio, K_s/K_n, of the thermal conductivity in the superconducting and normal states when plotted against the reduced temperature T/T_c shows a steep positive slope of about 5 near $T=T_c$. For tin[2] and indium,[3] on the other hand, the experiments yield a smaller slope of about 1.6.

A theory of the electronic thermal conductivity of superconductors based on the quasiparticle approximation and the Boltzmann equation approach of Bardeen, Rickayzen, and one of the present authors[4] has been carried through previously.[5] The results obtained are in substantial agreement with the data on tin and indium. The lack of agreement between the theory given in I and the data on lead is not surprising since, as shown in the work of Schrieffer, Scalapino, and Wilkins,[6] the strong electron-phonon coupling causes the quasiparticle picture to be quite meaningless over much of the energy spectrum.

It therefore seems reasonable to study the thermal conductivity of lead on the basis of the strong-coupling theory used by Schrieffer *et al.*[6] in explaining tunneling characteristics. This is the aim of the present paper. We use the method of thermodynamic Green's functions[7] and thereby avoid the quasiparticle approximation. We expect that in the limit of almost stable excitations our theory will reduce to the theory developed in I, and this expectation is realized. In this paper we carry the theory as far as we are able to without using numerical methods. We expect to use the formulas obtained here as the basis for further calculation.

Our starting point is the Kubo formula in which the thermal conductivity is expressed in terms of the correlation function of two heat current operators.[8] For the superconducting state it is convenient to use the two component space introduced by Nambu.[9] In Sec. II the problem is treated in the Hartree-Fock approximation which means that the correlation function is factored into two Nambu matrix Green's functions. The momentum integration in the expression for the thermal

conductivity can be carried out if one makes the weak-momentum approximation introduced by Eliashberg,[10] that is, if one neglects the $\hat{p}$ dependence of the renormalization function $Z_p(\omega)$ and the gap function $\Delta_p(\omega)$. In contrast to the result of the quasiparticle approach, the thermal conductivity is expressed as an integral over all excitation energies rather than over all momenta. The integrand contains the complex functions $Z(\omega)$ and $\Delta(\omega)$. These functions have to be determined from the generalization to finite temperatures of Eliashberg's gap equations. The generalized gap equations are given in Appendix A. In the limit of zero temperature these equations have been solved for lead by Schrieffer *et al.* However, for the problem of the thermal conductivity one needs the solutions near T_c.

In Sec. III the problem is treated in the more general ladder approximation in the Nambu space. This is the approximation that must be used with the superconducting approximation to the single-particle self-energy operator in order to preserve conservation laws[11] or, equivalently, Ward identities. To facilitate the treatment of this approximation we use a method introduced recently by Langer, Maradudin, and Wallis[12] in discussing optical absorption by anharmonic crystals. The integral equation for the vertex part is simplified by using a double spectral representation (derived in Appendix B) for the vertex function. The resulting integral equation for one of the spectral functions corresponds to a generalized Boltzmann equation in which this function essentially plays the role of the non-equilibrium part of the distribution function. The integral equation simplifies if one makes an Ansatz for the vector part of the spectral function which corresponds to Bloch's Ansatz in the elementary theory, and further, if one again uses the weak-momentum approximation. In this way one obtains an integral equation in the energy variable alone which represents the generalization of Bloch's equation for thermal conductivity to a strongly coupled superconductor. In the limit of weak electron-phonon interaction the equation reduces to the Boltzmann equation used in I.

II. HARTREE-FOCK APPROXIMATION

If we neglect the entropy flow and measure energies with respect to the chemical potential,[13] the Kubo formula for the thermal conductivity K may be written as follows (we use units in which $\hbar=1$):

$$K=\frac{2}{3VT}\,\mathrm{Im}\int_{-\infty}^{0}dt_2t_2\int d^3x_1d^3x_2\langle\mathbf{u}(\mathbf{x}_1,0)\cdot\mathbf{u}(\mathbf{x}_2,t_2)\rangle. \quad (2.1)$$

Above V is the volume of the system, T is the temperature, and $\mathbf{u}$ is the heat-current density operator at the space-time point $1=(\mathbf{x}_1,t_1)$. The brackets denote an average in the grand canonical ensemble. For the interacting electron-phonon system $\mathbf{u}$ has the form $\mathbf{u}=\mathbf{u}_{\mathrm{el}}+\mathbf{u}_{\mathrm{ph}}$, where

$$\mathbf{u}_{\mathrm{el}}=-\frac{1}{2m}\sum_\sigma\left(\frac{\partial}{\partial t_1}\nabla_{1'}+\frac{\partial}{\partial t_{1'}}\nabla_1\right)\psi_\sigma^\dagger(1')\psi_\sigma(1)\,|_{1'=1} \quad (2.2)$$

is the heat current for the electronic system. It includes that part of the electron-phonon interaction energy which is due to electronic charge fluctuations. [The operators $\psi_\sigma^\dagger(1')$ and $\psi_\sigma(1)$ create and annihilate electrons with spin σ at $1'$ and 1, respectively.]

The detailed form of the phonon part of the heat-current density operator[14] is not needed for the purposes of this paper. It suffices to note that the correlation function of $\mathbf{u}_{\mathrm{ph}}$ with itself gives rise through Eq. (2.1) to a thermal conductivity which may be interpreted as the thermal conductivity of the lattice as limited by electron scattering.[15] In the normal state this contribution is proportional to T^2 and is too small to be observed in a pure system. In the superconducting state the lattice thermal conductivity is increased relative to that in the normal state because the energy gap in the electronic spectrum leads to an increase in the relaxation time for phonons. However, because of the smallness of the lattice term, the electronic contribution (though rapidly falling) will dominate the thermal conductivity just below T_c which is the region of interest to us. The cross terms in the expression (2.1) between $\mathbf{u}_{\mathrm{el}}$ and $\mathbf{u}_{\mathrm{ph}}$ describe "phonon drag" effects which are totally negligible for heat conduction because the electronic heat current is odd with respect to reflections in the Fermi surface. In what follows, therefore, we take (2.2) as the expression for the heat current operator and drop the subscript "el." In the language of conventional transport theory we are assuming that the lattice is always in equilibrium. The contribution to the thermal conductivity of the processes by which the lattice does in fact achieve equilibrium are, as we have seen, small in the region of interest to us.

Let us introduce the correlation function

$$P(1,2)=\langle T[\mathbf{u}(1)\cdot\mathbf{u}(2)]\rangle, \quad (2.3)$$

where T is Wick's time ordering operator. In the standard way we make Fourier transformations in the spatial and imaginary time difference coordinates, so

that

$$P(1,2)=\int\frac{d^3q}{(2\pi)^3}\frac{i}{\beta}\sum_{\nu_m}P(q,\nu_m)\times\exp\{i[\mathbf{q}\cdot(\mathbf{x}_1-\mathbf{x}_2)-\nu_m(t_1-t_2)]\}. \quad (2.4)$$

Here $\nu_m=2\pi mi/\beta$, m runs over all integers, and $\beta=(k_BT)^{-1}$ with k_B Boltzmann's constant. In terms of $P(q,\nu_m)$ Eq. (2.1) becomes

$$K=-\frac{1}{3T}\frac{d}{d\nu}\{\mathrm{Re}[P(q,\nu_m)|_{\nu_m=\nu-i0^+}]\}|_{\substack{\nu=0\\q=0}}. \quad (2.5)$$

It is convenient to use Nambu's two-component field operators defined by

$$\psi(1)=\begin{pmatrix}\psi_\uparrow(1)\\ \psi_\downarrow^\dagger(1)\end{pmatrix},\quad \psi^\dagger(1)=(\psi_\uparrow^\dagger(1)\psi_\downarrow(1)).$$

In terms of these and the Pauli spin matrices τ_i the correlation function may be written as follows

$$P(1,2)=\frac{1}{4m^2}\left(\frac{\partial}{\partial t_1}\nabla_1'+\frac{\partial}{\partial t_1'}\nabla_1\right)\cdot\left(\frac{\partial}{\partial t_2}\nabla_2'+\frac{\partial}{\partial t_2'}\nabla_2\right)(\tau_3)^{ij}(\tau_3)^{kl}\times\langle T[\psi_i(1)\psi_k(2)\psi_l^\dagger(2')\psi_j^\dagger(1')]\rangle|_{\substack{1'=1^+\\2'=2^+}}. \quad (2.6)$$

In writing the correlation function in the form (2.6) we have neglected certain discontinuity terms that arise from the time derivatives acting on the time ordering operator. These terms make no contribution to the thermal conductivity.

In this section we shall derive the expression for K in the Hartree-Fock approximation. This is defined by

$$\langle T[\psi_i(1)\psi_k(2)\psi_l^\dagger(2')\psi_j^\dagger(1')]\rangle\rightarrow\mathcal{G}_{il}(12')\mathcal{G}_{kj}(21'), \quad (2.7)$$

where $\mathcal{G}_{il}$ is Nambu's matrix Green's function

$$\mathcal{G}_{il}(12)=-i\langle T[\psi_i(1)\psi_l^\dagger(2)]\rangle. \quad (2.8)$$

Then we obtain from Eqs. (2.6), (2.7), and (2.4)

$$P(q,\nu_m)=\frac{1}{4m^2}\int\frac{d^3p}{(2\pi)^3}\frac{i}{\beta}\sum_{\zeta_l}e^{\zeta_l0^+}[\zeta_l(\mathbf{p}+\mathbf{q})+(\zeta_l+\nu_m)\mathbf{p}]^2\times\mathrm{Tr}\{\tau_3\mathcal{G}(p+q,\zeta_l+\nu_m)\tau_3\mathcal{G}(p,\zeta_l)\}, \quad (2.9)$$

where $\zeta_l=(2l+1)\pi i/\beta$ and l takes on integral values. The Hartree-Fock approximation for the heat-current correlation function is represented by the diagram in Fig. 1.

We now insert the spectral representation for $\mathcal{G}(p,\zeta_l)$,

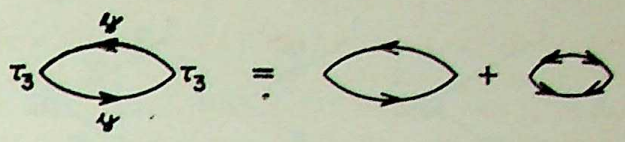

FIG. 1. Diagrammatic representation of the Hartree-Fock approximation for the heat-current correlation function of superconductors. The solid lines on the left of the equality sign represent Nambu matrix propagators $\mathcal{G}$. The equivalent diagrammatic representation in terms of Gorkov's normal and anomalous Green's functions is shown on the right. In the present formalism the terms on the right arise from taking the trace $\mathrm{Tr}[\tau_3\mathcal{G}\tau_3\mathcal{G}]$.

namely,

$$\mathcal{G}(p,\zeta_l)=\int_{-\infty}^{\infty}\frac{d\omega}{2\pi}\frac{a(p,\omega)}{\zeta_l-\omega} \quad (2.10)$$

into (2.9) and carry out the sum over ζ_l. Introducing the result into (2.5) one finds

$$K=\frac{1}{24m^2k_BT^2}\int\frac{d^3pd\omega}{(2\pi)^4}p^2\omega^2\,\mathrm{sech}^2(\tfrac{1}{2}\beta\omega)\times\mathrm{Tr}\{\tau_3a(p,\omega)\tau_3a(p,\omega)\}. \quad (2.11)$$

The Nambu matrix propagator $\mathcal{G}(p,\zeta_l)$ with ζ_l continued to the complete complex z plane has the form

$$\mathcal{G}(p,z)=\frac{zZ_p(z)+\epsilon_p\tau_3+\phi_p(z)\tau_1}{z^2Z_p{}^2(z)-\epsilon_p{}^2-\phi_p{}^2(z)}, \quad (2.12)$$

where $\epsilon_p=(p^2/2m)-\mu$. The renormalization function $Z_p(z)$ and the gap function $\phi_p(z)$, both complex, have to be determined from the Nambu-Eliashberg self-consistency condition. We now make the weak-momentum approximation introduced by Eliashberg, that is we neglect the p dependence of $Z_p(z)$ and $\phi_p(z)$. Then the integration over p, or ϵ_p, in Eq. (2.11) can be done. The spectral function $a(p,\omega)$ is obtained from (2.12) from the relation

$$a(p,\omega)=2\,\mathrm{Im}\mathcal{G}(p,\omega-i0^+)=(1/i)[\mathcal{G}(p,\omega-i0^+)-\mathcal{G}(p,\omega+i0^+)]. \quad (2.13)$$

The integrals over ϵ that are then needed are

$$I_1=\int_{-\infty}^{\infty}d\epsilon\,\mathrm{Tr}\{\tau_3\mathcal{G}(p,\omega-i0^+)\tau_3\mathcal{G}(p,\omega-i0^+)\}=0, \quad (2.14)$$

and

$$I_2=\int_{-\infty}^{\infty}d\epsilon\,\mathrm{Tr}\{\tau_3\mathcal{G}(p,\omega-i0^+)\tau_3\mathcal{G}(p,\omega+i0^+)\}=\frac{\pi}{|\mathrm{Im}\{Z(\omega)[\omega^2-\Delta^2(\omega)]^{1/2}\}|}\times\left(1+\frac{\omega^2-|\Delta(\omega)|^2}{|\omega^2-\Delta^2(\omega)|}\right). \quad (2.15)$$

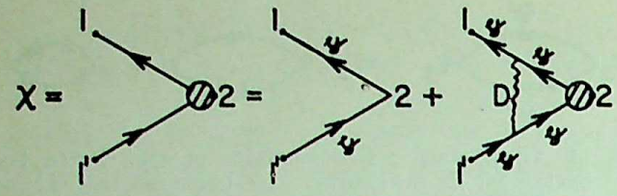

FIG. 2. Integral equation for the vertex function in the ladder approximation, represented in terms of diagrams. $\mathcal{G}$ and D denote particle and phonon propagators, respectively.

The integrations are straightforward and are sketeched in Appendix C. The complex functions $Z(\omega)$ and $\Delta(\omega)$, the latter being the complex energy gap parameter, are related to the functions occurring in (2.12) by

$$Z(\omega)=Z_1(\omega)+iZ_2(\omega)=Z(z=\omega-i0^+);$$
$$\Delta(\omega)=\Delta_1(\omega)+i\Delta_2(\omega) \qquad (2.16)$$
$$=\phi(z=\omega-i0^+)/Z(z=\omega-i0^+).$$

The thermal conductivity K is now given by

$$K=\frac{n}{8mk_BT^2}\int_0^\infty d\omega\frac{\omega^2\,\mathrm{sech}^2(\tfrac{1}{2}\beta\omega)}{|\mathrm{Im}\{Z(\omega)[\omega^2-\Delta^2(\omega)]^{1/2}\}|}\times\left(1+\frac{\omega^2-|\Delta(\omega)|^2}{|\omega^2-\Delta^2(\omega)|}\right). \qquad (2.17)$$

Above n is the density of electrons. Near $T=0$ the factor in the large brackets becomes zero for $\omega<\Delta_0$, where $\Delta_0=\Delta_1(\Delta_0)$ is the gap edge, since Δ_2 vanishes for $\omega<\Delta_0$. At finite temperatures the existence of thermally excited phonons may cause Δ_2 to have a small nonzero value for $\omega<\Delta_0$.

If for those frequencies ω that contribute predominantly to the integral in (2.17) the inequality $2\Delta_2\Delta_1<\omega^2-\Delta_1^2+\Delta_2^2$ is satisfied, the following approximate formula for K obtains

$$K=\frac{n}{8mk_BT^2}\int_0^\infty d\omega\frac{\omega^2(\omega^2-\Delta_1^2+\Delta_2^2)^{1/2}}{|Z_2(\omega^2-\Delta_1^2+\Delta_2^2)-Z_1\Delta_1\Delta_2|}\times\mathrm{sech}^2(\tfrac{1}{2}\beta\omega)\left(1+\frac{\omega^2-\Delta_1^2-\Delta_2^2}{|\omega^2-\Delta_1^2+\Delta_2^2|}\right). \qquad (2.18)$$

To first order in Δ_2 and Z_2 the expression in the denominator of the integrand in (2.18) reduces to $\omega Z_1\Gamma$, where Γ is one-half the decay rate for a quasiparticle as calculated in II. Equation (2.18) is thus somewhat more general than the quasiparticle approximation. In the case of lead it would appear that the condition $\Delta_2\Delta_1<\omega^2-\Delta_1^2+\Delta_2^2$ is reasonably well satisfied for frequencies below 2 or $3k_BT_c$, the latter being roughly the frequency which contributes maximally to K, but in a numerical calculation it is probably no harder to use the exact form (2.17).

III. GENERALIZED BOLTZMANN EQUATION

We now wish to obtain a Boltzmann-like equation for the correlation function $P(1,2)$. It is convenient first to rewrite the expression for this quantity as follows:

$$P(1,2)=\frac{1}{2m}\left(\frac{\partial}{\partial t_1}\nabla_{1'}+\frac{\partial}{\partial t_{1'}}\nabla\right)\cdot\mathrm{Tr}\{\tau_3\chi(1,2,1')\}|_{1'=1^+}, \qquad (3.1)$$

where the three-point function $\chi(1,2,1')$ is defined by

$$\chi_{ij}=\langle T[\psi_i(1)\mathbf{u}(2)\psi_j^\dagger(1')]\rangle. \qquad (3.2)$$

[In writing (3.1) we have again neglected, for the same reason as given below Eq. (2.6), terms arising from the nonzero commutator of the time derivative and time-ordering operations.] Because of the homogeneity of space and time χ depends only on two space-time coordinate differences, so that $\chi=\chi(1\text{–}2,2\text{–}1')$. Since, furthermore, this quantity has periodicity properties along the imaginary time axis, one may make Fourier integral and series expansions in both space-time arguments. We shall denote the Fourier transform by $\chi(\mathbf{p}+\mathbf{q},\zeta_l+\nu_m;\mathbf{p},\zeta_l)$. Inserting the Fourier expansion for χ into (3.1) one obtains the following expression for $P(q,\nu_m)$:

$$P(q,\nu_m)=-\frac{1}{2m}\frac{i}{\beta}\sum_{\zeta_l}e^{\zeta_l0^+}\int\frac{d^3p}{(2\pi)^3}[(\zeta_l+\nu_m)\mathbf{p}+\zeta_l(\mathbf{p}+\mathbf{q})]\cdot\mathrm{Tr}\{\tau_3\chi(\mathbf{p}+\mathbf{q},\zeta_l+\nu_m;\mathbf{p},\zeta_l)\}. \qquad (3.3)$$

In Appendix B we have derived the following double spectral representation for χ (see also Ref. 12)

$$\chi(\mathbf{p}+\mathbf{q},\zeta_l+\nu_m;\mathbf{p},\zeta_l)=\int_{-\infty}^\infty\int_{-\infty}^\infty\frac{d\omega_1d\omega_2}{(2\pi)^2}\left[\frac{\mathbf{f}^{(1)}(\mathbf{p}+\mathbf{q},\omega_1;\mathbf{p},\omega_2)}{(\zeta_l-\omega_1)(\nu_m-\omega_2)}+\frac{\mathbf{f}^{(2)}(\mathbf{p}+\mathbf{q},\omega_1;\mathbf{p},\omega_2)}{(\zeta_l+\nu_m-\omega_1)(\nu_m-\omega_2)}\right]. \qquad (3.4)$$

The explicit forms of the spectral functions $\mathbf{f}^{(1)}$ and $\mathbf{f}^{(2)}$ are given in Appendix B. We insert Eq. (3.4) into Eq. (3.3), perform the sum over ζ_l, and introduce the result for $P(q,\nu_m)$ into (2.5). The result for K in terms of $\mathbf{f}^{(1)}$ and $\mathbf{f}^{(2)}$ is then found to be

$$K=\frac{1}{12mT}\int\frac{d^3pd\omega}{(2\pi)^4}\mathbf{p}\cdot\mathrm{Tr}\left\{\tfrac{1}{2}\beta\omega\,\mathrm{sech}^2(\tfrac{1}{2}\beta\omega)\tau_3\mathbf{f}_\mathbf{p}^{(2)}(\omega,0)-(e^{\beta\omega}+1)^{-1}\left[\tau_3(\mathbf{f}_\mathbf{p}^{(1)}(\omega,0)+\mathbf{f}_\mathbf{p}^{(2)}(\omega,0))+2\omega\tau_3\frac{\partial}{\partial\nu}(\mathbf{f}_\mathbf{p}^{(1)}(\omega,\nu)+\mathbf{f}_\mathbf{p}^{(2)}(\omega+\nu,\nu))|_{\nu=0}\right]\right\}. \qquad (3.5)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Here we have used the abbreviation $\mathbf{f}_p^{(i)}(\omega,\nu)=\mathbf{f}^{(i)}(\mathbf{p},\omega,\mathbf{p},\nu)$, $i=1, 2$.

To proceed further we must determine the spectral functions $\mathbf{f}^{(1)}$ and $\mathbf{f}^{(2)}$ in some approximation. We consider the integral equation for χ in the ladder approximation which is represented by the diagrams in Fig. 2 and is given by

$$\chi(\mathbf{p},\zeta_l+\nu_m;\mathbf{p},\zeta_l)=-\frac{1}{2m}\mathbf{p}(2\zeta_l+\nu_m)\mathcal{G}(p,\zeta_l+\nu_m)\tau_3\mathcal{G}(p,\zeta_l)+\frac{1}{2m}\mathbf{p}[\mathcal{G}(p,\zeta_l+\nu_m)\tau_3+\tau_3\mathcal{G}(p,\zeta_l)]$$
$$-\frac{1}{\beta}\sum_{\mu_n}\int\frac{d^3k}{(2\pi)^3}\mathcal{G}(p,\zeta_l+\nu_m)\tau_3\chi(\mathbf{p}-\mathbf{k},\zeta_l+\nu_m-\mu_n;\mathbf{p}-\mathbf{k},\zeta_l-\mu_n)\tau_3\mathcal{G}(p,\zeta_l)D(\mathbf{k},\mu_n). \quad (3.6)$$

Here $D(\mathbf{k},\mu_n)$ is the phonon propagator ($\mu_n=2\pi ni/\beta$ with n an integer) which has the spectral representation

$$D(\mathbf{k},\mu_n)=\int_{-\infty}^{\infty}\frac{d\nu}{2\pi}\frac{d(k,\nu)}{\mu_n-\nu}. \quad (3.7)$$

Introducing this spectral representation as well as those for $\mathcal{G}$ and χ into (3.6) and doing the sum over n we find

$$\int\frac{d\omega_1 d\omega_2}{(2\pi)^2}\left[\frac{\mathbf{f}_p^{(1)}(\omega_1,\omega_2)}{(\zeta_l-\omega_1)(\nu_m-\omega_2)}+\frac{\mathbf{f}_p^{(2)}(\omega_1,\omega_2)}{(\zeta_l+\nu_m-\omega_1)(\nu_m-\omega_2)}\right]$$
$$=-\frac{\mathbf{p}}{2m}(2\zeta_l+\nu_m)\int\frac{d\omega_1 d\omega_2}{(2\pi)^2}\frac{a(p,\omega_1)\tau_3 a(p,\omega_2)}{(\zeta_l+\nu_m-\omega_1)(\zeta_l-\omega_2)}$$
$$+\frac{\mathbf{p}}{2m}\left[\int\frac{d\omega_1}{2\pi}\left(\frac{a(p,\omega_1)\tau_3}{\zeta_l+\nu_m-\omega_1}+\frac{\tau_3 a(p,\omega_1)}{\zeta_l-\omega_1}\right)\right]+\int\frac{d^3k}{(2\pi)^3}\int\frac{d\nu_1 d\nu_2 d\nu_3 d\mu_1 d\mu_2}{(2\pi)^5}[f(-\mu_1)+N(\nu_3)]d(k,\nu_3)$$
$$\times\frac{a(p,\nu_1)\tau_3}{\zeta_l+\nu_m-\nu_1}\left[\frac{\mathbf{f}_{p-k}^{(1)}(\mu_1,\mu_2)}{\zeta_l-\mu_1-\nu_3}+\frac{\mathbf{f}_{p-k}^{(2)}(\mu_1,\mu_2)}{\zeta_l+\nu_m-\mu_1-\nu_3}\right]\frac{\tau_3 a(p,\nu_2)}{(\nu_m-\mu_2)(\zeta_l-\nu_2)}. \quad (3.8)$$

The Fermi and Planck functions are abbreviated by f and N, respectively. From Eq. (3.8) we can derive two coupled equations for $\mathbf{f}^{(1)}$ and $\mathbf{f}^{(2)}$ by calculating first the discontinuity across the real ζ_l axis at $\zeta_l=\omega$ for fixed imaginary ν_m and then the discontinuity across the real ν_m axis at $\nu_m=\nu$, or by carrying out these operations in the opposite order. The two equations are

$$\mathbf{f}_p^{(1)}(\omega,\nu)=-(\mathbf{p}/2m)(2\omega+\nu)a(p,\omega+\nu)\tau_3 a(p,\omega)+(2\pi)^{-8}\int d^3k d\nu_1 d\nu_2 d\nu_3 d\mu_1 d\mu_2[f(-\mu_1)+N(\nu_3)]d(k,\nu_3)$$
$$\times a(p,\nu_1)\tau_3\{\mathbf{f}_{p-k}^{(1)}(\mu_1,\mu_2)2\,\mathrm{Im}[(\omega-\nu_3-\mu_1-i0^+)^{-1}(\omega-\nu_2-i0^+)^{-1}]$$
$$\times 2\,\mathrm{Im}[(\omega+\nu-\nu_1-i0^+)^{-1}(\nu-\mu_2-i0^+)^{-1}]+\mathbf{f}_{p-k}^{(2)}(\mu_1,\mu_2)2\pi\delta(\omega-\nu_2)$$
$$\times 2\,\mathrm{Im}[(\nu-\mu_2-i0^+)^{-1}(\omega+\nu-\nu_1-i0^+)^{-1}(\omega+\nu-\nu_3-\mu_1-i0^+)^{-1}]\}\tau_3 a(p,\nu_2), \quad (3.9)$$

and

$$\mathbf{f}_p^{(1)}(\omega,\nu)+\mathbf{f}_p^{(2)}(\omega+\nu,\nu)=(2\pi)^{-7}\int d^3k d\nu_1 d\nu_2 d\nu_3 d\mu_1[f(-\mu_1)+N(\nu_3)]d(k,\nu_3)a(p,\nu_1)\tau_3$$
$$\times\{\mathbf{f}_{p-k}^{(1)}(\mu_1,\nu)2\,\mathrm{Im}[(\omega+\nu-\nu_1-i0^+)^{-1}(\omega-\nu_3-\mu_1-i0^+)^{-1}(\omega-\nu_2-i0^+)^{-1}]+\mathbf{f}_{p-k}^{(2)}(\mu_1,\nu)$$
$$\times 2\,\mathrm{Im}[(\omega+\nu-\nu_3-\mu_1-i0^+)^{-1}(\omega+\nu-\nu_1-i0^+)^{-1}(\omega-\nu_2-i0^+)^{-1}]\}\tau_3 a(p,\nu_2). \quad (3.10)$$

We note that the second and third terms on the right of Eqs. (3.6) and (3.8), which are discontinuity terms of the type we have previously omitted, do not in fact contribute to the double spectral functions of physical interest. Let us now consider Eq. (3.10) in the limit $\nu\to 0$. We make the Ansatz

$$\mathbf{f}_p^{(i)}(\omega,0)=(\mathbf{p}/m)g^{(i)}(\epsilon_p,\omega), \quad i=1, 2, \quad (3.11)$$

and obtain from (3.10) an equation for $g^{(1)}+g^{(2)}$. On the right-hand side of this equation there occurs the angular factor $(\mathbf{p}-\mathbf{k})\cdot\mathbf{p}/p^2$, which may be replaced by 1 if one neglects terms of order k_BT/μ and k_BT/cp_F (where c is a typical velocity of sound). The d^3k integration may now be transformed into integrations over k, or the phonon

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

frequencies $\omega_\lambda(k)$, where λ designates the phonon branch, and over ϵ_{p-k}. Since the latter integral runs over practically all ϵ_{p-k}, we introduce the functions

$$g^{(i)}(\omega)=\int_{-\infty}^{\infty} d\epsilon g^{(i)}(\epsilon,\omega) \tag{3.12}$$

and integrate both sides of the equation for $g^{(1)}(\epsilon,\omega)+g^{(2)}(\epsilon,\omega)$ over all ϵ. The result can be written in the form

$$g^{(1)}(\omega)+g^{(2)}(\omega)=(2\pi)^{-4}\int d\epsilon d\nu_1 d\nu_2 d\nu_3 d\mu_1 \sum_\lambda \int d\omega_\lambda F_\lambda(\omega_\lambda) d_\lambda(\omega_\lambda,\nu_3)[f(-\mu_1)+N(\nu_3)]a(\epsilon,\nu_1)$$
$$\times\tau_3[g^{(1)}(\mu_1)+g^{(2)}(\mu_1)]\tau_3 a(\epsilon,\nu_2)2\ \mathrm{Im}[(\omega-\nu_1-i0^+)^{-1}(\omega-\nu_3-\mu_1-i0^+)^{-1}(\omega-\nu_2-i0^+)^{-1}]. \tag{3.13}$$

Above we have followed Schrieffer *et al.* in characterizing the phonons by frequency distributions $F_\lambda(\omega_\lambda)$ and spectral functions $d_\lambda(\omega_\lambda,\nu)$ which are of the form

$$d_\lambda(\omega_\lambda,\nu)=2\pi\alpha_\lambda^2(\omega_\lambda)[\delta(\nu-\omega_\lambda)-\delta(\nu+\omega_\lambda)], \tag{3.14}$$

where α_λ measures the strength of the electron-phonon coupling. All of the constants arising from transforming the variables of integration are contained in α_λ.

The functions $g^{(i)}(\omega)$ are matrices in the Nambu space. We make the decomposition

$$g^{(i)}(\omega)=g_0^{(i)}(\omega)1+g_1^{(i)}(\omega)\tau_1 +g_2^{(i)}(\omega)\tau_2+g_3^{(i)}(\omega)\tau_3. \tag{3.15}$$

On the left side of (3.13) we are interested only in the τ_3 component because only this enters the integral for the thermal conductivity. One finds that the terms containing $g_2^{(i)}$ on the right of (3.13) do not enter the τ_3 component of the equation. The terms proportional to $g_0^{(i)}$ and $g_1^{(i)}$ make no contribution to the τ_3 component when integrated over ϵ since the integrands are odd in ϵ. We are then left with a homogeneous integral equation for $g_3^{(1)}(\omega)+g_3^{(2)}(\omega)$. We may now explicitly do the ϵ integral and perform the sum in the Nambu space. When this is done one finds that the right-hand side is *zero* because there occurs an integral we have met with in Sec. II, namely,

$$I_1=\int_{-\infty}^{\infty} d\epsilon\ \mathrm{Tr}[\tau_3 \mathcal{G}(\epsilon,\omega-i0^+)\tau_3\mathcal{G}(\epsilon,\omega-i0^+)]=0. \tag{3.16}$$

(See Appendix C for the evaluation.)

We have thus shown that

$$\frac{1}{2\mu}\int d\epsilon\mathbf{p}\cdot\mathrm{Tr}\{\tau_3[\mathbf{f}_p^{(1)}(\omega,0)+\mathbf{f}_p^{(2)}(\omega,0)]\} =g_3^{(1)}(\omega)+g_3^{(2)}(\omega)=0. \tag{3.17}$$

Hereafter we shall write

$$g_3^{(1)}(\omega)=-g_3^{(2)}(\omega)\equiv g(\omega). \tag{3.18}$$

One can also show, using time reversal invariance and (3.17), that in our approximation we may take $g(\omega)$ to be real (Appendix B).

Using (3.17) in the general expression for the thermal conductivity (3.5) we see that the second term in this last equation does not contribute. The third term on the right-hand side of (3.5) also does not contribute. To see this we take the derivative of both sides of Eq. (3.10) with respect to ν and then set $\nu=0$. We now remove the vector dependence by an Ansatz similar to (3.11) and integrate the resulting equation for scalar quantities over all ϵ. The procedure is identical to that described above Eq. (3.13). We then take the τ_3 projection and find that the right-hand side is zero either because of oddness in ϵ or because of (3.16) and (3.17). In other words, in our approximation we have

$$\int d\epsilon\mathbf{p}\cdot\mathrm{Tr}\left\{\tau_3\frac{\partial}{\partial\nu}[\mathbf{f}_p^{(1)}(\omega,\nu)+\mathbf{f}_p^{(2)}(\omega+\nu,\nu)]|_{\nu=0}\right\}=0. \tag{3.19}$$

We therefore see that the thermal conductivity (3.5) is entirely determined by the τ_3 component of $\mathbf{p}\cdot\mathbf{f}_p^{(2)}(\omega,0)$ or equivalently, through Eqs. (3.11), (3.12), (3.15), and (3.18), by the scalar function $g(\omega)$. To determine this function let us consider Eq. (3.9) in the limit $\nu=0$. In the curly bracket on the right of (3.9) there are eight terms which arise from explicitly taking the imaginary parts. It is convenient to increase this number from eight to ten by adding and subtracting the term $4\pi^4\mathbf{f}_{p-k}^{(1)}(\mu_1,\mu_2)\delta(\omega-\nu_3-\mu_1)\delta(\omega-\nu_2)\delta(\omega-\nu_1)\delta(\mu_2)$ in the curly bracket. The resulting equation for $\mathbf{f}_p^{(1)}(\omega,0)$ may be written in the form

$$\mathbf{f}_p^{(1)}(\omega,0)=-a(p,\omega)\tau_3\mathbf{\Gamma}(\mathbf{p},\omega)\tau_3 a(p,\omega)$$
$$+(2\pi)^{-4}\left\{\int d^3k d\nu[f(\nu-\omega)+N(\nu)]d(k,\nu)\tfrac{1}{2}[\mathcal{G}(p,\omega-i0^+)\tau_3\mathbf{f}_{p-k}^{(1)}(\omega-\nu,0)\tau_3\mathcal{G}(p,\omega+i0^+)\right.$$
$$\left.+\mathcal{G}(p,\omega+i0^+)\tau_3\mathbf{f}_{p-k}^{(1)}(\omega-\nu,0)\tau_3\mathcal{G}(p,\omega-i0^+)]\right\}+\mathbf{f}_p'(\omega,0). \tag{3.20}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(The occurrence of the $+i0^+$'s in the arguments of the Green's functions in the curly bracket will be important in what follows.) In (3.20) $\mathbf{\Gamma}(\mathbf{p},\omega)$ describes the corrected vertex associated with the ladder approximation and is given by

$$\mathbf{\Gamma}(\mathbf{p},\omega)=\omega(\mathbf{p}/m)\tau_3-\int\frac{d^3k}{(2\pi)^3}\int\frac{d\mu_1 d\mu_2 d\nu_3}{(2\pi)^3}\{[f(-\mu_1)+N(\nu_3)]d(k,\nu_3)[\mathbf{f}_{\mathbf{p}-\mathbf{k}}{}^{(1)}(\mu_1,\mu_2)+\mathbf{f}_{\mathbf{p}-\mathbf{k}}{}^{(2)}(\mu_1,\mu_2)]$$
$$\times\mathrm{Re}[(\omega-\nu_3-\mu_1-i0^+)^{-1}(-\mu_2-i0^+)^{-1}]\}. \quad (3.21)$$

The function $\mathbf{f}_p'(\omega,0)$ consists of four interference terms. The explicit form is

$$\mathbf{f}_p'(\omega,0)=2\int\frac{d^3k}{(2\pi)^3}\int\frac{d\mu_1 d\nu_3}{(2\pi)^2}[f(-\mu_1)+N(\nu_3)]d(k,\nu_3)P\frac{1}{\omega-\nu_3-\mu_1}[\mathrm{Re}\mathcal{G}(p,\omega-i0^+)]\tau_3[\mathbf{f}_{\mathbf{p}-\mathbf{k}}{}^{(1)}(\mu_1,0)+\mathbf{f}_{\mathbf{p}-\mathbf{k}}{}^{(2)}(\mu_1,0)]$$
$$\times\tau_3[\mathrm{Im}\mathcal{G}(p,\omega-i0^+)]-2\int\frac{d^3k}{(2\pi)^3}\int\frac{d\mu_2 d\nu_3}{(2\pi)^2}[f(\nu_3-\omega)+N(\nu_3)]d(k,\nu_3)P\left(\frac{1}{\mu_2}\right)$$
$$\times\{[\mathrm{Im}\mathcal{G}(p,\omega-i0^+)]\tau_3\mathbf{f}_{\mathbf{p}-\mathbf{k}}{}^{(1)}(\omega-\nu_3,\mu_2)\tau_3[\mathrm{Re}\mathcal{G}(p,\omega-i0^+)]$$
$$+[\mathrm{Re}\mathcal{G}(p,\omega-i0^+)]\tau_3\mathbf{f}_{\mathbf{p}-\mathbf{k}}{}^{(2)}(\omega-\nu_3,\mu_2)\tau_3[\mathrm{Im}\mathcal{G}(p,\omega-i0^+)]\}. \quad (3.22)$$

We shall return in a moment to $\mathbf{f}'$. However, let us first consider the vertex corrections (3.21). In general, we may define the Fourier coefficients of a vertex operator by the relation

$$\chi(\mathbf{p},\zeta_l+\nu_m;\mathbf{p},\zeta_l)$$
$$=(\mathbf{p}/2m)[\mathcal{G}(p,\zeta_l+\nu_m)\tau_3+\tau_3\mathcal{G}(p,\zeta_l)]$$
$$-\mathcal{G}(p,\zeta_l+\nu_m)\mathbf{\Gamma}_p(\zeta_l+\nu_m,\zeta_l)\mathcal{G}(p,\zeta_l). \quad (3.23)$$

The function $\mathbf{\Gamma}(\mathbf{p},\omega)$ is then related to the analytic continuation of the Fourier series coefficients by

$$\mathbf{\Gamma}(p,\omega)=\mathbf{\Gamma}_p(\omega+\nu,\nu)|_{\nu=0}, \quad (3.24)$$

where

$$\mathbf{\Gamma}_p(\omega+\nu,\nu)=\tfrac{1}{2}\{\mathbf{\Gamma}_p(\zeta_l+\nu_m,\zeta_l)|_{\substack{\zeta_l=\omega-i0^+\\ \nu_m=\nu-i0^+}}$$
$$+\mathbf{\Gamma}_p(\zeta_l+\nu_m,\zeta_l)|_{\substack{\zeta_l=\omega+i0^+\\ \nu_m=\nu+i0^+}}\}. \quad (3.25)$$

It is straightforward to verify that $\mathbf{\Gamma}(\mathbf{p},\omega)$ as defined by (3.23)–(3.25) is in fact given by (3.21) in the ladder approximation of (3.6).

There exists a Ward identity, reflecting the conservation of energy density, for the vertex function introduced above. This Ward identity has been discussed with great clarity by Langer,[8] and it is therefore not necessary to give the derivation here. The result in terms of Fourier series coefficients is[16]

$$\mathbf{\Gamma}_p(\zeta_l,\zeta_l)=-\zeta_l\nabla_p\mathcal{G}^{-1}(p,\zeta_l)$$
$$=-\zeta_l\nabla_p[\zeta_l-((p^2/2m)-\mu)\tau_3-\Sigma(p,\zeta_l)]. \quad (3.26)$$

[16] In Langer's result (Ref. 8) there occur additional terms due to the nonlocality in space of the Coulomb interaction he considers. Such terms do not occur for the electron-phonon interaction. For the direct Coulomb interaction it is in any case consistent with the Eliashberg approximation to neglect such terms. It should also be remarked that since the Ward identity (3.26) follows from the strict conservation of energy density it requires the inclusion in the vertex function of the heat current $\mathbf{u}_{ph}$ introduced above Eq. (2.2) and then rapidly discarded. This means that in using (3.26) we are including a part of the "phonon-drag" thermal conduction. Since we have already argued that processes of this type have a negligible effect on the thermal conductivity, their inclusion here is of no consequence.

We notice that in the Eliashberg approximation of neglecting the momentum dependence of the self-energy operator the vertex correction is zero. We may therefore make the replacement

$$\mathbf{\Gamma}(\mathbf{p},\omega)\rightarrow(\mathbf{p}/m)\omega\tau_3. \quad (3.27)$$

In a more exact treatment one would have to include the effective mass and wave function renormalization corrections implied by (3.26).

We now return to Eq. (3.20), remove the vector dependence, and integrate both sides of the resulting equation over all ϵ. The τ_3 component of this equation is then found to be

$$g(\omega)=-\frac{\pi\omega}{|\mathrm{Im}Z(\omega^2-\Delta^2)^{1/2}|}\left(1+\frac{\omega^2-|\Delta|^2}{|\omega^2-\Delta^2|}\right)$$
$$\times\left\{1-\frac{1}{2\omega}\int\frac{d\nu}{2\pi}\sum_\lambda\int d\omega_\lambda F_\lambda(\omega_\lambda)d_\lambda(\omega_\lambda,\nu)\right.$$
$$\left.\times[f(\nu-\omega)+N(\nu)]g(\omega-\nu)\right\}+g'(\omega), \quad (3.28)$$

where $g'(\omega)$ comes from the interference terms $\mathbf{f}'$ given in (3.22). Whereas in the other terms of (3.20) the τ_3 component on the left is only coupled to the τ_3 component on the right, g' turns out to depend only on g_2. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

explicit form we find is

$$g'(\omega)=\frac{i\pi\omega\,\mathrm{Im}\Delta}{|\mathrm{Im}Z(\omega^2-\Delta^2)^{1/2}||\omega^2-\Delta^2|}$$
$$\times\Big\{\int\frac{d\nu d\mu_1}{(2\pi)^2}[f(-\mu_1)+N(\nu)]$$
$$\times\sum_\lambda\int d\omega_\lambda\frac{F_\lambda(\omega_\lambda)d_\lambda(\omega_\lambda,\nu)}{(\omega-\nu-\mu_1)_p}[g_2^{(1)}(\mu_1)+g_2^{(2)}(\mu_2)]$$
$$+\int\frac{d\nu d\mu_2}{(2\pi)^2}[f(\nu-\omega)+N(\nu)]$$
$$\times\sum_\lambda\int d\omega_\lambda\frac{F_\lambda(\omega_\lambda)d_\lambda(\omega_\lambda,\nu)}{(\mu_2)_p}$$
$$\times[g_2^{(1)}(\omega-\nu,\mu_2)-g_2^{(2)}(\omega-\nu,\mu_2)]\Big\}. \quad (3.29)$$

The coupling between the τ_3 and the τ_2 components, though physically interesting, appears to be of negligible importance for our problem. In the first place, an examination of Eq. (3.13) shows that the τ_2 component on the left is coupled only to the τ_2 component on the right. In other words, $g_2^{(1)}(\omega)+g_2^{(2)}(\omega)$ satisfies a linear homogeneous integral equation. Therefore this quantity can at most be nonzero for certain values of the electron-phonon coupling constant, an unphysical possibility which it seems safe to ignore. In comparing the remaining term in Eq. (3.29) with the homogeneous term in (3.28) we encounter the ratio $[\mathrm{Im}\Delta(\omega)/\omega]$. From the numerical results of Schrieffer *et al.* we see that for the frequencies of interest, i.e., $\omega<10kT_c$, this factor is less than 0.1 at $T=0$ and consequently exceedingly small just below $T=T_c$. Thus, barring the occurrence of other large factors, the second term in (3.29) is also negligible. An order of magnitude comparison of the integrands of this term and the homogeneous term in (3.28) yields the ratio $\Gamma(\omega-\nu)/(\omega-\nu)$, where $\Gamma(\omega-\nu)$ is a typical width at frequency $(\omega-\nu)$. Although this factor is not small over the entire region of interest, it is never large. It therefore seems safe to conclude that the terms in g' are of no significance. These terms evidently describe weak-relaxation processes peculiar to the superconducting state which involve the motion of condensed pairs relative to the single-particle excitations.[17] We plan to study these processes further.

Since the coupling between different components in the Nambu space came solely from g' in (3.28), none remains when this term is omitted. On introducing the spectral function (3.14) we then obtain

$$g(\omega)=-\frac{\pi\omega}{|\mathrm{Im}Z(\omega^2-\Delta^2)^{1/2}|}\left(1+\frac{\omega^2-|\Delta|^2}{|\omega^2-\Delta^2|}\right)$$
$$\times\Big\{1-(2\omega)^{-1}f^{-1}(-\omega)\sum_\lambda\int d\omega_\lambda\alpha_\lambda^2(\omega_\lambda)F_\lambda(\omega_\lambda)$$
$$\times[f(\omega_\lambda-\omega)(1+N(\omega_\lambda))g(\omega-\omega_\lambda)$$
$$+f(-\omega_\lambda-\omega)N(\omega_\lambda)g(\omega+\omega_\lambda)]\Big\}. \quad (3.30)$$

It follows from (3.30) that $g(\omega)$ is odd in ω, which one also expects on general grounds. Further one sees that near $T=0$ $g(\omega)=0$ for $\omega<\Delta_0$. From (3.5) and our subsequent analysis we see that the thermal conductivity K is determined once $g(\omega)$ is known by the quadrature

$$K=-\frac{n}{4mk_BT^2}\int_0^\infty\frac{d\omega}{2\pi}\omega\,\mathrm{sech}^2(\tfrac{1}{2}\beta\omega)g(\omega). \quad (3.31)$$

The Hartree-Fock result (2.17) is recovered if we approximate $g(\omega)$ by the inhomogeneous term of (3.30). In the small width limit $|\mathrm{Im}[Z(\omega^2-\Delta^2)^{1/2}]|^{-1}\to(\omega^2-\Delta_1^2)^{1/2}/\omega\Gamma$. If one introduces instead of $g(\omega)$ a new function $G(\omega)$ defined according to

$$g(\omega)=-\pi\,\mathrm{sgn}\omega(\omega^2-\Delta_1^2)^{1/2}\left(1+\frac{\omega^2-\Delta_1^2}{|\omega^2-\Delta_1^2|}\right)G(\omega), \quad (3.32)$$

one obtains an integral equation for $G(\omega)$ which is identical to the integral equation obtained previously from the Boltzmann equation. [Essentially Eq. (2.18) of I if the differences in phonon spectra used are taken into account.]

If the width is not small, (3.30) is the most convenient form for numerical calculations. The complex functions $\Delta(\omega)$ and $Z(\omega)$ have to be determined from the set of integral equations given in Appendix A.

IV. CONCLUSIONS

In spite of some anfractuous analysis, we have been led to a relatively straightforward scheme for calculating the electronic thermal conductivity of strongly coupled superconductors. The Eliashberg approximation of weak momentum dependence is essential for much of the final simplicity. We have found in this approximation that the thermal conductivity is determined by an integral of the expression $\omega\,\mathrm{sech}^2(\frac{1}{2}\beta\omega)g(\omega)$ over all excitation energies ω. The function $g(\omega)$ plays the role of the deviation from an equlibrium distribution and satisfies the generalized Boltzmann equation (3.30).

If one neglects the difference between the transport and the scattering cross sections, or equivalently keeps only the inhomogeneous term of the integral equation (3.30), one recovers the result of the Hartree-Fock

[17] This is a situation reminiscent of the collective excitation which occurs in the response of the superconductor to finite frequency and wave number electromagnetic disturbances.

approximation of Sec. II. In this case, for frequencies not too far above the gap edge $g(\omega)$ becomes approximately equal to $-2\pi(\omega^2-\Delta_1^2)^{1/2}/\Gamma(\omega)$, where $\Gamma(\omega)$ plays the role of a width parameter and is in the weak-coupling limit identical with the reciprocal of twice the quasiparticle lifetime as calculated in II. The expression for $\Gamma(\omega)$ is $\Gamma(\omega)\approx|Z_2(\omega^2-\Delta_1^2)-Z_1\Delta_1\Delta_2|\omega^{-1}$. The renormalization function $Z(\omega)$ and the gap function $\Delta(\omega)$ have to be determined from the Eliashberg gap equations given in Appendix A.

The gap equations have been solved for lead by Schrieffer *et al.* in the limit of zero temperature, but not for temperatures near T_c which are of interest here. We can therefore only speculate about the manner in which the great reduction in the thermal conductivity of superconducting lead might be explained by our theory. The calculations in I have shown that in the small width limit the decrease of K_s/K_n with decreasing temperature is mainly due to the increase of Δ_1 in the factor $(\omega^2-\Delta_1^2)^{1/2}$ in the integrand of K_s, while $T^3\Gamma_s^{-1}$ (as a function of $\beta\omega$) is relatively insensitive to changes in temperature near T_c. Let us assume that this is also true for lead. Then it is important to note that near T_c energies up to about $\omega_m=10k_BT_c$ contribute to the heat current. This means that the first peak in the curve for $\Delta_1(\omega)$ calculated by Schrieffer *et al.* which occurs at $\omega_1{}'=4.4\times10^{-3}$ eV$\approx10k_BT_c$ occurs roughly at ω_m. If the shape of the $\Delta_1(\omega)$ curve were preserved at temperatures near T_c or, more precisely, if the ratio $\Delta_1(\omega)/\Delta_0$ were nearly independent of T, then the effective gap Δ_1 for the excitations predominantly carrying the heat current would clearly be much greater than the gap edge Δ_0. This would lead to a substantial reduction of K_s/K_n compared to the value obtained in the small width limit.

To go beyond the Hartree-Fock approximation one must numerically solve the integral equation (3.30). From the experience of the calculations reported in I, it is not expected that this more exact treatment will drastically affect the thermal conductivity. Nevertheless, without a solution of the integral equation it seems difficult to estimate the errors introduced by the Hartree-Fock approximation. It is worth noting that the most complicated part of the integral equation (3.30), which depends on the solution of the gap equations, is the Hartree-Fock value of $g(\omega)$ which occurs as a factor in both the homogeneous and inhomogeneous terms. It should also be noted that the same electron-phonon coupling strengths, α_λ, and phonon frequency distributions $F_\lambda(\omega_\lambda)$ occur in the integral equation for $g(\omega)$ and those for $\Delta(\omega)$ and $Z(\omega)$.

In the small width limit, i.e., $\alpha_\lambda\to0$, we have indicated how (3.30) may be transformed into the Bloch-Boltzmann equation for the superconducting state. A byproduct of the analysis given in the present paper has thus been the justification of the use of this equation, as in I, for example. In our extreme long-wavelength low-frequency limit the only validity criterion for the use of the Boltzmann equation is that well defined quasiparticles exist in the thermally excited frequency range below roughly $10k_BT$. This criterion also applies to the normal state, and when it fails one must resort to the more general approach described in this paper.

ACKNOWLEDGMENTS

It is a pleasure to thank Professor L. P. Kadanoff for a useful discussion. Much of the contribution of the first named author (V. A.) was performed during a six week visit to the Bell Telephone Laboratories during the summer of 1963. The authors are happy to take the opportunity to thank the Bell Telephone Laboratories and in particular their friends and colleagues in the Theoretical Physics Department for their gracious hospitality.

APPENDIX A

In the Nambu representation the superconductive approximation to the electronic self-energy operator has the Fourier coefficients

$$\Sigma(p,\zeta_l)=-\frac{1}{\beta}\sum_{\nu_m}\int\frac{d^3q}{(2\pi)^3}\tau_3 \times\mathcal{G}(p-q,\zeta_l-\nu_m)\tau_3D(q,\nu_m). \quad \text{(A1)}$$

Here

$$\mathcal{G}^{-1}(p,z)=z-\epsilon_p-\Sigma(p,z) \quad \text{(A2)}$$

and the Nambu Ansatz for $\Sigma(p,z)$ is

$$\Sigma(p,z)=z\zeta_p(z)+\chi_p(z)\tau_3+\phi_p(z)\tau_1. \quad \text{(A3)}$$

Following Eliashberg we neglect χ the even in frequency component of the diagonal (in Nambu space) part of Σ as contributing only a shift in the chemical potential. Then $\mathcal{G}^{-1}$ has the form given in Eq. (2.12), namely

$$\mathcal{G}^{-1}(p,z)=zZ(z)-\epsilon\tau_3-\phi(z)\tau_1, \quad \text{(A4)}$$

where $Z(z)=1-\zeta(z)$. The functions ϕ and Z have the properties

$$\begin{aligned} &Z(z^*)=Z^*(z);\quad Z(-z)=Z(z),\\ &\phi(z^*)=\phi^*(z);\quad \phi(-z)=\phi(z). \end{aligned} \quad \text{(A5)}$$

$Z(z)$ is even because $z\zeta(z)$ is the odd component of the diagonal part of Σ. The function $\phi(z)$ may be taken to be even in z for s state pairing because of spin-rotation invariance, time-reversal symmetry, and spatial-inversion symmetry.[18] Using (A5) it is easily seen that the spectral function $a(p,\omega)$ defined by Eq. (2.13) has the properties

$$\begin{aligned} &\mathrm{Tr}[a(p,\omega)]=\mathrm{Tr}[a(p,-\omega)],\\ &\mathrm{Tr}[\tau_i a(p,\omega)]=-\mathrm{Tr}[\tau_i a(p,-\omega)]. \end{aligned} \quad \text{(A6)}$$

Now we insert the spectral representations for $\mathcal{G}$ and D

[18] Questions of symmetry are very carefully considered in P. Nozieres, *Theory of Interacting Fermion Systems* (W. A. Benjamin, Inc., New York, 1963).

[Eqs. (2.10) and (3.7)] into (A1) and perform the sum over ν_m. We then make the weak-momentum approximation for ϕ and Z and perform the integral over d^3q in the manner discussed in Sec. III. The integral of $a(\epsilon,\omega)$ over all ϵ which is needed here is given by[6,10]

$$\int_{-\infty}^{\infty} d\epsilon a(\epsilon,\omega) = -2\pi \,\mathrm{Re}\left\{\frac{\omega Z(\omega)+\phi(\omega)\tau_1}{\epsilon_1(\omega)}\right\}, \quad \text{(A7)}$$

where ϵ_1 is the root of $\epsilon^2+\phi^2(\omega)-(\omega-i0^+)^2Z^2(\omega)=0$ which lies in the upper half-plane. [For real argument ω, $\phi(\omega)$ and $Z(\omega)$ are given by (2.16).] After performing the steps outlined above, we decompose the integral equation for $\Sigma(z)$ in the Nambu space and equate coefficients of 1 and τ_3 on the right and left sides. The symmetries (A6) may be used to simplify the equations. The final equations are

$$\Delta(z)=\frac{1}{Z(z)}\int_0^\infty d\omega_1 \,\mathrm{Re}\left\{\frac{\Delta(\omega_1)}{[\omega_1^2-\Delta^2(\omega_1)]^{1/2}}\right\}\sum_\lambda \int d\omega_\lambda \alpha_\lambda^2(\omega_\lambda)F_\lambda(\omega_\lambda)$$
$$\times\{[N(\omega_\lambda)+f(-\omega_1)][(\omega_1+\omega_\lambda+z)^{-1}+(\omega_1+\omega_\lambda-z)^{-1}]$$
$$-[N(\omega_\lambda)+f(\omega_1)][(-\omega_1+\omega_\lambda+z)^{-1}+(-\omega_1+\omega_\lambda-z)^{-1}]\}, \quad \text{(A8)}$$

$$z[1-Z(z)]=\int_0^\infty d\omega_1 \,\mathrm{Re}\left\{\frac{\omega_1}{[\omega_1^2-\Delta^2(\omega_1)]^{1/2}}\right\}\sum_\lambda \int d\omega_\lambda \alpha_\lambda^2(\omega_\lambda)F_\lambda(\omega_\lambda)$$
$$\times\{[N(\omega_\lambda)+f(-\omega_1)][(\omega_1+\omega_\lambda+z)^{-1}-(\omega_1+\omega_\lambda-z)^{-1}]$$
$$+[N(\omega_\lambda)+f(\omega_1)][(-\omega_1+\omega_\lambda+z)^{-1}-(-\omega_1+\omega_\lambda-z)^{-1}]\}.$$

The physical values of Δ and Z are obtained by setting $z=\omega-i0^+$ in (A8). The sign of the square root in (A8) is to be determined by $\mathrm{Im}\{Z(\omega^2-\Delta^2)^{1/2}\}<0$.

APPENDIX B

The spectral representation (3.4) for the object $\chi_{ij}(t_1,t_2,t_3)\equiv T\langle\psi_i(t_1)\mathbf{u}(t_2)\psi_j^\dagger(t_3)\rangle$ follows from its periodicity properties for imaginary times. (We suppress the spatial arguments for brevity.) Consider the region of time $\mathrm{Re}t_1,\ t_2,\ t_3=0$; $0>\mathrm{Im}t_1,\ t_2,\ t_3>-\beta\equiv i\tau$, and let T order the operators from right to left in order of increasing negative imaginary time.[7] Then measuring energies with respect to the chemical potential, and using the cyclic invariance of the trace operation contained in the ground canonical ensemble average, one finds the periodicity properties

$$\begin{aligned}\chi_{ij}(0,t_2,t_3)&=-\chi_{ij}(\tau,t_2,t_3),\\ \chi_{ij}(t_1,0,t_3)&=+\chi_{ij}(t_1,\tau,t_3),\\ \chi_{ij}(t_1,t_2,0)&=-\chi_{ij}(t_1,t_2,\tau).\end{aligned} \quad \text{(B1)}$$

As a result we may make the Fourier series expansion

$$\chi_{ij}(t_1,t_2,t_3)=\frac{1}{\tau^3}\sum_{lmn}\chi_{ij}(n,m,l)e^{-i\zeta_n t_1}e^{-i\nu_m t_2}e^{-i\zeta_l t_3}, \quad \text{(B2)}$$

where $\zeta_n=(2n+1)\pi/\tau$, $\nu_m=2\pi m/\tau$, $\zeta_l=(2l+1)\pi/\tau$. Because $\chi(t_1,t_2,t_3)=\chi(t_1-t_2,\ t_2-t_3)$ we expect $\chi(nml)$ to be zero unless $\zeta_n+\nu_m+\zeta_l=0$. Inverting the Fourier series we have

$$\chi_{ij}(n,m,l)=\int_0^\tau dt_1\int_0^\tau dt_2\int_0^\tau dt_3\chi_{ij}(t_1,t_2,t_3)$$
$$\times e^{i\zeta_n t_1}e^{i\nu_m t_2}e^{i\zeta_l t_3}. \quad \text{(B3)}$$

To do the integral we break up the domain of integration into six regions corresponding to the six time-ordered constituents of χ. In each of these regions the time dependence of the Heisenberg operators can be displayed and the integrals trivially performed. One verifies that $\chi(nml)$ is indeed zero unless the condition written above (B3) is satisfied. It is convenient to take as independent variables ζ_l and ν_m and to introduce $\chi(\zeta_l+\nu_m,\zeta_l)\equiv\tau\chi(l+m,-m,-l-1)$ so that the Fourier expansion reads

$$\chi_{ij}(t_1-t_2,\ t_2-t_3)=\frac{1}{\tau^2}\sum_{lm}\chi_{ij}(\zeta_l+\nu_m,\zeta_l)$$
$$\times e^{-i(\zeta_l+\nu_m)(t_1-t_2)}e^{-i\zeta_l(t_2-t_3)}. \quad \text{(B4)}$$

After explicitly carrying out the time integrals in (B3) in the manner indicated above, one finds that the Fourier coefficient $\chi(\zeta_l+\nu_m,\zeta_l)$ can be written in the form (3.4). The spectral functions $\mathbf{f}^{(1)}$ and $\mathbf{f}^{(2)}$ obtained explicitly in this way are sums of products of three matrix elements, and two delta functions involving the frequencies ω_1 and ω_2. After some rearrangement one finds that the spectral functions may be written compactly in the form

$$\mathbf{f}_{ij}^{(1)}(\omega_1,\omega_2)=\int_{-\infty}^{\infty}dt_1\int_{-\infty}^{\infty}dt_2$$
$$\times\langle\{[\mathbf{u}(-t_2),\psi_i(0)],\psi_j^\dagger(-t_1)\}\rangle$$
$$\times e^{i\omega_1 t_1}e^{i\omega_2 t_2}, \quad \text{(B5)}$$

and

$$\mathbf{f}_{ij}^{(2)}(\omega_1,\omega_2)=\int_{-\infty}^{\infty}dt_1\int_{-\infty}^{\infty}dt_2\langle\{[\mathbf{u}(-t_2),\psi_j^\dagger(0)],\psi_i(t_1)\}\rangle$$
$$\times e^{i\omega_1 t_1}e^{i\omega_2 t_2}. \quad \text{(B6)}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Above, the curly bracket indicates the anticommutator and the square bracket the commutator.

We now wish to substantiate the remarks made after Eq. (3.18) about the reality of $g(\omega)$. If one uses time reversal invariance on the closed forms (B5) and (B6) one finds the relation

$$\mathbf{f}_{ij}^{(1)}(\omega_1,\omega_2)=-(\tau_2)_{ik}\mathbf{f}_{lk}^{(2)}(-\omega_1,\omega_2)^*(\tau_2)_{lj}. \quad \text{(B7)}$$

Further from explicit complex conjugation of (B5) and (B6) one finds

$$\mathbf{f}_{ij}^{(1)}(\omega_1,\omega_2)^*=-\mathbf{f}_{ji}^{(2)}(\omega_1,-\omega_2). \quad \text{(B8)}$$

From (B7) and (B8) we can derive the exact identity

$$\mathrm{Tr}[\mathbf{f}^{(2)}(\omega_1,\omega_2)\tau_3]=-\mathrm{Tr}[f^{(1)}(\omega_1,-\omega_2)\tau_3]^*. \quad \text{(B9)}$$

In the ladder approximation we have proved that

$$\int d\epsilon\mathbf{p}\cdot\mathrm{Tr}\{\tau_3[\mathbf{f}^{(1)}(\omega,0)+\mathbf{f}^{(2)}(\omega,0)]\}=0. \quad \text{(B10)}$$

It follows from (B9) and (B10) that in our approximation

$$\int d\epsilon\mathbf{p}\cdot\mathrm{Tr}[\tau_3\mathbf{f}^{(1)}(\omega,0)] = \int\left\{d\epsilon\mathbf{p}\cdot\mathrm{Tr}[\tau_3\mathbf{f}^{(1)}(\omega,0)]\right\}^*. \quad \text{(B11)}$$

Using the definition of $g(\omega)$ contained in Eqs. (3.18), (3.15), and (3.11) we see that (B11) implies that this function is real.

APPENDIX C

Here we sketch the evaluation of the integrals I_1 and I_2 given in Eqs. (2.14) and (2.15). Although the evaluation is straightforward it seems worth presenting, particularly because (2.14) plays an important role in Sec. III.

Consider first I_1. We have using (2.12)

$$I_1=\int_{-\infty}^{\infty}d\epsilon\,\mathrm{Tr}[\tau_3\mathcal{G}(\epsilon,\omega-i0^+)\tau_3\mathcal{G}(\epsilon,\omega-i0^+)]$$

$$=2\int_{-\infty}^{\infty}d\epsilon\frac{\omega^2Z^2+\epsilon^2-\phi^2}{(\epsilon-\epsilon_1)^2(\epsilon+\epsilon_1)^2}, \quad \text{(C1)}$$

where $\epsilon=\pm\epsilon_1$ are the roots of

$$\omega^2Z^2-\epsilon^2-\phi^2=0. \quad \text{(C2)}$$

We choose $+\epsilon_1$ to lie in the upper half-plane. Then by contour integration

$$I_1=4\pi i\left[-\frac{\omega^2Z^2-\phi^2}{4\epsilon_1^3}+\frac{1}{4\epsilon_1}\right]=0, \quad \text{(C3)}$$

where the last step follows from (C2). The integral I_2, on the other hand, is given by

$$I_2=\int_{-\infty}^{\infty}d\epsilon\,\mathrm{Tr}[\tau_3\mathcal{G}(\epsilon,\omega-i0^+)\tau_3\mathcal{G}(\epsilon,\omega+i0^+)]$$

$$=2\int_{-\infty}^{\infty}d\epsilon\frac{\omega^2|Z|^2+\epsilon^2-|\phi|^2}{(\epsilon-\epsilon_1)(\epsilon+\epsilon_1)(\epsilon-\epsilon_1^*)(\epsilon+\epsilon_1^*)}. \quad \text{(C4)}$$

Since ϵ_1 is in the upper half-plane, so is $-\epsilon_1^*$. By a straightforward contour integration,

$$I_2=4\pi i\left[\frac{\omega^2|Z|^2-|\phi|^2+\epsilon_1^2}{8i\epsilon_1\,\mathrm{Im}\epsilon_1\,\mathrm{Re}\epsilon_1}+\frac{\omega^2|Z|^2-|\phi|^2+(\epsilon_1^*)^2}{8i\,\mathrm{Re}\epsilon_1\,\mathrm{Im}\epsilon_1\cdot\epsilon_1^*}\right]$$

$$=\frac{\pi}{\mathrm{Im}\epsilon_1}\left[\frac{\omega^2|Z|^2-|\phi|^2+|\epsilon_1|^2}{|\epsilon_1|^2}\right]. \quad \text{(C5)}$$

Using (C2) and the relation $\Delta(\omega)=\phi(\omega)/Z(\omega)$, (C5) may be put in the form given in (2.15).

Dissipation in Quantum Mechanics. Two-Level System. II

I. R. SENITZKY
U. S. Army Electronics Research and Development Laboratories, Fort Monmouth, New Jersey

(Received 20 December 1963)

The theory of a previous article, dealing with two types of two-level systems coupled to a loss mechanism (LM), is extended. The first extension consists of the consideration of the most general type of two-level system (TLS), in which the dipole moment is expanded in terms of the three Pauli spin matrices and unit matrix, the expansion coefficients being vectors (dipole vectors). The second extension consists of the addition to the thermal-reservoir type of LM of a large number of systems identical to the TLS under consideration. The TLS is described in terms of the time development of the Pauli matrices and differential equations are obtained for their expectation value in the presence of arbitrary driving fields. The Bloch equations for a magnetic dipole of spin $\frac{1}{2}$ are exhibited as a special case of these equations, corresponding to a particular combination of the dipole vectors. All other combinations describe electric dipole systems. Equations for two simple special cases of such systems are presented, one treated in the previous article and the other having permanent dipole moment. The frequency of oscillation of a freely decaying TLS is derived and shown to be shifted by an amount that depends on the relationship between the dipole vectors. It is pointed out that the commonly held belief that any TLS can be represented as a magnetic dipole of spin $\frac{1}{2}$ is only approximately correct in the presence of dissipation. The conditions under which the differential equations for the expectation values of the dynamical variables of the TLS can be converted into differential equations for macroscopic variables are discussed.

INTRODUCTION

IN a previous article,[1] it was pointed out that there are many important physical problems which may be considered, with some simplification, as that of a two-level system (TLS) coupled to a loss mechanism (LM), and a study was made of this problem. The LM was a thermal reservoir type of system, and two types of TLS were considered, the magnetic dipole type and the electric dipole type without permanent dipole moment that couples to its environment through one dynamical variable only. In the present article the analysis of I will be extended in two aspects. One extension is the consideration of the most general type of two-level dipole system, of which the two types considered in I are special cases.[2] The results will produce, on the one hand, a unified method of treating all two-level systems, and on the other hand, an explicit and systematic exhibition of differences among two-level systems. The other extension is the consideration of a more complicated LM, one which consists not only of a thermal reservoir but also—in addition to the reservoir—of a large number of systems identical to the TLS under consideration, loosely coupled to it, and surrounded by the same environment. (In the language of magnetic resonance, coupling of the "spin-spin" type as well as the "spin-lattice" type will be considered.) Part I and part II contain the first and second extensions, respectively. Some consequences of the results and several special cases are discussed in part III.

[1] I. R. Senitzky, Phys. Rev. **131**, 2827 (1963); hereafter referred to as I.

[2] The electric dipole TLS is far richer in possibilities than the magnetic dipole TLS, since the latter is restricted by the special properties of angular momentum. All cases other than the two considered in I are electric dipole types.

I.

The defining property of a dipole system may be given by the form of the interaction energy of the system with an electric or magnetic field,

$$H_{\text{int}}=-\mathbf{d}\cdot\mathbf{E},\ -\mathbf{d}\cdot\mathbf{H}, \tag{1}$$

respectively, where $\mathbf{d}$, the dipole moment, is an operator referring only to the system under consideration. Since our system is a TLS, the components of $\mathbf{d}$, that is d_x, d_y, and d_z are 2×2 Hermitian matrices, and for the most general TLS, these are arbitrary. Now, any 2×2 Hermitian matrix may be written as a linear superposition of the Pauli spin matrices together with the unit matrix. We may therefore write

$$\mathbf{d}=\mu\sum_{\alpha=1}^{4}\mathbf{a}_\alpha\sigma_\alpha, \tag{2}$$

where σ_4 is the unit matrix, σ_1, σ_2, and σ_3 are the three Pauli spin matrices, μ is a quantity having the dimension of dipole moment, and the $\mathbf{a}$'s are four real 3-dimensional vectors (determined by 12 real numbers, as many as determine three Hermitian 2×2 matrices) which determine completely the dipole moment operator of the TLS. The three Pauli spin matrices obey the well-known properties

$$\sigma_i^2=1,\quad \{\sigma_i,\sigma_j\}=0,\quad [\sigma_k,\sigma_l]=2i\sigma_m, \tag{3}$$

where $i\neq j$, $\{\ \}$ is the anticommutator bracket, and k, l, m stand for the cyclic permutation of 1, 2, 3. The $\mathbf{a}_i$'s may be normalized by the requirement that

$$d^2(\equiv\mathbf{d}\cdot\mathbf{d})=n\mu^2, \tag{4}$$

[the right side of Eq. (4) is to be considered multiplied

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

by the unit matrix] which gives

$$\sum_{\alpha=1}^{4} a_\alpha^2 = n, \tag{5}$$

where n is a number of the order of unity chosen for convenience in the particular case under consideration. The representation of the σ's is such that the energy of the TLS is given by $\frac{1}{2}\hbar\omega\sigma_3$. For an electric dipole system, nothing more can be said about the $\mathbf{a}$'s without additional information about the system. For a magnetic dipole TLS, however, the proportionality between magnetic moment and angular momentum requires that $\mathbf{a}_4=0$, and that $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ be perpendicular to each other and equal in magnitude.

The TLS is subject to fields produced by the LM and to externally imposed fields, $\mathbf{E}_{\rm LM}$ and $\mathbf{E}_{\rm ext}$, respectively, for the electric system, and $\mathbf{H}_{\rm LM}$ and $\mathbf{H}_{\rm ext}$ for magnetic system. We introduce the notation

$$\mathbf{F}=-(2/\hbar)\mu\mathbf{E}_{\rm LM}, \quad \mathbf{f}=-(2/\hbar)\mu\mathbf{E}_{\rm ext} \tag{6a}$$

for the electric dipole case, and

$$\mathbf{F}=-(2/\hbar)\mu\mathbf{H}_{\rm LM}, \quad \mathbf{f}=-(2/\hbar)\mu\mathbf{H}_{\rm ext} \tag{6b}$$

for the magnetic dipole case. The Hamiltonian may now be written, for either case, as

$$H=H_{\rm LM}+\tfrac{1}{2}\hbar\omega\sigma_3+\tfrac{1}{2}\hbar\textstyle\sum_\alpha \sigma_\alpha \mathbf{a}_\alpha\cdot\mathfrak{F}, \tag{7}$$

where

$$\mathfrak{F}=\mathbf{F}+\mathbf{f}. \tag{7a}$$

Comparison of Eq. (7) with Eqs. (I.60) and (I.70) shows that the electric dipole case in I corresponds to $a_\alpha=\delta_{\alpha 1}$ and the magnetic case corresponds to $\mathbf{a}_1=\hat{x}$, $\mathbf{a}_2=\hat{y}$, $\mathbf{a}_3=\hat{z}$, $\mathbf{a}_4=0$, $\hat{x}$, $\hat{y}$, $\hat{z}$ being unit Cartesian coordinate vectors.

A TLS can have only three linearly independent dynamical variables, since each variable corresponds to a 2×2 Hermitian matrix and, as mentioned previously, there are only three such linearly independent matrices possible, aside from the physically uninteresting unit matrix. In the present analysis, (as in I), the TLS will be described by the three Pauli spin matrices. Once we have these, we can obtain the dipole moment, the energy, and any other variable. The LM will be described (likewise as in I) by $H_{\rm LM}$ and $\mathbf{F}$.

The expression for the Hamiltonian, Eq. (7), may be rewritten as

$$H=H_{\rm LM}+\tfrac{1}{2}\hbar\omega\sigma_3+\tfrac{1}{2}\hbar\sum_{\alpha=1}^{4}\sum_{m=1}^{3}\sigma_\alpha a_{\alpha m}\mathfrak{F}_m, \tag{8}$$

where the vectors have been resolved along Cartesian axes labeled 1, 2, and 3. As in I, we consider F_1, F_2, and F_3 to act independently of one another; we assume that they refer to three independent but identical LM's. Correspondingly, we write

$$H_{\rm LM}=H_1+H_2+H_3. \tag{9}$$

(This separation of $H_{\rm LM}$ was not indicated explicitly in I, but is implicit in the argument used there.) The equations of motion for the TLS and LM, obtained from Eqs. (8) and (9), are

$$\dot{\sigma}_1=-\omega\sigma_2+\textstyle\sum_m(a_{2m}\mathfrak{F}_m\sigma_3-a_{3m}\mathfrak{F}_m\sigma_2), \tag{10a}$$

$$\dot{\sigma}_2=\omega\sigma_1+\textstyle\sum_m(a_{3m}\mathfrak{F}_m\sigma_1-a_{1m}\mathfrak{F}_m\sigma_3), \tag{10b}$$

$$\dot{\sigma}_3=\textstyle\sum_m(a_{1m}\mathfrak{F}_m\sigma_2-a_{2m}\mathfrak{F}_m\sigma_1), \tag{10c}$$

$$\dot{F}_m=-(i/\hbar)[F_m,H_m], \tag{10d}$$

$$\dot{H}_m=-(i/2)\textstyle\sum_\alpha a_{\alpha m}\sigma_\alpha[H_m,F_m]. \tag{10e}$$

The last two equations may be combined to give

$$\dot{F}_m(t)=-(i/\hbar)[F_m,H_m(0)]+(1/2\hbar)\sum_\alpha a_{\alpha m}\int_0^t dt_1 \times[F_m(t),[F_m(t_1),H_m(t_1)]\sigma_\alpha(t_1)], \tag{11}$$

which may be rewritten as an integral equation

$$F_m(t)=F_m^{(0)}(t)+(1/2\hbar)\sum_\alpha a_{\alpha m}\int_0^t dt_1\int_0^{t_1} dt_2\, U_m(t-t_1) \times[F_m(t_1),[F_m(t_2),H_m(t_2)]\sigma_\alpha(t_2)]U_m^{-1}(t-t_1), \tag{12}$$

where

$$U(\tau)=\exp[(i/\hbar)H_m(0)\tau], \tag{12a}$$

and where $F_m^{(0)}(t)$ is defined by

$$F_m^{(0)}(t)=F_m(0), \tag{12b}$$

$$\dot{F}_m^{(0)}(t)=-(i/\hbar)[F_m^{(0)}(t),H_m(0)]. \tag{12c}$$

The important properties of $F^{(0)}(t)$ needed for present purposes, and derived in I, are the following:

$$\langle F_m^{(0)}(t)\rangle=0, \tag{13}$$

$$\langle F_m^{(0)}(t_1)F_n^{(0)}(t_2)\rangle = \delta_{nm}(2/\pi)\int_0^\infty d\omega'[\eta(\omega')\cos\omega'(t_1-t_2) - i\xi(\omega')\sin\omega'(t_1-t_2)], \tag{14}$$

where

$$\xi(\omega')=\tfrac{1}{2}\pi\hbar Z^{-1}B(\omega')[1-\exp(-\hbar\omega'/kT)], \tag{14a}$$

$$\eta(\omega')=\tfrac{1}{2}\pi\hbar Z^{-1}B(\omega')[1+\exp(-\hbar\omega'/kT)], \tag{14b}$$

$$Z=\int_0^\infty dE\rho(E)\exp(-E/kT), \tag{14c}$$

$$B(\omega')=\int_0^\infty dE\rho(E+\hbar\omega')\rho(E) \times\tilde{F}^2(E+\hbar\omega',E)\exp(-E/kT), \tag{14d}$$

$\rho(E)$ being the density of energy states of the LM, $\tilde{F}^2(E_i,E_k)$ being the average over small ranges of E_i and E_k of $|F_{ik}^{(0)}|^2$, and T being the LM temperature. Both $\eta(\omega')$ and $\xi(\omega')$ are assumed to become vanishingly small

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

as ω' approaches zero, and approximately constant in the neighborhood of $\omega'=\omega$, the values in this neighborhood being denoted by η and ξ (without argument) respectively. The expression $\langle F^{(0)}(t_1)F^{(0)}(t_2)\rangle$ will occur, in the present analysis, as a factor in an integrand, the integration being over t_1, or t_2, or both. Consider the expression

$$\int_0^t dt_1\varphi(t_1)\langle F^{(0)}(t_1)F^{(0)}(t_2)\rangle \tag{15}$$

for $t\gg\omega^{-1}$. Substituting from Eq. (14) into (15), and interchanging the order of integration, one sees that if $\varphi(t_1)$ is approximately an oscillating function with angular frequency ω'', the main contribution to the integration comes from the neighborhood $\omega'\sim\omega''$. The same argument applies if the integration in (15) is over t_2 [with $\varphi(t_2)$ instead of $\varphi(t_1)$]. We may therefore write for use in subsequent integration

$$\langle F^{(0)}(t_1)F^{(0)}(t_2)\rangle \approx 2\left[\eta(\omega'')\delta(t_1-t_2)-\frac{i}{\pi}\xi(\omega'')\frac{\mathcal{P}}{t_1-t_2}\right], \tag{16a}$$

and

$$\langle\{F^{(0)}(t_1),F^{(0)}(t_2)\}\rangle\approx 4\eta(\omega'')\delta(t_1-t_2). \tag{16b}$$

The values of ω'' to be encountered in the present article will be only ω and 0. For the latter value, it is clear that $\langle F^{(0)}(t_1)F^{(0)}(t_2)\rangle=0$.

Equations (12) may be written as

$$F_m(t)=F_m{}^{(0)}(t)+\sum_\alpha a_{\alpha m}F_{\alpha m}{}^{(1)}(t), \tag{17}$$

where

$$F_{\alpha m}{}^{(1)}(t)=\frac{1}{2\hbar}\int_0^t dt_1\int_0^{t_1} dt_2 U_m(t-t_1) \times[F_m(t_1),[F_m(t_2),H_m(t_2)]\sigma_\alpha(t_2)] \times U_m{}^{-1}(t-t_1). \tag{17a}$$

By use of approximations based on the fact that the LM is affected only slightly by the TLS, it is shown in I that

$$F_{1m}{}^{(1)}(t)=-\bar\xi\sigma_2(t), \tag{18a}$$

$$F_{2m}{}^{(1)}(t)=\bar\xi\sigma_1(t), \tag{18b}$$

where $\bar\xi$ is a (c-number) function of t which is zero at $t=0$ and approaches the constant ξ in a time large compared to ω^{-1} but short compared to the time during which secular changes (in the TLS) take place. It is also shown in I [Eq. (I.76)] that

$$F_{3m}{}^{(1)}(t)=0, \tag{19a}$$

and by an identical argument[3] it can be shown that

$$F_{4m}{}^{(1)}(t)=0. \tag{19b}$$

[3] Equation (19a) follows from the fact that $\sigma_3(t)$ is a slowly varying function [while $\sigma_1(t)$ and $\sigma_2(t)$ are approximately oscillatory functions with (angular) frequency ω]. Equation (19b) follows from the fact that σ_4 is the unit matrix and does not vary at all.

Substituting from Eqs. (18) and (19) into (17), we obtain

$$F_m(t)=F_m{}^{(0)}(t)-a_{1m}\bar\xi\sigma_2(t)+a_{2m}\bar\xi\sigma_1(t). \tag{20}$$

This expression for $F_m(t)$ may now be substituted into Eqs. (10a)–(10c), the equations of motion for the TLS. Before we do that, however, it is convenient to rewrite the products of $\mathfrak{F}_m$ and σ_α in these equations as symmetrized products. (Note that $[F_m(t),\sigma_\alpha(t)]=0$.) Then, by substituting from Eq. (20) and utilizing the properties of the σ's given in Eq. (3), we get

$$\dot\sigma_1=-\omega\sigma_2+\sum_m(\tfrac{1}{2}a_{2m}\{\mathfrak{F}_m{}^{(0)},\sigma_3\} -\tfrac{1}{2}a_{3m}\{\mathfrak{F}_m{}^{(0)},\sigma_2\}+a_{1m}a_{3m}\bar\xi), \tag{21a}$$

$$\dot\sigma_2=\omega\sigma_1+\sum_m(\tfrac{1}{2}a_{3m}\{\mathfrak{F}_m{}^{(0)},\sigma_1\} -\tfrac{1}{2}a_{1m}\{\mathfrak{F}_m{}^{(0)},\sigma_3\}+a_{2m}a_{3m}\bar\xi), \tag{21b}$$

$$\dot\sigma_3=\sum_m[\tfrac{1}{2}a_{1m}\{\mathfrak{F}_m{}^{(0)},\sigma_2\}-\tfrac{1}{2}a_{2m}\{\mathfrak{F}_m{}^{(0)},\sigma_1\} -(a_{1m}{}^2+a_{2m}{}^2)\bar\xi], \tag{21c}$$

where

$$\mathfrak{F}_m{}^{(0)}\equiv F_m{}^{(0)}+f_m.$$

Equations (21) contain as unknowns, dynamical variables referring to the TLS only. $\mathbf{F}^{(0)}$ is a "prescribed" field, and so is, of course, $\mathbf{f}$. $\mathbf{F}^{(0)}$ is the quantum-mechanical version of a stochastic force. With $\bar\xi$ replaced by ξ, and with $f=0$, Eqs. (21) are of the type referred to in I as the Langevin equations for a TLS.

It should be noted that, while $F_m(t)$ and $\sigma_\alpha(t)$ commute, $F_m{}^{(0)}(t)$ and $\sigma_\alpha(t)$ do not. The commutation relations between the latter two operators may be obtained from Eq. (20), utilizing the fact that $[F_m(t),\sigma_\alpha(t)]=0$; the result is

$$[\sigma_1,F_m{}^{(0)}]=2ia_{1m}\bar\xi\sigma_3, \tag{22a}$$

$$[\sigma_2,F_m{}^{(0)}]=2ia_{2m}\bar\xi\sigma_3, \tag{22b}$$

$$[\sigma_3,F_m{}^{(0)}]=-2i\bar\xi(a_{1m}\sigma_1+a_{2m}\sigma_2). \tag{22c}$$

The problem may now be considered as formally defined by Eqs. (21)—Eqs. (22) being part of the prescription for $F^{(0)}$—with initial values for the σ's given by (their usual description when the Schrödinger picture is used)

$$\sigma_1(0)=\begin{pmatrix}0&1\\1&0\end{pmatrix},\quad \sigma_2(0)=\begin{pmatrix}0&-i\\i&0\end{pmatrix},\quad \sigma_3(0)=\begin{pmatrix}1&0\\0&-1\end{pmatrix}. \tag{23}$$

From Eqs. (21) and (22) it can be shown, in a manner similar to that employed in I, that the solutions of Eqs. (22) subject to the initial conditions (23) are true spin operators, satisfying Eqs. (3). These solutions, of course, are operators both with respect to the TLS and LM. It is easy to see that this satisfactory state of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

affairs is due to the fact that $\bar{\xi}$ vanishes at $t=0$, since $F(0)$ and $\sigma_\alpha(0)$ are taken to be the uncoupled operators, and the coupling between TLS and LM is assumed to begin at $t=0$. Having shown the consistency of the formalism, we now replace $\bar{\xi}$ by ξ, as approximation for compulational purposes.

A solution of Eqs. (21) that is an operator in both TLS and LM spaces has not been found (even when all $\mathbf{a}$'s but $\mathbf{a}_1$ vanish, as in the electric dipole case in I). In order to make progress with Eqs. (21), we take expectation values in LM space. This does not simplify the situation automatically since expectation values of products, $\langle\{F_m{}^{(0)},\sigma_\alpha\}\rangle$, occur, and they are certainly not equal to the product of the expectation values. The evaluation of expectation values of these products will involve a significant approximation.

We consider $\mathfrak{F}^{(0)}$ (that is, both $F^{(0)}$ and f) to be a small quantity (compared to ω) of first order. Equations (21) can be rewritten as integral equations for the σ's in which the kernels are of first order. Defining the symbols $\Phi_1(t)$, $\Phi_2(t)$, $\Phi_3(t)$ by rewriting Eqs. (21) as

$$\sigma_1(t)=-\omega\sigma_2(t)+\Phi_1(t)\,, \tag{24a}$$

$$\dot{\sigma}_2(t)=\omega\sigma_1(t)+\Phi_2(t)\,, \tag{24b}$$

$$\dot{\sigma}_3(t)=\Phi_3(t)\,, \tag{24c}$$

we obtain, as equivalent integral equations,

$$\sigma_1=\sigma_1{}^{(0)}+\int_0^t dt_1\cos\omega(t-t_1)\Phi_1(t_1) -\int_0^t dt_1\sin\omega(t-t_1)\Phi_2(t_1)\,, \tag{25a}$$

$$\sigma_2=\sigma_2{}^{(0)}+\int_0^t dt_1\cos\omega(t-t_1)\Phi_2(t_1) +\int_0^t dt_1\sin\omega(t-t_1)\Phi_1(t_1)\,, \tag{25b}$$

$$\sigma_3=\sigma_3{}^{(0)}+\int_0^t dt_1\Phi_3(t_1)\,, \tag{25c}$$

where the $\sigma^{(0)}$'s are the solution for the free TLS satisfying the initial conditions. A substitution is now made from Eqs. (25) into all products $\{F_m{}^{(0)},\sigma_\alpha\}$ occurring in Eqs. (21). Thus

$$\begin{aligned}\langle\{F_m{}^{(0)}(t_1),\sigma_1(t_1)\}\rangle_{\rm LM}&\\ =\tfrac{1}{2}\sum_n\int_0^t dt_1\langle[a_{1n}\sin\omega(t-t_1)&\\ +a_{2n}\cos\omega(t-t_1)]\{F_m{}^{(0)}(t),\{\mathfrak{F}_n{}^{(0)}(t_1),\sigma_3(t_1)\}\}&\\ -a_{3n}\{F_m{}^{(0)}(t),\{\mathfrak{F}_n{}^{(0)}(t_1),\sigma_2(t_1)\}\}\cos\omega(t-t_1)&\\ -a_{3n}\{F_m{}^{(0)}(t),\{\mathfrak{F}_n{}^{(0)}(t_1),\sigma_1(t_1)\}\}&\\ \times\sin\omega(t-t_1)\rangle_{\rm LM}\,,&\end{aligned} \tag{26}$$

where use has been made of the fact that $\langle F_m{}^{(0)}\sigma_\alpha{}^{(0)}\rangle_{\rm LM}=\langle F_m{}^{(0)}\rangle\sigma_\alpha{}^{(0)}$, and of Eq. (13).[4] The significant approximation consists of ignoring the noncommutativity of σ_α and $F_m{}^{(0)}$ and replacing the product of the LM variables by its expectation value, both operations to be performed only in terms of higher order than the first. (See I for a discussion of this approximation.) Utilizing Eq. (13) and the Krönecker delta of Eq. (14), we obtain, with the above approximation,

$$\begin{aligned}\langle\{F_m{}^{(0)},\sigma_1\}\rangle_{\rm LM}&\\ =\int_0^t dt_1\langle\{F_m{}^{(0)}(t),F_m{}^{(0)}(t_1)\}\rangle&\\ \times\{\sigma_3(t_1)[a_{1m}\sin\omega(t-t_1)+a_{2m}\cos\omega(t-t_1)]&\\ -a_{3m}[\sigma_1(t_1)\sin\omega(t-t_1)+\sigma_2(t_1)\cos\omega(t-t_1)]\}\,.&\end{aligned} \tag{27}$$

The considerations related to Eqs. (15) and (16) may now be applied. $\sigma_3(t_1)$ is a slowly varying function of t_1, so that Eq. (16b) with $\omega''=\omega$ must be used for the integration associated with first square bracket in Eq. (27). The second square bracket is shown in I [Eq. (I.81); note that σ_1 and σ_2 approximately oscillate with frequency ω] to be itself a slowly varying function of t_1, so that Eq. (16b) with $\omega''=0$ must be used for the integration associated with the second square bracket, and the contribution of this integration vanishes. The result is

$$\langle\{F_m{}^{(0)},\sigma_1\}\rangle_{\rm LM}=2a_{2m}\eta\langle\sigma_3\rangle_{\rm LM}\,. \tag{28a}$$

In an entirely similar manner, one obtains

$$\langle\{F_m{}^{(0)},\sigma_2\}\rangle_{\rm LM}=-2a_{1m}\eta\langle\sigma_3\rangle_{\rm LM}\,, \tag{28b}$$

and

$$\langle\{F_m{}^{(0)},\sigma_3\}\rangle_{\rm LM}=2\eta(a_{1m}\langle\sigma_2\rangle_{\rm LM}-a_{2m}\langle\sigma_1\rangle_{\rm LM})\,. \tag{28c}$$

Substituting from Eqs. (28) into Eqs. (21), we have

$$\dot{\sigma}_1=(-\omega+\mathbf{a}_1\cdot\mathbf{a}_2\eta)\sigma_2-a_2{}^2\eta\sigma_1+\mathbf{a}_1\cdot\mathbf{a}_3\eta(\sigma_3-\sigma_0) +\mathbf{a}_2\cdot\mathbf{f}\sigma_3-\mathbf{a}_3\cdot\mathbf{f}\sigma_2\,, \tag{29a}$$

$$\dot{\sigma}_2=(\omega+\mathbf{a}_1\cdot\mathbf{a}_2\eta)\sigma_1-a_1{}^2\eta\sigma_2+\mathbf{a}_2\cdot\mathbf{a}_3\eta(\sigma_3-\sigma_0) +\mathbf{a}_3\cdot\mathbf{f}\sigma_1-\mathbf{a}_1\cdot\mathbf{f}\sigma_3\,, \tag{29b}$$

$$\dot{\sigma}_3=-(a_1{}^2+a_2{}^2)\eta(\sigma_3-\sigma_0)+\mathbf{a}_1\cdot\mathbf{f}\sigma_2-\mathbf{a}_2\cdot\mathbf{f}\sigma_1\,, \tag{29c}$$

where the notation

$$\sigma_0\equiv-\xi/\eta \tag{29d}$$

is used, and where LM expectation value brackets are omitted. (Since these are operator equations in TLS space, σ_0 is to be understood as being multiplied by the unit matrix.) It is easily seen that the results of I for the magnetic and electric dipole cases treated there are obtained by setting $a_{im}=\delta_{im}$ in the former case and $a_{im}=\delta_{i1}\delta_{m1}$ in the latter. Equations (29) describe the

[4] Where brackets are used to indicate expectation value with respect to the LM, the subscript "LM" will be added if the enclosed expression refers to both the TLS and LM, while no subscript will be used if the enclosed expression refers only to the LM.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

behavior of the most general TLS coupled to a thermal-reservoir type LM.

We can take expectation values with respect to the TLS in Eqs. (29). This leaves the equations formally unaltered, and the σ's now stand for their respective expectation values in both LM and TLS spaces. Henceforth, Eqs. (29) will be understood to refer to these expectation values. Discussion of the physical significance of these equations will be postponed until the second generalization has been carried out.

II.

The second generalization refers directly to the LM rather than to the TLS. Instead of assuming the LM to be only a thermal reservoir of given temperature, we consider the LM to consist of two parts: The first part (to be referred to as LM_1) is the same thermal reservoir considered heretofore; the second part (to be referred to as LM_2) consists of a large number of two-level systems identical to the TLS under consideration, situated in a similar environment, and loosely and randomly coupled to our system and to each other. The individual two-level systems of LM_2 are thus coupled (in addition to the coupling to each other and to the TLS under consideration) to a thermal reservoir and to external forces. The thermal reservoir may be LM_1 itself, but since the possibility of the transmission of effects through LM_1 will be excluded, it is simpler to consider the systems of LM_2 coupled to a thermal reservoir that is identical to LM_1 but independent. In the notation to be used, LM_2 consists of the mutually coupled two-level systems only, the thermal reservoir and external forces being described separately.

The Hamiltonian for our problem is obtained by adding several terms to the expression in Eq. (7), the result being

$$H=\tfrac{1}{2}\hbar\omega\sigma_3+\tfrac{1}{2}\hbar\sum_\alpha \sigma_\alpha \mathbf{a}_\alpha\cdot(\mathbf{F}^{(1)}+\mathbf{F}^{(2)}+\mathbf{f}) +H_{\mathrm{LM1}}+H_{\mathrm{LM2}}+H^{(2)}, \quad (30)$$

where H_{LM1} and H_{LM2} are the energy operators of LM_1 and LM_2, respectively, $F^{(1)}$ and $F^{(2)}$ are the coordinates through which LM_1 and LM_2, respectively, couple to the TLS, and $H^{(2)}$ contains the coupling term of LM_2 to any other systems, the energy operators for those systems, and the coupling term of LM_2 with prescribed external forces; that is, $H^{(2)}$ refers to everything that couples to LM_2 except the TLS under consideration.

We pass now from the Heisenberg picture, which has been used in the preceding discussion, to the interaction picture. All the operators are transformed into primed quantities in the manner[5]

$$A'=UAU^*, \quad (31)$$

where U is a unitary operator satisfying the differential equation and initial condition

$$i\hbar\dot{U}(t)=U(t)H^{(2)}(t), \quad (31a)$$

$$U(0)=1. \quad (31b)$$

All the primed operators now satisfy the equation of motion

$$i\hbar\dot{A}'=[A', H'-H^{(2)\prime}]+i\hbar(\partial A'/\partial t); \quad (32)$$

in other words, the effective Hamiltonian that enters into the equations of motion for the primed operators no longer contains any reference to the influence of external systems or forces on LM_2. Formally, LM_1 and LM_2 appear equivalently in these equations. In this transformation, the effect of the external influences on LM_2 has been removed from the operators and transferred to the state vector, which becomes

$$\Psi'(t)=U(t)\Psi. \quad (33)$$

It should be remembered that Ψ is independent of the time and would be the initial state if the Schrödinger picture were used; Eq. (33) may be written as

$$\Psi'(t)=U(t)\Psi'(0). \quad (34)$$

Now, if there were no coupling between the TLS and LM_2, Eq. (34) would yield the entire time development of LM_2, and leave all the other systems to which reference is made in the Hamiltonian of Eq. (30) unaffected, that is in their Heisenberg (initial) state. The presence of the $\frac{1}{2}\hbar\sigma_\alpha\mathbf{a}_\alpha\cdot\mathbf{F}^{(2)}$ coupling term affects U only indirectly through the time development of $H^{(2)}(t)$ [note that $H^{(2)}(0)$ does not contain this coupling term] and does not produce lowest order effects. The difference between $\Psi'(t)$ and the corresponding state in which there is no coupling between the TLS and LM_2 is due only to the effect on LM_2 of the TLS, and is slight. We approximate by ignoring this effect in $\Psi'(t)$ and consider $\Psi'(t)$ to denote the state in which the TLS and LM_1 are unaffected while LM_2 has developed under the influence of those systems (and external forces) explicitly entering into $H^{(2)}$. (This approximation is similar in spirit to approximations previously made for LM_1, where LM variables in interaction terms were replaced by their uncoupled values. In the present instance, LM_2 may be uncoupled only from the TLS but not from the effect of $H^{(2)}$. This is the essential difference between LM_1 and LM_2.)

Analytically, the approximation just performed may be described as follows: Set

$$\Psi=\psi_{\mathrm{TLS}}\psi_{\mathrm{LM1}}\psi_{\mathrm{LM2}}, \quad (35a)$$

(this implies that the coupling is turned on at $t=0$), which is the same as

$$\Psi'(0)=\psi_{\mathrm{TLS}}'(0)\psi_{\mathrm{LM1}}'(0)\psi_{\mathrm{LM2}}'(0). \quad (35b)$$

Consider $H^{(2)}(t)$ to be obtained from $H^{(2)}(0)$ (by means of the Heisenberg equations of motion) by neglecting

[5] It should be noted that the interaction picture is obtained here by starting with the Heisenberg picture. This accounts for the order of the factors in the right side of Eq. (31a), the opposite of that used when starting with the Schrödinger picture.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the $F^{(2)}$ term in Eq. (30). Then $H^{(2)}(t)$ and, therefore—as is evident from Eq. (31a)—$U(t)$ contain only LM_2 variables. Thus,

$$\Psi'(t)=\psi_{TLS}'(0)\psi_{LM1}'(0)U(t)\psi_{LM2}'(0)$$
$$=\psi_{TLS}'(0)\psi_{LM1}'(0)\psi_{LM2}'(t). \quad (36)$$

Since LM_1 and LM_2 are large and incompletely described systems, we will describe their initial states, as has been done previously for LM_1, by ensemble averages. For this purpose, it is more convenient to use density matrices instead of state vectors. We therefore write, in place of Eq. (36),

$$P'(t)=\rho_{TLS}'(0)\rho_{LM1}'(0)\rho_{LM2}'(t), \quad (37)$$

where P is the density matrix for the combination of systems, and the ρ's are individual density matrices. Both $\psi_{LM2}'(t)$ and $\rho_{LM2}'(t)$ describe the development of LM_2 in the absence of coupling to the TLS under consideration.

We come now to the essential aspect, and significant approximation, of the analysis of LM_2. LM_2 is obviously not a thermal reservoir, since the individual two-level systems of which it is composed can interchange an amount of energy comparable to their own energy with the thermal reservoir and external forces to which they are coupled. LM_2 cannot, therefore, be described by a fixed temperature. We assume, however, that the randomness associated with LM_2 (due, mainly, to the random coupling among the individual two-level systems) is sufficiently great so that at any given time LM_2 may be described by a temperature, this temperature being, in general, a function of the time.[6] According to this assumption, the density matrix for LM_2 is given by

$$\rho_{LM2}'(t)=Z_2^{-1}\exp[-H_{LM2}/kT(t)], \quad (38)$$

where

$$Z_2(t)=\text{Trace}\exp[-H_{LM2}/kT(t)]. \quad (38a)$$

$T(t)$ is left unspecified for the time being, but we assume that it changes slowly compared to $\exp(i\omega t)$.

Now, LM_2, like LM_1, is a large system with many energy levels closely spaced. It may therefore be treated, in the analysis of its interaction with the TLS, in the same manner as LM_1, but with cognizance of the time dependence of the temperature. (It is to be noted that the temperature enters into the analysis only through the density matrix.) Our problem thus reduces itself to the analysis of the interaction of a TLS with external fields and with two LM's, one of which has a time-dependent temperature.

Before this problem is considered, it is useful to look at a simpler situation, one in which there are two LM's with different, but *fixed*, temperatures. Very little analysis is required to notice that the change required in the results obtained for a single LM is the replacement of η by $\eta^{(1)}+\eta^{(2)}$, and the replacement of ξ by $\xi^{(1)}+\xi^{(2)}$, where the superscripts (1) and (2) refer to LM_1 and LM_2, respectively, and $\xi^{(i)}$ and $\eta^{(i)}$ are defined for each LM in the same manner as ξ and η, respectively, by Eqs. (14a) and (14b). From Eq. (29d) we have

$$\sigma_0^{(i)}=-\xi^{(i)}/\eta^{(i)}; \quad (39)$$

thus Eqs. (29a)–(29c) remain valid provided we set

$$\eta=\eta^{(1)}+\eta^{(2)}, \quad (40a)$$

and

$$\sigma_0=(\sigma_0^{(1)}\eta^{(1)}+\sigma_0^{(2)}\eta^{(2)})(\eta^{(1)}+\eta^{(2)})^{-1} \quad (40b)$$

We return now to situation in which $T^{(2)}$ is time-dependent. This time dependence affects several calculations that lead to Eqs. (29). First, there is the computation of expectation values of LM_2 variables. The expectation value of an operator $A'(t)$ referring to a single time (and uncoupled from the TLS) poses no problem since it is given by Trace $\rho_{LM}'(t)A'(t)$. The expectation value of an operator of the type $\{A_1'(t_1),A_2'(t_2)\}$, referring to two different times, requires, in general, another method of evaluation. In the present analysis, however, this type of expectation value is needed only in cases where the result is negligible unless t_1 is very close to t_2. [See, for instance, Eqs. (14) and (16).] Bearing in mind that $T^{(2)}(t)$ is a slowly varying function, we can use previous results for this type of expectation value, with $\xi^{(2)}$ and $\eta^{(2)}$—which are functions of $T^{(2)}$—evaluated at either t_1, t_2, or an intermediate value. Then, there is the question of time integration where $\xi^{(2)}$ or $\eta^{(2)}$ is part of the integrand. [See, for instance, Eq. (27).] Here too, no formal modification of the final result is necessary, for in this integration the main contribution comes only from a very small neighborhood of a definite time, so that $\xi^{(2)}$ or $\eta^{(2)}$ may be evaluated at that time and taken outside the integral. It is seen, therefore, that Eqs. (29a)–(29c) and (40) remain formally unchanged, but with $\eta^{(2)}$ and $\sigma_0^{(2)}$ being considered now functions of t (the same argument as that of the σ's and **f**).

Our final task is the evaluation of $T^{(2)}$, or, more directly, of $\sigma_0^{(2)}$ and $\eta^{(2)}$, through which the behavior of the TLS depends on $T^{(2)}$. From Eqs. (39), (14a), and (14b), we have

$$\sigma_0^{(2)}=\frac{\exp(-\hbar\omega/kT^{(2)})-1}{\exp(-\hbar\omega/kT^{(2)})+1}. \quad (41)$$

This is the expectation value of the energy, in units of $\frac{1}{2}\hbar\omega$, of a TLS of the type under consideration when it is in thermal equilibrium with a reservoir at temperature $T^{(2)}$. We may therefore regard $\sigma_0^{(2)}$ as the average energy (at time t) of the two-level systems that constitute LM_2. Since these two-level systems are identical to the TLS under consideration and are situated in a

[6] Since LM_2 is composed of two-level systems, its temperature may assume negative as well as positive values, depending on the average energy of the two-level systems.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

similar environment, this energy is also equal to $\sigma_3(t)$.[7] Thus, we have the important result

$$\sigma_0^{(2)}=\sigma_3(t). \tag{42}$$

As far as $\eta^{(2)}$ is concerned, no such simple consideration applies. The best that can be done within the scope of the present analysis is to observe that $\eta^{(2)}$ is not as strongly dependent on $T^{(2)}$ as $\sigma_0^{(2)}$ (or $\xi^{(2)}$)—as can be seen from Eqs. (14)—and to approximate it by an average value.

From Eqs. (29a)–(29c), (40), and (42) we finally obtain

$$\dot\sigma_1=(-\omega+\tilde\eta\mathbf{a}_1\cdot\mathbf{a}_2)\sigma_2-\tilde\eta a_2^2\sigma_1+\eta\mathbf{a}_1\cdot\mathbf{a}_3(\sigma_3-\sigma_0)+\mathbf{a}_2\cdot\mathbf{f}\sigma_3-\mathbf{a}_3\cdot\mathbf{f}\sigma_2, \tag{43a}$$

$$\dot\sigma_2=(\omega+\tilde\eta\mathbf{a}_1\cdot\mathbf{a}_2)\sigma_1-\tilde\eta a_1^2\sigma_2+\eta\mathbf{a}_2\cdot\mathbf{a}_3(\sigma_3-\sigma_0)+\mathbf{a}_3\cdot\mathbf{f}\sigma_1-\mathbf{a}_1\cdot\mathbf{f}\sigma_3, \tag{43b}$$

$$\dot\sigma_3=-(a_1^2+a_2^2)\eta(\sigma_3-\sigma_0)+\mathbf{a}_1\cdot\mathbf{f}\sigma_2-\mathbf{a}_2\cdot\mathbf{f}\sigma_1, \tag{43c}$$

where

$$\tilde\eta\equiv\eta^{(1)}+\eta^{(2)},\quad \eta\equiv\eta^{(1)},\quad \sigma_0\equiv\sigma_0^{(1)}. \tag{43d}$$

In summary, these equations describe the behavior (in terms of expectation values) of a general TLS subject to external fields and coupled both to a thermal reservoir and a large number of systems identical to itself. The dipole moment is given in terms of the σ's by Eq. (2), and the energy is $\frac{1}{2}\hbar\omega\sigma_3$. Two relaxation constants, $\tilde\eta$ and η (with η being a better "constant" than $\tilde\eta$, which may be regarded as depending to some extent on the energy of the TLS) and an equilibrium energy σ_0 enter into these equations. The equilibrium energy is that associated with the temperature T_1 of the thermal reservoir, and is obtained by replacing superscript (2) with superscript (1) in Eq. (41).[8]

III.

A few special types of TLS are of immediate interest. As mentioned previously, the magnetic dipole type has $\mathbf{a}_1=\hat x$, $\mathbf{a}_2=\hat y$, $\mathbf{a}_3=\hat z$, $\mathbf{a}_4=0$. Equations (43) become

$$\dot\sigma_x=-\omega\sigma_y-\tilde\eta\sigma_x+f_x\sigma_z-f_z\sigma_x, \tag{44a}$$

$$\dot\sigma_y=\omega\sigma_x-\tilde\eta\sigma_y+f_z\sigma_x-f_x\sigma_z, \tag{44b}$$

$$\dot\sigma_z=-2\eta(\sigma_3-\sigma_0)+f_x\sigma_y-f_y\sigma_x. \tag{44c}$$

These are essentially the Bloch equations,[9] with $(2\eta)^{-1}$ being the longitudinal relaxation time T_1, and $\tilde\eta^{-1}$ being the transverse relaxation time T_2. If the spin-lattice coupling is regarded as coupling between the TLS and a thermal reservoir, and spin-spin coupling as coupling among identical two-level systems, then Eqs. (44) and (43d) show the contribution of each type of coupling to the relaxation process. It should be noticed that it is not, in general, correct to refer to T_2 as the spin-spin relaxation time (as is often done) unless $\eta^{(1)}$ is negligible compared to $\eta^{(2)}$. If $\eta^{(2)}$ is zero, Eqs. (44) reduce to the results of I [Eqs. (I.84)].

As far as the electric dipole TLS is concerned, there are many possible types, depending on the choice of the $\mathbf{a}$'s. $\mathbf{a}_4$ does not enter into the equations of motion and, therefore, does not affect the behavior of the TLS. $\mathbf{a}_4$ and $\mathbf{a}_3$ determine the "permanent" dipole moment, or the nonoscillating part of the (expectation value of the) dipole moment of the free TLS, for only σ_3 can have a nonoscillating value different from zero when $f=\tilde\eta=\eta=0$ in Eqs. (43). Since $\mathbf{a}_4$ plays no dynamic role, we will ignore it henceforth, and refer to the constant part of σ_3 (times $\mu\mathbf{a}_3$) as the permanent dipole moment. A case in which the dipole moment has a particularly simple appearance is that in which $\mathbf{a}_2=\mathbf{a}_3=0$, so that $\mathbf{d}=\mu\mathbf{a}_1\sigma_1$. This is the electric dipole case treated in I. Taking $a_1^2=1$, $\mathbf{a}_1\cdot\mathbf{f}\equiv f$, Eqs. (43) become

$$\dot\sigma_1=-\omega\sigma_2, \tag{45a}$$

$$\dot\sigma_2=\omega\sigma_1-\tilde\eta\sigma_2-f\sigma_3, \tag{45b}$$

$$\dot\sigma_3=-\eta(\sigma_3-\sigma_0)+f\sigma_2, \tag{45c}$$

which, for $\eta^{(2)}=0$, reduce to Eqs. (I.67). A permanent dipole moment may be added to this case, while still maintaining a relatively simple form of the equations, by considering $\mathbf{a}_2=0$, $\mathbf{a}_3=\epsilon\mathbf{a}_1$. (Here, the permanent dipole moment has the same spatial direction as the oscillating dipole moment.) The result is

$$\dot\sigma_1=-\omega\sigma_2-\epsilon\dot\sigma_3, \tag{46a}$$

$$\dot\sigma_2=\omega\sigma_1-\tilde\eta\sigma_2+\epsilon f\sigma_1-f\sigma_3, \tag{46b}$$

$$\dot\sigma_3=-\eta(\sigma_3-\sigma_0)+f\sigma_2, \tag{46c}$$

where Eq. (46a) has been simplified in appearance by substitution from Eq. (46c).

It is not the purpose of the present article to present equations for large number of special cases, although there are many others than the above three particularly simple ones that are of interest. Neither is it the purpose of the present article to discuss the solution of the above equations for given driving fields, which will be done in a forthcoming article. We will, however, discuss the solution of the equations in the absence of a driving field, that is, the free decay of a TLS from given initial conditions. For the sake of simplicity, we consider only

[7] Strictly speaking, there is an approximation involved in this statement, since LM expectation values are averages both with respect to a thermal (canonical) ensemble—implicit in the density matrix employed—and a quantum-mechanical ensemble, while TLS expectation values are averages only with respect to the latter.

[8] Equations (43), involving two dissipation parameters, $\tilde\eta$ and η, are more general than the LM considered in the above discussion. More general loss mechanisms may be obtained by replacing LM_1 with several thermal reservoirs at different temperatures, some of these temperatures being, possibly, prescribed slowly varying functions of the time. Equations of the form of Eq. (40) can then be used to obtain new values for the two dissipation parameters with Eqs. (43) remaining formally unchanged.

[9] F. Bloch, Phys. Rev. **70**, 460 (1946); R. K. Wangsness and F. Bloch, *ibid.* **89**, 728 (1953).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the case in which $\mathbf{a}_3$ is either perpendicular to both $\mathbf{a}_1$ and $\mathbf{a}_2$, or is equal to zero. From Eqs. (43) we have, under the above conditions,

$$\sigma_1=(-\omega+\tilde{\eta}\mathbf{a}_1\cdot\mathbf{a}_2)\sigma_2-\tilde{\eta}a_2^2\sigma_1, \tag{47a}$$

$$\dot{\sigma}_2=(\omega+\tilde{\eta}\mathbf{a}_1\cdot\mathbf{a}_2)\sigma_1-\tilde{\eta}a_1^2\sigma_2, \tag{47b}$$

$$\dot{\sigma}_3=-(a_1^2+a_2^2)\eta(\sigma_3-\sigma_0). \tag{47c}$$

The last equation may be solved immediately, the result being

$$\sigma_3=\sigma_0+[\sigma_3(0)-\sigma_0]\exp[-(a_1^2+a_2^2)\eta t]. \tag{48}$$

Equations (47a) and (47b) yield the same equation for both σ_1 and σ_2:

$$\ddot{\sigma}_{1,2}+\tilde{\eta}(a_1^2+a_2^2)\dot{\sigma}_{1,2}+\{\omega^2+\tilde{\eta}^2[a_1^2a_2^2-(\mathbf{a}_1\cdot\mathbf{a}_2)^2]\}\sigma_{1,2}=0. \tag{49}$$

The solution of Eq. (49) is

$$\sigma_1=\exp[-\tilde{\eta}(a_1^2+a_2^2)t][a_1\cos\Omega t+B_1\sin\Omega t], \tag{50a}$$

$$\sigma_2=\exp[-\tilde{\eta}(a_1^2+a_2^2)t][a_2\cos\Omega t+B_2\sin\Omega t], \tag{50b}$$

where A_i and B_i are constants determined by the initial conditions, and

$$\Omega^2=\omega^2\{1-(\tilde{\eta}^2/\omega^2)[(\mathbf{a}_1\cdot\mathbf{a}_2)^2+\tfrac{1}{4}(a_1^2-a_2^2)^2]\}. \tag{50c}$$

We see that σ_3 approaches exponentially its equilibrium value, and that σ_1 and σ_2 undergo exponentially damped oscillation. The frequency of oscillation Ω is of interest. For $\mathbf{a}_1$ and $\mathbf{a}_2$ equal in magnitude and perpendicular to each other, Ω is equal to ω, the frequency of the free TLS; otherwise Ω is less than ω. Equation (50c) puts into perspective the results of I, where it was found that the frequency of the undriven damped oscillator was equal to that of the free oscillator for the magnetic dipole case but not for the electric dipole case. It is seen, now, that the magnetic dipole TLS has just that combination of $\mathbf{a}$'s which yields $\Omega=\omega$, but the electric dipole TLS treated in I has $\mathbf{a}_2=0$, $a_1^2=1$, giving

$$\Omega^2=\omega^2[1-\tfrac{1}{4}(\tilde{\eta}^2/\omega^2)], \tag{51}$$

in accordance with the results of I.[10]

One encounters occasionally the statement that any TLS is equivalent to a system of spin $\frac{1}{2}$ in an appropriate magnetic field.[11] While this statement is true in the absence of dissipation, it is only an approximation when the TLS is coupled to an LM, as the above frequency consideration reveals, and as can be seen from the dependence of Eqs. (43) on the type of TLS considered.

It was shown previously [Eqs. (44)] that the Bloch equations are a special case of Eqs. (43). The Bloch equations were developed originally for macroscopic matter. They also apply to the expectation values for a microscopic system, and, in this sense, correspond to a special case of Eqs. (43). One might ask how the present theory applies to macroscopic matter, or to a large number of systems identical to—but possibly, with different orientation than—the TLS under consideration. Can one, as in the case of the Bloch equations, regard a linear combination of the (four) σ's as the component of dipole moment along a given direction for macroscopic matter containing N systems similar to our TLS? The macroscopic dipole moment $\mathbf{D}$ is given by

$$\mathbf{D}=\sum_{j=1}^{N}\mathbf{d}^{(j)}=\sum_{j=1}^{N}\sum_{\alpha=1}^{4}\mathbf{a}_\alpha^{(j)}\sigma_\alpha^{(j)}, \tag{52}$$

where the superscript j refers to the jth TLS. The above question is equivalent to asking if $\sigma_\alpha^{(j)}$ is independent (except for a multiplicative constant) of j. It is clear that if the systems are all oriented in the same manner, then $\mathbf{a}_\alpha^{(j)}=\mathbf{a}_\alpha$, $\sigma_\alpha^{(j)}=\sigma_\alpha$,

$$\mathbf{D}=N\mathbf{d}, \tag{53}$$

and the answer to the above question is, obviously, in the affirmative. If the microscopic systems are not all oriented similarly, then the coefficients $\mathbf{a}_i^{(j)}\cdot\mathbf{f}$ in Eq. (43a) are different for differently oriented systems. If, because of symmetry conditions, the solutions of Eqs. (43) are essentially unaffected by a particular distribution of orientations, then the answer is still in the affirmative, but if no such symmetry exists, then Eqs. (43) cannot be regarded as equations for macroscopic polarization. The macroscopic result must be obtained through Eq. (52), that is, by solving first the microscopic problem, and then superposing the solutions.

The essential aspects of the orientation of a magnetic dipole TLS are determined by the field that is responsible for the level separation. If this field is the same for all the two-level systems, Eqs. (43)—which reduce in this instance to the Bloch equations—may be regarded as equations for macroscopic polarization. Such is the case for macroscopic matter in an external (laboratory) field. If, however, the field responsible for level separation is an internal field and has different orientation for different dipoles, the above equations may be applied only on a microscopic scale.

ACKNOWLEDGMENT

The author wishes to thank Professor Julian Schwinger for illuminating discussion and for his reading of the manuscript.

[10] A comparison might be made between Eqs. (47a) and (47b) on the one hand, and equations for the coordinate and momentum of a harmonic oscillator with dissipation on the other. If both coordinate and momentum couple to the loss mechanism, then the equations of motion for the harmonic oscillator variables (in appropriate units) are

$$\dot{p}=-\omega q-\eta_1 p, \quad \dot{q}=\omega p-\eta_2 q.$$

It is seen that if $\mathbf{a}_1$ and $\mathbf{a}_2$ are orthogonal, σ_2 and σ_1 correspond to the coordinate and momentum, respectively, of the harmonic oscillator. It can also be seen readily that the oscillatory frequency of the freely decaying harmonic oscillator is equal to ω only if $\eta_1=\eta_2$. Comparison with the dissipation terms in Eqs. (47a) and (47b) shows that this corresponds to our requirement (in addition to that of orthogonality) that $a_1^2=a_2^2$.

Cluster Expansion in the Heitler–London Approach to Many-Electron Problems*

TADASHI ARAI
Argonne National Laboratory, Argonne, Illinois
(Received 2 January 1964)

The Heitler–London method based on nonorthogonal atomic orbitals is applied to arrays of an infinitely large number of atoms. The electronic energy is given by a quotient with strongly divergent numerator and denominator, which until now has defied correct computation. By noticing some resemblance of this problem to the linked-cluster expansion in many-body problems, we have now developed a new method to compute the Heitler–London energy. Here, the numerator and denominator are divided simultaneously by a common factor, which leads to a set of recurrence relations between the normalization matrices **F**. The matrices **F** are essential parts of the quotient to be calculated. When an overlap integral $\langle k|h\rangle$ is represented by a line starting from h and ending at k, the calculation of **F** using the recurrence relations is carried out systematically by drawing diagrams consisting of connected loops. Since our present aim in applying the Heitler–London method is to compute spin-wave spectra, the calculation is carried out in the complete space of spin waves and the energy expression is given by a Hermitian matrix. This introduces additional matrices **A**. The computation of **A** is also carried out by the diagram technique, since **A** can be expanded into an asymptotic series using **F**. Finally the energy matrix is written as a sum over connected diagrams, in accordance with the speculation obtained from the linked-cluster expansion. An error introduced by truncating the series of diagrams is also calculated. The present method not only ensures that the energy density in the Heitler–London method is finite, but also provides an accurate and practical way to compute the Heitler–London energy, which has never been accomplished previously. To calculate the ground-state energy the technique is simplified since the computation of **A** can be completely eliminated.

I. INTRODUCTION

FOR many years, the concept of exchange coupling has played an important role in theories of chemical bond and magnetism. This concept was first introduced in the Heitler–London theory[1] of molecular binding and applied by Heisenberg[2] to ferromagnetism. Although the Heisenberg theory has been formulated in a very attractive form by Van Vleck[3] and Møller[4] and much theoretical work in magnetism has used this formalism, the method has been criticized in many respects.

In this paper, we will limit our discussion to one of the difficulties inherited in the Heitler–London approach to magnetic problems; that is, the nonorthogonality difficulty in calculating energy spectra. The other aspects of the difficulties will be found in, for example, review articles by Herring.[5]

The nonorthogonality difficulty can be stated as follows. If we assume that there are no spin-orbit terms in the Hamiltonian, the calculation of the Heitler–London energy of the form

$$E=\int\Psi^*\mathcal{H}\Psi d\tau\Big/\int\Psi^*\Psi d\tau \tag{1.1}$$

is reduced to that of the Heisenberg exchange Hamiltonian

$$\mathcal{H}_{\rm eff}=-2\sum_{i>j}J_{ij}\mathbf{S}_i\cdot\mathbf{S}_j, \tag{1.2}$$

provided the wave function Ψ of this system is constructed from *orthogonal* atomic orbitals.

The orthogonality of atomic orbitals makes the exchange integrals J_{ij} thus obtained all positive. Since a positive exchange integral in the Heisenberg theory corresponds to ferromagnetism, this approach leads to the obviously absurd conclusion that all substances are ferromagnetic.

To utilize the Heitler–London method to full advantage, nonorthogonal atomic orbitals should be used as the basis. However, the calculation of energy spectra becomes extremely difficult since both numerator and denominator of the energy expression (1.1) diverge when the number N of electrons involved increases. It is not at all obvious if it is permissible to discard, from the energy expression, terms of higher order in overlaps. Such terms may appear N times, N^2 times, or even more. Slater[6] and Inglis[7] pointed out this difficulty, which led to grave doubts as to the validity of the Heisenberg exchange Hamiltonian[8,9] (1.2).

Previously,[10] we have discussed this difficulty. (This paper will be referred to as paper I.) The remaining problems will also be examined in detail and will be published elsewhere.[11] The conclusions will be summarized as follows: The exact calculation of the Heitler–London energy can be converted to the eigenvalue problem of a spin Hamiltonian of the form

$$\mathcal{H}_{\rm spin}=\sum_P(-1)^P J_P P^\sigma, \tag{1.3}$$

where P is a permutation operator and P^σ the corresponding permutation of spin variables. The exchange energy J_P for a single interchange P of electrons is very nearly equal to the value one would compute by neglecting terms of higher order in overlaps. The con-

tribution from the higher order terms in Hamiltonian $\sum_P'(-1)^P J_P P^\sigma$, where the summation $\sum_P'$ excludes all single interchanges, is small.

This gives a rigorous justification for using the Heisenberg exchange Hamiltonian in the calculation of thermodynamical functions.[12] However, we have not succeeded in evaluating the value of J_P when P is not a single interchange. Although we have bounded the total energy E as well as the exchange energy J_P for a single interchange by applying algebraic identities that exist between J_P's, the values of the bounds are merely first order in the approximation. The method cannot be extended immediately to narrow the bounds beyond the single interchange approximation. This implies that the accuracy of the Heitler–London method so far is limited up to that of the Heisenberg model.

If we would like to use the Heitler–London method as a rigorous mathematical tool to calculate many-electron systems, we have to provide an expansion technique with which the energy expression (1.1) as well as the expectation value of any observable quantity can be calculated up to a desired accuracy. This is the purpose of the present paper.

To achieve this goal, we have to carry out more detailed calculations of both the numerator and the denominator of (1.1). It is, of course, impossible to proceed with the calculation directly. However, we find that our problem has some resemblance to the linked cluster expansion for Green functions.[13] In either case, the quantity to be calculated is a quotient with divergent denominator and numerator. Use of Dyson's equation[14] reduces the numerator of a Green function to a factor multiplying all connected diagrams. Since the factor is exactly equal to the denominator and cancelled by it, the Green function consists of just the sum over all connected diagrams.

In the Heitler–London calculation, a set of recurrence relations (3.14) and (3.15) for the **F** matrices will take the place of Dyson's equation. Here the **F** matrices defined by (3.1) are the normalization matrices and the essential quantities to be calculated. Since the recurrence relations reduces the **F** matrices for N-electron systems to those for $N-1, N-2, \cdots$ electron systems, the successive application of the relations leads to the complete expansion of the **F** matrices in terms of overlaps. The expansion technique is similar to that used in both classical and quantum-theoretical treatments of many-body problems, and use of diagrams will facilitate the computation. It will be finally found that **F** is written as a sum over connected diagrams, when an overlap integral of the type $\langle\chi_k|\chi_h\rangle$ is denoted by a line starting from the center h of the atomic orbital χ_h and ending at k of χ_k. Following the prescriptions (i)–(iv) described in Sec. III(1b), diagrams for **F** can be drawn without knowledge of the expansion technique used. An error accompanied by truncating the expansion will be calculated by using a theorem which will be probed in the Appendix.

Since the energy matrix should be Hermitian, it is necessary to calculate, in addition to **F**, the matrix **A** defined by (3.2). The matrix **A** is to correct the deviation of **F** from Hermitian form. Although **A** is close to a unit matrix, the straight forward calculation is very difficult. In Sec. III(2), we shall, instead, develop an asymptotic expansion of **A** and discuss the convergence of the series. The calculation can also be carried out automatically by drawing diagrams.

By multiplying **F** by **A**, the energy matrix can be obtained and it will be found that the energy matrix is also written as a sum over connected diagrams.

The significance of the present method will be summarized as follows.

(1) By using this method, a rigorous calculation of the Heitler–London method including all overlaps can be carried out without difficulty. The effect of overlaps between distant atoms has been cancelled out rigorously. Such a calculation has never been performed for a many-electron system previously.[15,16] In fact, this has been considered impossible from the mathematical point of view.[8]

(2) The awesome task of calculating the inverse of the overlap matrix[17] is completely eliminated. The calculation can be carried out just by drawing diagrams. Even for a system with a small number of electrons, therefore, this method will be more convenient than inverting the overlap matrix directly.

(3) The fact that the energy matrix consists of just a sum over connected diagrams implies that the energy density is a finite number. This will, in practice, eliminate the nonorthogonality difficulties. Actually, a rigorous proof for this problem will be given in a forthcoming paper.[11]

So far, the calculation was carried out in the total space of the Heitler–London wave functions aiming at the computation of spin-wave spectra. The wave functions are naturally described by a vector in that space and the energy matrix is given in the form (2.26) or (2.27) rather than (1.1). This is why the matrix **A** appears. If, on the other hand, one is interested in the

[12] For a general review of the theory of direct exchange see C. Herring, in *Magnetism*, edited by G. Rado and H. Suhl (Academic Press Inc., New York, to be published).

[14] F. J. Dyson, Phys. Rev. **75**, 486 (1949).

[15] The only exception is the calculation by F. Takano, J. Phys. Soc. Japan **14**, 348 (1959). He has calculated the energies of the ferromagnetic ground state and the excited states obtained from the ground state by reversing only one spin.

[16] Also see W. J. Carr, Phys. Rev. **92**, 28 (1953).

[17] The overlap matrix **D** in this paper is defined by (2.4). Here the ij element of **D** is given by the overlap between N-electron wave functions ψ_i and ψ_j. Under this definition of **D**, neither the inverse of **D** nor **D** itself has ever been calculated correctly when N is large. When the overlap matrix Δ is defined by overlaps between atomic orbitals so that its kh element is given by $\langle k|h\rangle$, the inverse Δ^{-1} has been expanded into a power series of Δ by P. O. Löwdin, Advan. Phys. **5**, 1 (1956). However, there is very little relation between Δ and **D**.

ground state carrying a suitable spin function Θ, the wave function is simply written as (2.1) and the calculation of $\mathbf{A}$ can be bypassed. This will simplify the calculation considerably as we shall describe in Sec. IV.

Most of the present discussion will be carried out as if we are dealing with arrays of one-electron atoms. However, this limitation is merely an aid to keep track of the formulas and manipulations. In Sec. IV(3), we shall give a brief discussion of problems which arise when arrays of many-electron atoms are considered.

Before we start to calculate $\mathbf{F}$ and $\mathbf{A}$ in Sec. III, we shall review the method used in the previous paper I in Sec. II.

II. THE HEITLER–LONDON METHOD

Let us consider an array of N one-electron atoms. The Heitler–London wave function for this system is given by

$$\Psi=(N!)^{-1/2}\sum_P^{N!}(-1)^P P^r\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)\times P^\sigma\Theta(\sigma_1,\sigma_2,\cdots,\sigma_N), \quad (2.1)$$

where $\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)$ is a product of occupied atomic orbitals $\chi_h(\mathbf{r}_h)$,

$$\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)=\chi_1(\mathbf{r}_1)\chi_2(\mathbf{r}_2)\cdots\chi_N(\mathbf{r}_N), \quad (2.2)$$

$\Theta(\sigma_1,\sigma_2,\cdots,\sigma_N)$ is an arbitrary function of the spin variables, and P^r and P^σ are permutations P of coordinate and spin variables. (P^r and P^σ are considered as corresponding to the same abstract permutation P.) The summation $\sum_P$ in (2.1) includes all $N!$ permutations P.

There are many ways to construct $\Theta(\sigma_1,\sigma_2,\cdots,\sigma_N)$ of N spins, but, in any case, we will find 2^N linearly independent and orthonormal functions $\Theta_1, \Theta_2, \cdots$. Starting from an orbital product $\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)$, therefore it is possible to generate, in principle, 2^N linearly independent functions $\Psi_1, \Psi_2, \cdots$ of this array. Let $\boldsymbol{\Theta}$ be the row matrix $\boldsymbol{\Theta}=(\Theta_1,\Theta_2,\cdots)$, whose elements are 2^N linearly independent and orthonormal functions Θ_i of N spins. Similarly $\boldsymbol{\Psi}$ is the row matrix $\boldsymbol{\Psi}=(\Psi_1,\Psi_2,\cdots)$. Then the wave functions Ψ_i introduced by (2.1) are written as

$$\boldsymbol{\Psi}=(N!)^{-1/2}\sum_P^{N!}(-1)^P P^r\Lambda P^\sigma\boldsymbol{\Theta} \quad (2.3)$$

by using the matrix representation.

The wave functions $\boldsymbol{\Psi}=(\Psi_1,\Psi_2,\cdots)$ thus obtained are not normalized because of the nonorthogonality of the atomic orbitals χ_k used as basis. Instead, it will be found that the overlap between Ψ_i and Ψ_j is given by

$$D_{ij}\equiv\int\Psi_i^*\Psi_j d\tau=\int[\sum_P(-1)^P P^r\Lambda P^\sigma\Theta_i]^*\Lambda\Theta_j d\tau=\sum_P\langle P\Lambda|\Lambda\rangle\tilde{U}_{ij}(P), \quad (2.4)$$

where $\langle P\Lambda|\Lambda\rangle$ represents the integral over the coordinate variables

$$\langle P\Lambda|\Lambda\rangle\equiv\int P^r\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)^*\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)dv, \quad (2.5)$$

while the integral over the spin variables is denoted by $\tilde{U}_{ij}(P)$ as follows:

$$\tilde{U}_{ij}(P)\equiv(-1)^P\int P^\sigma\Theta_i^*\Theta_j d\sigma. \quad (2.6)$$

From (2.4), it is clear that the normalization constants D_{ii} can become very large, which leads to the difficulty of calculating the Heitler–London energy.

The overlap integral D_{ij} can be regarded as the ij element of the overlap matrix $\mathbf{D}$, and similarly $\tilde{U}_{ij}(P)$ as the ij element of matrix $\tilde{\mathbf{U}}(P)$. Using the matrix notation, Eqs. (2.4) and (2.6) are written as

$$\mathbf{D}\equiv\int\boldsymbol{\Psi}^\dagger\boldsymbol{\Psi}d\tau=\sum_P\langle P\Lambda|\Lambda\rangle\tilde{\mathbf{U}}(P), \quad (2.7)$$

and

$$\tilde{\mathbf{U}}(P)=(-1)^P\int P^\sigma\boldsymbol{\Theta}^\dagger\cdot\boldsymbol{\Theta}d\sigma. \quad (2.8)$$

It is easily proved that the matrix $\tilde{\mathbf{U}}(PQ)$ corresponding to the successive application of two permutations Q and P is given by the product of two matrices $\tilde{\mathbf{U}}(Q)$ and $\tilde{\mathbf{U}}(P)$ as follows[18,19]:

$$\tilde{\mathbf{U}}(PQ)=\tilde{\mathbf{U}}(Q)\tilde{\mathbf{U}}(P). \quad (2.9)$$

---

[18] The matrix $\mathbf{U}(P)$ introduced by (2.8) is unitary and is a representation matrix of the permutation group. Use of representation matrices of permutation groups in the calculation of electronic energy levels is originally due to R. Serber [Phys. Rev. **45**, 461 (1934)] and T. Yamanouchi [Proc. Phys. Math. Soc. Japan **18**, 623 (1936)]. Also see the review by M. Kotani in *Table of Molecular Integrals*, edited by M. Kotani *et al.* (Maruzen Co., Ltd., Tokyo, 1955). In the present paper, however, we shall not use any group-theoretical argument except in (2.9) and (3.39). It is more convenient to understand that $\tilde{\mathbf{U}}(P)$ is merely a notation representing the integral appearing on the right of (2.8) and has the property described by (2.9).

[19] The relation (2.9) will be obtained as follows. Since 2^N linearly independent and orthonormal spin functions Θ_i, for $i=1, 2, \cdots, 2^N$, are complete in the spin space, we can expand $P^\sigma\Theta_i$ in terms of Θ_i as follows:

$$P^\sigma\Theta_i=(-1)^P\sum_j\Theta_j U_{ji}(P)^*, \quad (1)$$

where $U_{ji}(P)^*$ is merely an expansion coefficient but it is easily recognized that $U_{ji}(P)$ defined above is equivalent to $\tilde{U}_{ij}(P)$ introduced by (2.6). Here $\tilde{\mathbf{U}}(P)$ is the transpose of matrix $\mathbf{U}(P)$. Let us apply two permutations Q^σ and P^σ successively to Θ_i. Then

$$P^\sigma Q^\sigma\Theta_i=(-1)^Q\sum_k P^\sigma\Theta_k U_{ki}(Q)^*=(-1)^{PQ}\sum_j\sum_k\Theta_j U_{jk}(P)^*U_{ki}(Q)^*. \quad (2)$$

On the other hand, we can write this as follows:

$$P^\sigma Q^\sigma\Theta_i=(-1)^{PQ}\sum_j\Theta_j U_{ji}(PQ)^*. \quad (3)$$

Comparison of the above two equations yields

$$\mathbf{U}(PQ)=\mathbf{U}(P)\,\mathbf{U}(Q), \quad (4)$$

which is equivalent to (2.9).

The orthonormal wave functions Ψ_N of the array are then given by

$$\Psi_N=\Psi\mathbf{D}^{-1/2}. \tag{2.10}$$

Our problem is to calculate the Heitler–London energy of a Hamiltonian of the form

$$\mathcal{H}=\sum_{h=1}^{N} f(\mathbf{r}_h)+\tfrac{1}{2}\sum_{h_1=1}^{N}\sum_{h_2=1}^{N}{}' g(\mathbf{r}_{h_1},\mathbf{r}_{h_2}), \tag{2.11}$$

where the summation $\sum_{h_2=1}^{N}{}'$ excludes $h_2=h_1$. For this purpose, it is convenient to split off, from the N-electron wave function Ψ, one or several atomic orbitals, which are of particular interest for the manipulations we want to perform. This will be carried out as follows. An antisymmetric wave function of N electrons is constructed by taking the summation over $N!$ permutations P as is shown in (2.3). Here the $N!$ permutations P can be divided into two sets; the first set includes $(N-1)!$ permutations $Q[h]$ of $N-1$ electrons $1, 2, \cdots, h-1, h+1, \cdots, N$, while the second one consists of N permutations $P(k\leftarrow h)$ taking electron h to orbital k, where $k=1, 2, \cdots, N$. The original $N!$ permutations are given by $Q[h]\cdot P(k\leftarrow h)$ and the summation over $N!$ permutations P in (2.3) splits into two; the summations over $(N-1)!$ permutations $Q[h]$ and over k's. If we take the summation over $(N-1)!$ permutations $Q[h]$ after operating a particular permutation $P(k\leftarrow h)$, this portion of the wave function is antisymmetric with respect to electrons $1, 2, \cdots, h-1, h+1, \cdots, N$, but electron h always occupies orbital k. To emphasize this situation, let us denote the sum by $\chi_k(\mathbf{r}_h)\Psi_i[k(h)]$ where $i=1, 2, \cdots, N$. The original wave function Ψ is then written as

$$\Psi=N^{-1/2}\sum_k \chi_k(\mathbf{r}_h)\Psi[k(h)], \tag{2.12}$$

where $\Psi[k(h)]$ is the row matrix whose elements $\Psi_i[k(h)]$ are functions of $N-1$ orbitals and N spins as described above. More explicitly,

$$\Psi[k(h)]\equiv[(N-1)!]^{-1/2}\sum_{Q[h]}(-1)^{Q[h]P(k\leftarrow h)} \times Q^r[h]\Lambda[k(h)]Q^\sigma[h]P^\sigma(k\leftarrow h)\Theta, \tag{2.13}$$

and $\Lambda[k(h)]$ is a product of $N-1$ atomic orbitals, obtained from $\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)$ by applying $P^r(k\leftarrow h)$ and deleting $\chi_k(\mathbf{r}_h)$ as follows:

$$\Lambda[k(h)]\equiv\frac{1}{\chi_k(\mathbf{r}_h)}P^r(k\leftarrow h)\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N). \tag{2.14}$$

Similarly we introduce

$$\Psi[k_1(h_1)k_2(h_2)],\ \cdots,\ \Psi[k_1(h_1)\cdots k_n(h_n)].$$

For example,

$$\Psi[k_1(h_1)k_2(h_2)] \equiv[(N-2)!]^{-1/2}\sum_{Q[h_1h_2]}(-1)^{Q[h_1h_2]P(k_1k_2\leftarrow h_1h_2)} \times Q^r[h_1h_2]\Lambda[k_1(h_1)k_2(h_2)]Q^\sigma[h_1h_2] \times P^\sigma(k_1k_2\leftarrow h_1h_2)\Theta, \tag{2.15}$$

where

$$\Lambda[k_1(h_1)k_2(h_2)] \equiv\frac{1}{\chi_{k_1}(\mathbf{r}_{h_1})\chi_{k_2}(\mathbf{r}_{h_2})}P^\sigma(k_1k_2\leftarrow h_1h_2) \times\Lambda(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N), \tag{2.16}$$

and $Q[h_1h_2]$ represents $(N-2)!$ permutations not involving electrons h_1 and h_2, while $P(k_1k_2\leftarrow h_1h_2)$ is a permutation taking electrons h_1 and h_2 to orbitals k_1 and k_2. The functions

$$\Psi[k_1(h_1)k_2(h_2)],\quad \Psi[k_1(h_1)k_2(h_2)k_3(h_3)],$$

etc., are related to the original wave functions Ψ as follows:

$$\Psi=[N(N-1)]^{-1/2}\sum_{k_1}\sum_{k_2}{}'\chi_{k_1}(\mathbf{r}_{h_1})\chi_{k_2}(\mathbf{r}_{h_2}) \times\Psi[k_1(h_1)k_2(h_2)]=\text{etc.} \tag{2.17}$$

We further define the overlap matrices

$$S[k_1\cdots k_n|h_1\cdots h_n]$$

between the functions $\Psi[k_1(h_1)\cdots k_n(h_n)]$ as follows:

$$\mathbf{S}[k_1\cdots k_n|h_1\cdots h_n]\equiv\int\Psi[k_1(h_1)\cdots k_n(h_n)]^\dagger \times\Psi[k_1(h_1)\cdots k_n(h_n)]d\tau. \tag{2.18}$$

The method used in obtaining (2.4) is applied to the above matrices, which leads to

$$\mathbf{S}[k_1\cdots k_n|h_1\cdots h_n]=\sum_{Q[h_1\cdots h_n]}\langle Q[h_1\cdots h_n]\Lambda[k_1(h_1)\cdots k_n(h_n)|\Lambda[h_1(h_1)\cdots h_n(h_n)]\rangle \times\tilde{\mathbf{U}}(Q[h_1\cdots h_n]P(k_1\cdots k_n\leftarrow h_1\cdots h_n)). \tag{2.19}$$

Those overlap matrices are again related to the overlap matrix $\mathbf{D}$ between the original wave functions Ψ intro-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

duced by (2.4) as follows:

$$\mathbf{D}=\mathbf{S}[h|h]+\sum_k{}'\langle k|h\rangle\mathbf{S}[k|h] \tag{2.20}$$

$$=\mathbf{S}[h_1h_2|h_1h_2]+\langle h_1|h_2\rangle\langle h_2|h_1\rangle\mathbf{S}[h_2h_1|h_1h_2]$$
$$+\sum_k{}'\{\langle k|h_1\rangle\mathbf{S}[kh_2|h_1h_2]+\langle k|h_2\rangle\mathbf{S}[h_1k|h_1h_2]+\langle k|h_2\rangle\langle h_2|h_1\rangle\mathbf{S}[h_2k|h_1h_2]+\langle k|h_1\rangle\langle h_1|h_2\rangle\mathbf{S}[kh_1|h_1h_2]\}$$
$$+\sum_{k_1k_2}{}''\langle k_1|h_1\rangle\langle k_2|h_2\rangle\mathbf{S}[k_1k_2|h_1h_2] \tag{2.21}$$

$$=\text{etc.},$$

where

$$\langle k|h\rangle=\int\chi_k(\mathbf{r}_h)^*\chi_h(\mathbf{r}_h)d\tau_h, \tag{2.22}$$

and $\sum_k{}'$ excludes $k=h$, and $\sum_{k_1k_2}{}''$ excludes $k_1=h_1$, $k_2=h_2$ and also $k_1=h_2$, $k_2=h_1$. These results can be proved by inserting (2.19) into (2.20) and (2.21).

More generally, it will be found that

$$\mathbf{S}[k_1\cdots k_{n-1}|h_1\cdots h_{n-1}]$$
$$=\delta(h_n\neq k_1,\cdots,k_{n-1})\mathbf{S}[k_1\cdots k_{n-1}h_n|h_1\cdots h_{n-1}h_n]$$
$$+\sum_{k_n}{}^{(n)}\langle k_n|h_n\rangle\mathbf{S}[k_1\cdots k_{n-1}k_n|h_1\cdots h_{n-1}h_n], \tag{2.23}$$

where

$$\delta(h_n\neq k_1,\cdots,k_{n-1})=1, \quad \text{if } h_n \text{ is not included in } k_1,\cdots,k_{n-1},$$
$$=0, \quad \text{otherwise}$$

and, in the summation $\sum_{k_n}{}^{(n)}$, we exclude $k_n=k_1, k_2, \cdots, k_{n-1}, h_n$. Furthermore, the following equality will hold:

$$\mathbf{S}[h_{i_1}h_{i_2}\cdots h_{i_n}|h_1h_2\cdots h_n]=\tilde{\mathbf{U}}(P_i)\mathbf{S}[h_1h_2\cdots h_n|h_1h_2\cdots h_n], \tag{2.24}$$

where P_i is a permutation in which $h_1h_2\cdots h_n$ are taken to orbitals $h_{i_1}h_{i_2}\cdots h_{i_n}$. This relation will be proved easily by replacing $P(k_1\cdots k_n\leftarrow h_1\cdots h_n)$ in (2.19) by P_i and by splitting matrices $\tilde{\mathbf{U}}(Q[h_1\cdots h_n]P_i)$ as $\tilde{\mathbf{U}}(P_i)\tilde{\mathbf{U}}(Q[h_1\cdots h_n])$ by using the relation (2.9).

Now we are ready to calculate the energy matrix of the Hamiltonian (2.11). Since the Hamiltonian is totally symmetric and commutes with the antisymmetrizer $\sum_P(-1)^PP$ in the wave functions (2.3), the method used in obtaining (2.4) is again applied to this calculation and it will be found that

$$\langle\Psi|\sum_h f(\mathbf{r}_h)|\Psi\rangle\equiv\int\Psi^\dagger\sum_h f(\mathbf{r}_h)\Psi d\tau$$
$$=\sum_h\langle h|f(\mathbf{r}_h)|h\rangle\mathbf{S}[h|h]$$
$$+\sum_h\sum_k{}'\langle k|f(\mathbf{r}_h)|h\rangle\mathbf{S}[k|h]. \tag{2.25}$$

The normalized expectation values $\langle\mathbf{f}\rangle$, calculated by using the orthonormal wave functions Ψ_N defined by (2.10), are given by

$$\langle\mathbf{f}\rangle\equiv\langle\Psi_N|\sum_h f(\mathbf{r}_h)|\Psi_N\rangle$$
$$=\sum_h\langle h|f(\mathbf{r}_h)|h\rangle\mathbf{D}^{-1/2}\mathbf{S}[h|h]\mathbf{D}^{-1/2}$$
$$+\sum_h\sum_k{}'\langle k|f(\mathbf{r}_h)|h\rangle\mathbf{D}^{-1/2}\mathbf{S}[k|h]\mathbf{D}^{-1/2}. \tag{2.26}$$

Similarly the expectation values $\langle\mathbf{g}\rangle$ of two-body interaction $\frac{1}{2}\sum_{h_1}\sum_{h_2}{}'g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})$ are obtained by

$$\langle\mathbf{g}\rangle\equiv\langle\Phi_N|\tfrac{1}{2}\sum_{h_1}\sum_{h_2}{}'g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|\Phi_N\rangle$$
$$=\tfrac{1}{2}\sum_{h_1}\sum_{h_2}\sum_{k_1}\sum_{k_2}\langle k_1k_2|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle$$
$$\times\mathbf{D}^{-1/2}\mathbf{S}[k_1k_2|h_1h_2]\mathbf{D}^{-1/2}, \tag{2.27}$$

where h_1 and h_2 are also included in the summations $\sum_{k_1}\sum_{k_2}{}'$ for simplicity.

Here $\langle\mathbf{f}\rangle$ and $\langle\mathbf{g}\rangle$ are both matrices and can be calculated if the normalization matrices $\mathbf{D}^{-1/2}\mathbf{S}[k|h]\mathbf{D}^{-1/2}$ and $\mathbf{D}^{-1/2}\mathbf{S}[k_1k_2|h_1h_2]\mathbf{D}^{-1/2}$ are evaluated explicitly. The calculation of the normalization matrices is the main subject of the present paper and will be carried out in the following section.

III. CALCULATION OF THE NORMALIZATION MATRICES

Here we shall expand the normalization matrices of the type $\mathbf{D}^{-1/2}\mathbf{S}[k_1\cdots k_n|h_1\cdots h_n]\mathbf{D}^{-1/2}$ in terms of $\tilde{\mathbf{U}}(P)$ and evaluate the expansion coefficients. To proceed with the problem, let us divide the expansion into two steps and first consider the calculation of matrices of the following form:

$$\mathbf{F}[k_1\cdots k_n|h_1\cdots h_n]\equiv\mathbf{S}[k_1\cdots k_n|h_1\cdots h_n]\mathbf{D}^{-1}$$
$$=\sum_P f_P[k_1\cdots k_n|h_1\cdots h_n]\tilde{\mathbf{U}}(P). \tag{3.1}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The second expansion to be calculated is of the form:

$$\mathbf{A}^{(1/2)}(R)\equiv\mathbf{D}^{-1/2}\tilde{\mathbf{U}}(R)\mathbf{D}^{1/2}=\sum_P a_P{}^{(1/2)}(R)\tilde{\mathbf{U}}(P). \quad (3.2)$$

The original matrix is thus expanded as

$$\begin{aligned}&\mathbf{D}^{-1/2}\mathbf{S}[k_1\cdots k_n|h_1\cdots h_n]\mathbf{D}^{-1/2}\\&=\mathbf{D}^{-1/2}\mathbf{S}[k_1\cdots k_n|h_1\cdots h_n]\mathbf{D}^{-1}\cdot\mathbf{D}^{1/2},\\&=\sum_Q f_Q[k_1\cdots k_n|h_1\cdots h_n]\mathbf{D}^{-1/2}\tilde{\mathbf{U}}(Q)\mathbf{D}^{1/2},\\&=\sum_P\sum_Q f_Q[k_1\cdots k_n|h_1\cdots h_n]a_P{}^{(1/2)}(Q)\tilde{\mathbf{U}}(P). \quad (3.3)\end{aligned}$$

Previously,[10,20] we have shown that, as long as atomic orbitals χ used as basis are linearly independent, the inverse $\mathbf{D}^{-1}$ exists and can be expanded as (24) of paper I, that is,

$$\mathbf{D}^{-1}=\sum_P T_P\tilde{\mathbf{U}}(P). \quad (3.4)$$

Multiplication of this expression with (2.19) yields (3.1). The second equation (3.2), which is similarly obtainable, has been introduced previously by (68) of paper I.

Our problem now is to expand the coefficients $f_P[k_1\cdots k_n|h_1\cdots h_n]$ and $a_P{}^{(1/2)}(R)$ in terms of overlap integrals so that f_P and $a_P{}^{(1/2)}(R)$ can be evaluated explicitly.

(1) Expansion of the F Matrices

(a) *The Recurrence Relations for the Expansion*

Let us first consider the matrices of the form $\mathbf{F}[h_1\cdots h_n|h_1\cdots h_n]$ and show that, by using the relations (2.20), (2.21), and (2.23), the matrices can be decomposed into a sum of products of two parts: The first ones denoted by $\Gamma[P]$ are made of overlaps between electrons $h_1\cdots h_n$ and the other electrons, and can be calculated up to any desired accuracy explicitly while the second parts are equivalent to the $\mathbf{F}$ matrices originally considered except that the new matrices are for a new array which can be obtained by removing electrons $h_1\cdots h_n$ from the original array. Therefore we can repeat the same calculation in the second parts. This expansion will converge since overlap between electron h and a distant electron decreases exponentially.

For example let us consider the simplest case, the matrix $\mathbf{F}[h|h]=\mathbf{S}[h|h]\mathbf{D}^{-1}$. By inserting (2.20) into $\mathbf{F}[h|h]$, we find that

$$\begin{aligned}\mathbf{F}[h|h]&=\mathbf{S}[h|h]\{\mathbf{S}[h|h]+\sum_k{}'\langle k|h\rangle\mathbf{S}[k|h]\}^{-1}\\&=(1+\mathbf{X}[h])^{-1},\end{aligned} \quad (3.5)$$

where

$$\mathbf{X}[h]\equiv\sum_k{}'\langle k|h\rangle\mathbf{S}[k|h]\mathbf{S}[h|h]^{-1}. \quad (3.6)$$

Repeated use of (2.23) in $\mathbf{X}[h]$ yields

$$\begin{aligned}\mathbf{X}[h]=&\sum_{k_1}{}'\langle h|k_1\rangle\langle k_1|h\rangle\mathbf{S}[k_1h|hk_1]\mathbf{S}[h|h]^{-1}\\&+\sum_{k_2}{}''\sum_{k_1}{}'\langle h|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle\mathbf{S}[k_1k_2h|hk_1k_2]\mathbf{S}[h|h]^{-1}\\&+\sum_{k_3}{}'''\sum_{k_2}{}''\sum_{k_1}{}'\langle h|k_3\rangle\langle k_3|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle\mathbf{S}[k_1k_2k_3h|hk_1k_2k_3]\mathbf{S}[h|h]^{-1}\\&+\cdots.\end{aligned} \quad (3.7)$$

Let us introduce the notation $\mathbf{F}_h[k_1\cdots k_n|k_1\cdots k_n]$ by defining

$$\mathbf{S}[hk_1\cdots k_n|hk_1\cdots k_n]\mathbf{S}[h|h]^{-1}\equiv\mathbf{F}_h[k_1\cdots k_n|k_1\cdots k_n]. \quad (3.8)$$

Use of this definition as well as (2.24) leads to

$$\begin{aligned}\mathbf{X}[h]=&\sum_{k_1}{}'\langle h|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1h)\mathbf{F}_h[k_1|k_1]\\&+\sum_{k_2}{}''\sum_{k_1}{}'\langle h|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1k_2h)\mathbf{F}_h[k_1k_2|k_1k_2]\\&+\sum_{k_3}{}'''\sum_{k_2}{}''\sum_{k_1}{}'\langle h|k_3\rangle\langle k_3|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1k_2k_3h)\mathbf{F}_h[k_1k_2k_3|k_1k_2k_3]\\&+\cdots,\end{aligned} \quad (3.9)$$

where $(k_1k_2\cdots k_nh)$ is a cyclic permutation in which electrons $h, k_1, \cdots, k_{n-1}, k_n$ are shifted to orbitals $k_1, k_2, \cdots, k_n, h$. In (3.9), terms such as $\langle h|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1k_2h)$ belong to the first part $\Gamma[P]$, while the matrices $\mathbf{F}_h[k_1\cdots k_n|k_1\cdots k_n]$ belonging to the second part are equivalent to $\mathbf{F}[k_1\cdots k_n|k_1\cdots k_n]$. For instance, $\mathbf{F}_h[k|k]$ can be calculated by (3.5) and (3.9) except that electron h should be excluded from the summations.

[20] The present method can be extended to the case where basic atomic orbitals are not linearly independent. See Sec. IV (3) and also Appendix B of paper I.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The equation (3.5) can be expanded formally as

$$\mathbf{F}[h|h]=1-\mathbf{X}[h]+\mathbf{X}[h]^2-\mathbf{X}[h]^3+\cdots. \tag{3.10}$$

This expansion converges as long as $\epsilon=\sum_P|x_P[h]|<1$ where $x_P[h]$ is the expansion coefficient of $\mathbf{X}[h]$:

$$\mathbf{X}[h]=\sum_P x_P[h]\tilde{\mathbf{U}}(P). \tag{3.11}$$

This will be proved in the Appendix.

Similarly $\mathbf{F}[h_1h_2|h_1h_2]$ is expanded as

$$\begin{aligned}\mathbf{F}[h_1h_2|h_1h_2]&=(1+\mathbf{X}[h_1h_2])^{-1}\\&\doteq 1-\mathbf{X}[h_1h_2]+\mathbf{X}[h_1h_2]^2-\mathbf{X}[h_1h_2]^3+\cdots,\end{aligned} \tag{3.12}$$

where

$$\begin{aligned}\mathbf{X}[h_1h_2]=&\langle h_1|h_2\rangle\langle h_2|h_1\rangle\tilde{\mathbf{U}}(h_1h_2)\\&+\sum_{k_1}\{\langle h_1|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(k_1h_1)+\langle h_2|k_1\rangle\langle k_1|h_2\rangle\mathbf{U}(k_1h_2)+\langle h_2|k_1\rangle\langle k_1|h_1\rangle\langle h_1|h_2\rangle\tilde{\mathbf{U}}(k_1h_2h_1)\\&\qquad+\langle h_1|k_1\rangle\langle k_1|h_2\rangle\langle h_2|h_1\rangle\tilde{\mathbf{U}}(h_2k_1h_1)\}\mathbf{F}_{h_1h_2}[k_1|k_1]\\&+\sum_{k_1k_2}\{\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(k_1k_2h_1)+\langle h_2|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_2\rangle\tilde{\mathbf{U}}(k_1k_2h_2)\\&\quad+\langle h_2|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\langle h_1|h_2\rangle\tilde{\mathbf{U}}(k_1k_2h_2h_1)+\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_2\rangle\langle h_2|h_1\rangle\tilde{\mathbf{U}}(h_2k_1k_2h_1)\\&\quad+\langle h_1|k_1\rangle\langle k_1|h_1\rangle\langle h_2|k_2\rangle\langle k_2|h_2\rangle\tilde{\mathbf{U}}((k_1h_1)(k_2h_2))\\&\quad+\langle h_1|k_2\rangle\langle k_2|h_2\rangle\langle h_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(k_1h_2k_2h_1)\}\mathbf{F}_{h_1h_2}[k_1k_2|k_1k_2]\\&+\cdots.\end{aligned} \tag{3.13}$$

The matrices $\mathbf{F}[h_1|h_1]$, $\mathbf{F}[h_1h_2|h_1h_2]$, $\cdots$, obtained by (3.9), (3.10), (3.12), and (3.13), can be inserted into replace (3.9) and (3.13). Thus the expansion develops further. These relations are more conveniently summarized by

$$\begin{aligned}\mathbf{F}[h(n)]&=(1+\mathbf{X}[h(n)])^{-1}\\&=1-\mathbf{X}[h(n)]+\mathbf{X}[h(n)]^2-\mathbf{X}[h(n)]^3+\cdots,\end{aligned} \tag{3.14}$$

and

$$\mathbf{X}[h(n)]=\sum_m\sum_k\Gamma[k(m)]\mathbf{F}_{h(n)}[k(m)], \tag{3.15}$$

where $h(n)$ and $k(n)$ are abbreviations of letters appearing in brackets of the matrices $\mathbf{F}[h_1\cdots h_n|h_1\cdots h_n]$, $\mathbf{X}[h_1\cdots h_n]$, etc., and n specifies the number of letters involved.

So far we consider matrices of the form $\mathbf{F}[h_1\cdots h_n|h_1\cdots h_n]$. More general ones $\mathbf{F}[k_1\cdots k_n|h_1\cdots h_n]$ introduced by (3.1) can also be reduced to the standard form by repeated use of (2.23). For instance,

$$\begin{aligned}\mathbf{F}[k|h]=&\langle h|k\rangle\tilde{\mathbf{U}}(hk)\mathbf{F}[hk|hk]\\&+\sum_{k_1}{}'\langle h|k_1\rangle\langle k_1|k\rangle\tilde{\mathbf{U}}(kk_1h)\mathbf{F}[hkk_1|hkk_1]\\&+\sum_{k_2}{}''\sum_{k_1}{}'\langle h|k_2\rangle\langle k_2|k_1\rangle\langle k_1|k\rangle\tilde{\mathbf{U}}(kk_1k_2h)\mathbf{F}[hkk_1k_2|hkk_1k_2]\\&+\cdots.\end{aligned} \tag{3.16}$$

(b) *Diagram Description*

To proceed with the calculation in practice, it is convenient to draw diagrams. Let us denote, by a solid line starting from point h_1 and ending at point h_2, the overlap integral $\langle h_2|h_1\rangle$ and similarly, by a broken line starting from h_1 going through $h_2,\cdots,h_n$ and coming back to h_1, a cyclic permutation $(h_2h_3\cdots h_nh_1)$. For example, the expansion (3.9) of $\mathbf{X}[h]$ is shown in Fig. 1, where, as a convenient way of explaining how diagrams are built up, points are classified *temporarily* as the following two kinds: a solid dot ● indicates the starting point of $\mathbf{X}[h]$ and no line comes back to this point any more in the course of expanding $\mathbf{X}[h]$, while an open dot ○ indicates that the expansion is not completed at

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

this point but a new $\mathbf{F}$ matrix starts from here. The first term has one open dot and therefore $\mathbf{F}_h[k_1|k_1]$ will follow. Two open dots of the second term show that $\mathbf{F}_h[k_1k_2|k_1k_2]$ follows. Since broken lines for permutations are the same as the solid lines, we have omitted them.

Similarly the expansion (3.13) of $\mathbf{X}[h_1h_2]$ is described in Fig. 2. There we have omitted terms obtained by interchanging h_1 and h_2.

To calculate $\mathbf{F}_h[k_1|k_1]$, $\mathbf{F}_h[k_1k_2|k_1k_2]$, etc., we further draw $\mathbf{X}_h[k_1|k_1]$, $\mathbf{X}_h[k_1k_2|k_1k_2]$, etc., starting from open dots. For example, the second term in Fig. 1 includes the series of diagrams in Fig. 3.

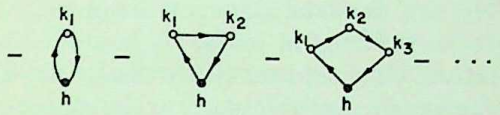

FIG. 1. The expansion of $\mathbf{X}[h]$ described by Eq. (3.9).

Solid lines can come into a point many times, but the representation of electron permutations should be reduced into the simplest form so that we can distinguish a permutation from others immediately. This implies that within one diagram, any one electron should not be shifted more than once, and hence a broken line can come into a point only once and come out only once. For instance, the second term in Fig. 3 represents the permutation $(k_1k_2)(k_1k_2h_1)$ which shifts electrons h_1, k_1, k_2 to k_1, k_2, h_1 and, after that, again interchanges k_1 and k_2, but this process is equivalent to a single interchange

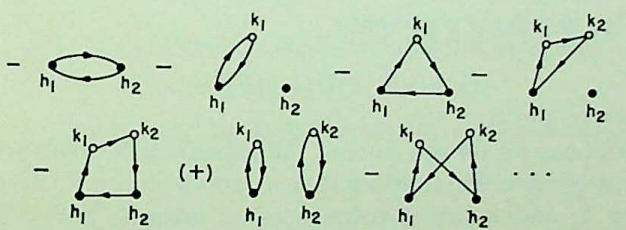

FIG. 2. The expansion of $\mathbf{X}[h_1h_2]$ described by Eq. (3.13).

of h_1 and k_2. Therefore the broken loop in this diagram illustrates the interchange (h_1k_2) only. The second term represents the quantity

$$|\langle k_1|k_2\rangle|^2\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_2).$$

Since $(k_1k_2h_1)(k_1k_2)=(h_1k_1)$ is a different permutation from the second term, it is important to remember the order in which these loops appear in a diagram.

In order to calculate $\mathbf{F}[h|h]$ by (3.14), we need to evaluate higher order terms $\mathbf{X}[h]^2$, $\mathbf{X}[h]^3$, $\cdots$. This will be carried out by multiplying diagrams we have generated. For instance, $\mathbf{X}[h]^2$ will be obtained from diagrams in Fig. 1. In case permutation $(k_1k_2h_1)$ appears first (on the left of $\mathbf{X}[h]\mathbf{X}[h]$) and then permutation (h_1k_1) follows it [(h_1k_1) appears on the right of $\mathbf{X}[h]\mathbf{X}[h]$], we obtain the diagram in Fig. 4, which corresponds to the quantity

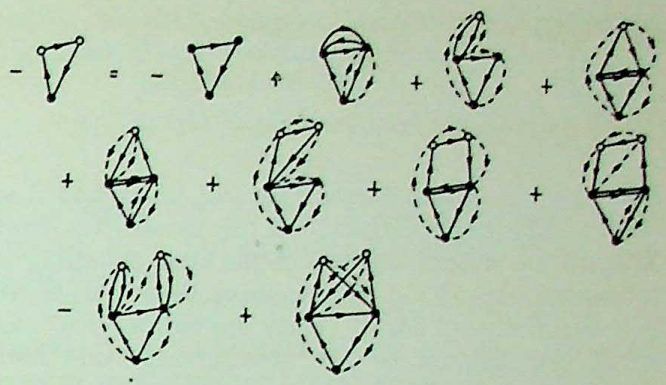

FIG. 3. Further expansion of the second term in Fig. 1.

$$|\langle h|k_1\rangle|^2\langle h|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1k_2).$$

Since all diagrams in $\mathbf{X}[h]$ start from h, solid lines come into h many times after the multiplication and the distinction between solid and open dots becomes obscure. Therefore, we shall not make this distinction in diagrams any more.

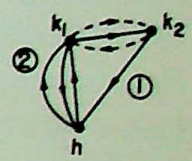

FIG. 4. The diagram of $\langle h|k_2\rangle\langle k_2|k_1\rangle \times\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1k_2h)\times\langle h|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1h)$. This term comes from $\mathbf{X}[h]^2$.

Similar multiplication should be added in those appearing in Fig. 3. Here we have drawn only $\mathbf{X}_h[k_1k_2|k_1k_2]$ instead of $\mathbf{F}_h[k_1k_2|k_1k_2]$. The expression will become complete if we include higher terms such as $\mathbf{X}_h[k_1k_2|k_1k_2]^2$, $\mathbf{X}_h[k_1k_2|k_1k_2]^3$, etc. The contribution from $\mathbf{X}_h[k_1k_2|k_1k_2]^2$ includes, for instance, the diagrams in Fig. 5. The first one is obtained by multiplication of the first and second diagrams in Fig. 2. The second one is obtained from two of the type appearing in the second term, but h_1 and h_2 are interchanged in the first one.

In (3.14), odd powered terms $\mathbf{X}[h(n)]^{2m+1}$ carry minus signs, which should also appear in diagrams. It is possible to associate a sign with the number of loops in a diagram. For instance, diagrams in Fig. 1 should have minus signs in $\mathbf{F}[h_1|h_1]$ since they are terms appearing in $\mathbf{X}[h_1]$. In fact, each of them consists of one loop. Those in Fig. 2 should also be minus. However, the fifth

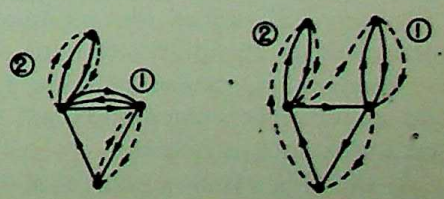

FIG. 5. Some of the contributing terms from $\mathbf{X}_h[k_1k_2|k_1k_2]^2$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

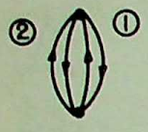

FIG. 6. The diagram of $\langle h|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1h)\times\langle h|k_1\rangle\langle k_1|h\rangle\tilde{\mathbf{U}}(k_1h)$.

term consists of two loops. This will be explained as follows. The same diagram can be constructed from $\mathbf{X}[h_1h_2]^2$ by multiplying two of the type appearing in the second term in Fig. 2, as we have already explained in connection with Fig. 5. There are two ways to construct the diagram by the multiplication and both carry a plus sign. Therefore, the total sum is $2-1=1$ in accordance with the proposed criterion. Matrix $\mathbf{X}[h_1h_2h_3]$ will include diagrams with three loops. However, the same diagram will be constructed from $\mathbf{X}[h_1h_2h_3]^2$ 6 times with plus sign and from $\mathbf{X}[h_1h_2h_3]^3$ 6 times with minus sign. The total is $-1+6-6=(-1)^3$. We can test this rule further. Let us assume that, up to t loops, total sum of all possible contributions to a particular diagram with r loops is $(-1)^r$, where $r\leqslant t$. A diagram with $t+1$ loops is constructed by multiplying a diagram with χ loops by all possible diagrams with total $t-\chi+1$ loops. By considering all possible ways to construct diagrams each of which carries χ loops and by adding all possible cases starting from $\chi=1$ and counting up to $\chi=t+1$, we obtain the total sum of all possible contributions to the diagram with $t+1$ loops. We can construct $\binom{t+1}{\chi}$ diagrams, each of which carries χ loops, while the total sum of all possible contributions to a diagram with $t-\chi+1$ loops is $(-1)^{t-\chi+1}$. Therefore, the total sum of all possible contributions to the desired diagram carrying $t+1$ loops is

$$\sum_{\chi=1}^{t+1}(-1)^{t-\chi+1}\binom{t+1}{\chi}=(-1)^{t+1}.$$

This proves the criterion on assigning signs to diagrams: *We count the number t of loops in solid lines in a diagram. The diagram should carry sign* $(-1)^t$.

Thus we have expanded the matrix $\mathbf{F}[h_1\cdots h_n|h_1\cdots h_n]$ in terms of overlap integrals and $\tilde{\mathbf{U}}(P)$. Comparison of the expansion with (3.1) yields that

$$f_P[h_1\cdots h_n|h_1\cdots h_n]=\sum_{t=1}^{\infty}\sum_{P_1P_2\cdots P_t}^{P}(-1)^tS_{P_1}S_{P_2}\cdots S_{P_t},\quad(3.17)$$

where P_i is a cyclic permutation and $S_{P_i}=\int P_i\Lambda^*\Lambda dv$ represents a loop. The summation takes all possible $P_1, P_2, \cdots, P_t$ under the condition $P=P_tP_{t-1}\cdots P_1$ and, at least, P_1 will include some of $h_1h_2\cdots h_n$.

From (3.17), we can calculate $f_P[h_1\cdots h_n|h_1\cdots h_n]$ for any P. The computation will be simplified if we draw diagrams as follows:

(i) We start from a point in $h_1h_2\cdots h_n$, and draw a loop. A loop must never go through a point more than once and always come back to the starting point.

(ii) By adding more loops, we can calculate terms in high order. Loops appear by successive expansion (Fig. 3) of $\mathbf{F}$ and by multiplication (Figs. 4 and 5) of $\mathbf{X}$. Number the loops according to the order with which the loops appear and attach sign $(-1)^t$ to the diagram, where t is the number of loops in the diagram.

(iii) After completing solid lines in a diagram, we describe the electron permutation by broken lines. The broken lines never go through one point more than once in a diagram and always come back to the starting point. If the line is equal to P, retain the diagram. Otherwise discard it.

(iv) We can draw all different diagrams, including differences in ordering of loops. If, however, loops are commutative, we should take only one of the diagrams we find by numbering the loops in different ways. An example of such a case is the second diagram in Fig. 5, where we have already counted all contributions when $(-1)^t$ was assigned to it. Another example is shown in Fig. 6, which, in fact, appears only once in the expansion.

(c) *Accuracy of the Expansion Technique*

In practice, the expansion described in this section cannot be carried out indefinitely and it is necessary to truncate the series. The upper bound to an error introduced by such truncation of the series can be calculated by using the inequality (A7) for sum L_n of absolute values of the expansion coefficients $f_P[h(n)]$.

Let us consider, for example, the series in Fig. 1. The first term represents

$$\langle h|k_1\rangle\langle k_1|h\rangle\mathbf{U}(k_1h)\mathbf{F}_h[k_1|k_1].$$

Suppose we do not pursue the expansion beyond point k_1 any more. This implies that we approximate $\mathbf{F}_h[k_1|k_1]$ by 1, and hence it introduces an error to the series. From (A7), it is easily found that the error is less than

$$\sum_{k_1}\langle h|k_1\rangle\langle k_1|h\rangle[(1-O(\Delta\Delta_0))^{-1}-1].$$

From the second term in Fig. 1, we get an error of

$$\sum_{k_1}\sum_{k_2}\langle h|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h\rangle[(1-O(\Delta\Delta_0))^{-2}-1],$$

by not taking further expansion terms beyond k_1 and k_2, and so on. Here the factor $[(1-O(\Delta\Delta_0))^{-m}-1]$ will increase when m increases, and the first term $(1-O(\Delta\Delta_0))^{-m}$ will eventually become dominant. Under such circumstances, there is no reason to write the large loop without further expansion, since the loop is merely a minority term in the further expansion. They should be neglected altogether. For instance, if we neglect, in

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the series in Fig. 1, the fourth term and higher, the error will be

$$\Delta^5(1-O(\Delta\Delta_0))^{-4}+\Delta^6(1-O(\Delta\Delta_0))^{-5}+\Delta^7(1-O(\Delta\Delta_0))^{-6}+\cdots.$$

A similar observation can be made for the series in Fig. 3. If we retain the first term and neglect all the others, the error will be

$$\Delta^3[(1-O(\Delta\Delta_0))^{-2}-1].$$

If we consider all diagrams that appear in Fig. 3 and neglect the higher orders, we have to estimate the error for each diagram one by one. This process is not so difficult. The first two diagrams are complete and therefore introduce no error. The next three carry an error $[(1-O(\Delta\Delta_0))^{-1}-1]$ times their values and so on. In addition, an error will be introduced by not considering terms such as $X_h[k(2)]^2$, $X_h[k(2)]^3$, etc.

In any case, it is possible to calculate the upper bound to an error introduced by truncation of an expansion of $\mathbf{F}$.

(2) Calculation of the A Matrices

(a) *Evaluation of* $\mathbf{A}^{(1)}(R)$

The calculation of matrix $\mathbf{A}^{(1/2)}(R)$ introduced by (3.2) involves more difficulties. In the present subsection, we shall compute, instead of $\mathbf{A}^{(1/2)}(R)$, the matrix $\mathbf{A}^{(1)}(R)$ defined by

$$\mathbf{A}^{(1)}(R)\equiv\mathbf{D}^{-1}\tilde{\mathbf{U}}(R)\mathbf{D}=\sum_P a_P{}^{(1)}(R)\tilde{\mathbf{U}}(P). \quad (3.18)$$

In subsection (b), the matrix $\mathbf{A}^{(1/2)}(R)$ will be calculated by using the expansion coefficients $a^{(1)}(R)$ obtained here.

We shall proceed with the calculation of $\mathbf{A}^{(1)}(R)$ by observing from (3.18) that $\mathbf{A}^{(1)}(R)$ can be expanded in terms of matrices $\mathbf{F}$ and consequently $a_P{}^{(1)}(R)$ in terms of f_P. To facilitate the expansion of $\mathbf{A}^{(1)}(R)$ in terms of $\mathbf{F}$, we shall consider the Hermitian conjugate of the expression (3.18), that is,

$$\mathbf{A}^{(1)}(R^{-1})^\dagger=\mathbf{D}\tilde{\mathbf{U}}(R)\mathbf{D}^{-1}=\sum_P a_P{}^{-1(1)}(R^{-1})^*\tilde{\mathbf{U}}(P). \quad (3.19)$$

Let us first consider a case where R is a simple interchange (h_1h_2). Use of the expansion (2.21) of $\mathbf{D}$ in $\mathbf{D}\tilde{\mathbf{U}}(R)\mathbf{D}^{-1}$ decomposes the matrix $\mathbf{A}^{(1)}(h_1h_2)^\dagger$ into a sum of matrices of the type

$$\langle k_1|h_1\rangle\mathbf{S}[k_1h_2|h_1h_2]\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}. \quad (3.20)$$

When the method used in obtaining the expansion (3.16) is applied in $\mathbf{S}[k_1h_2|h_1h_2]$, the above expression is rewritten as

---

$$\begin{aligned}
&\langle h_1|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_1)\mathbf{S}[h_1h_2k_1|h_1h_2k_1]\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}\\
&\quad+\sum_{k_2}{}''\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_1k_2)\mathbf{S}[h_1h_2k_1k_2|h_1h_2k_1k_2]\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}\\
&\quad+\sum_{k_3}{}'''\sum_{k_2}{}''\langle h_1|k_3\rangle\langle k_3|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_1k_2k_3)\mathbf{S}[h_1h_2k_1k_2k_3|h_1h_2k_1k_2k_3]\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}\\
&\quad+\cdots\\
&=\langle h_1|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_1h_2)\mathbf{F}[h_1h_2k_1|h_1h_2k_1]\\
&\quad+\sum_{k_2}{}'''\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_1k_2h_2)\mathbf{F}[h_1h_2k_1k_2|h_1h_2k_1k_2]\\
&\quad+\sum_{k_3}{}''''\sum_{k_2}{}'''\langle h_1|k_3\rangle\langle k_3|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\tilde{\mathbf{U}}(h_1k_1k_2k_3h_2)\mathbf{F}[h_1h_2k_1k_2k_3|h_1h_2k_1k_2k_3]\\
&\quad+\cdots. \qquad (3.21)
\end{aligned}$$

Similarly $\mathbf{D}$ in the expression $\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}\mathbf{D}^{-1}$ is expanded, where a term corresponding to (3.20) yields a series similar to (3.21), but $\tilde{\mathbf{U}}(h_1h_2k_1)$, $\tilde{\mathbf{U}}(h_1h_2k_1k_2)$, etc., will appear instead of $\tilde{\mathbf{U}}(h_1k_1h_2)$, $\tilde{\mathbf{U}}(h_1k_1k_2h_2)$, etc., in (3.21). The matrix

$$\langle k_1|h_2\rangle\mathbf{S}[h_1k_1|h_1h_2]\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}$$

will also produce an expansion obtained from (3.21) by interchanging h_1 and h_2.

By calculating all matrices appearing in the expansion of $\mathbf{D}$ and by taking the difference between $\mathbf{D}\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and $\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}\mathbf{D}^{-1}=\tilde{\mathbf{U}}(h_1h_2)$, it will finally be found that

$$\begin{aligned}\mathbf{A}^{(1)}(h_1h_2)^\dagger&=\mathbf{D}\tilde{\mathbf{U}}(h_1h_2)\mathbf{D}^{-1}\\&=\tilde{\mathbf{U}}(h_1h_2)+\sum_{k_1}{}'(\langle h_1|k_1\rangle\langle k_1|h_1\rangle-\langle h_2|k_1\rangle\langle k_1|h_2\rangle)[\tilde{\mathbf{U}}(h_1k_1h_2)-\tilde{\mathbf{U}}(h_2k_1h_1)]\mathbf{F}[h_1h_2k_1|h_1h_2k_1]\\&\quad+\sum_{k_1}{}''(\langle h_1|k_1\rangle\langle k_1|h_2\rangle\langle h_2|h_1\rangle-\langle h_2|k_1\rangle\langle k_1|h_1\rangle\langle h_1|h_2\rangle)[\tilde{\mathbf{U}}(h_2k_1)-\tilde{\mathbf{U}}(h_1k_1)]\mathbf{F}[h_1h_2k_1|h_1h_2k_1]\\&\quad+\sum_{k_2}{}'''\sum_{k_1}{}''(\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle-\langle h_2|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_2\rangle)\\&\qquad\times[\tilde{\mathbf{U}}(h_1k_1k_2h_2)-\tilde{\mathbf{U}}(h_2k_1k_2h_1)]\mathbf{F}[h_1h_2k_1k_2|h_1h_2k_1k_2]\\&\quad+\cdots\\&\quad+\sum_{k_2}{}'''\sum_{k_1}{}''(\langle h_1|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_2\rangle\langle h_2|h_1\rangle-\langle h_2|k_2\rangle\langle k_2|k_1\rangle\langle k_1|h_1\rangle\langle h_1|h_2\rangle)\\&\qquad\times[\tilde{\mathbf{U}}(h_2k_1k_2)-\tilde{\mathbf{U}}(h_1k_1k_2)]\mathbf{F}[h_1h_2k_1k_2|h_1h_2k_1k_2]\\&\quad+\cdots\\&\quad+\tfrac{1}{2}\sum_{k_2}{}'''\sum_{k_1}{}''(\langle h_1|k_1\rangle\langle k_1|h_1\rangle\langle h_2|k_2\rangle\langle k_2|h_2\rangle-\langle h_2|k_1\rangle\langle k_1|h_2\rangle\langle h_1|k_2\rangle\langle k_2|h_1\rangle)\\&\qquad\times[\tilde{\mathbf{U}}(h_1k_1h_2k_2)-\tilde{\mathbf{U}}(h_2k_1h_1k_2)]\mathbf{F}[h_1h_2k_1k_2|h_1h_2k_1k_2]\\&\quad+\cdots\\&\quad+\tfrac{1}{2}\sum_{k_2}{}'''\sum_{k_1}{}''(\langle h_1|k_1\rangle\langle k_1|h_2\rangle\langle h_2|k_2\rangle\langle k_2|h_1\rangle-\langle h_2|k_1\rangle\langle k_1|h_1\rangle\langle h_1|k_2\rangle\langle k_2|h_2\rangle)\\&\qquad\times[\tilde{\mathbf{U}}((h_1k_2)(h_2k_1))-\tilde{\mathbf{U}}((h_1k_1)(h_2k_2))]\mathbf{F}[h_1h_2k_1k_2|h_1h_2k_1k_2]\qquad(3.22)\\&\quad+\cdots.\end{aligned}$$

By using the expansion technique of the $\mathbf{F}$ matrices developed in the previous subsection (1), therefore, the matrix $\mathbf{A}^{(1)}(h_1h_2)$ can be calculated. The inequality (A7) ensures the convergence even if higher order terms in n of $\mathbf{F}[h(n)]$ are neglected.

Let us insert (3.1) and (3.17) into (3.22) and write the series in terms of loops S_P and $\mathbf{U}(P)$ as follows:

$$\begin{aligned}&\mathbf{A}^{(1)}(h_1h_2)^\dagger\\&\quad=\tilde{\mathbf{U}}(h_1h_2)+\sum_P\sum_t\sum_{P_0P_1\cdots P_n}^{P}(-1)^tC[(h_1h_2);P_0]\\&\qquad\times S_{P_1}S_{P_2}\cdots S_{P_t}\tilde{\mathbf{U}}(P),\qquad(3.23)\end{aligned}$$

where the summation $\sum_{P_0P_1\cdots P_t}{}^P$ takes all possible $P_0P_1\cdots P_t$ which satisfy the relation

$$P=P_tP_{t-1}\cdots P_2P_1(h_1h_2)P_0,\qquad(3.24)$$

and $C[(h_1h_2);P_0]$ represents a quantity in parentheses in (3.22). For instance,

$$\begin{aligned}&C[(h_1h_2);(h_1k_1)]=\langle h_1|k_1\rangle\langle k_1|h_1\rangle-\langle h_2|k_1\rangle\langle k_1|h_2\rangle,\\&C[(h_1h_2);(h_1h_2k_1)]=\langle h_1|k_1\rangle\langle k_1|h_2\rangle\langle h_2|h_1\rangle\\&\qquad-\langle h_2|k_1\rangle\langle k_1|h_1\rangle\langle h_1|h_2\rangle.\qquad(3.25)\end{aligned}$$

Comparison of (3.23) with (3.19) yields that

$$\begin{aligned}&a_{P^{-1}}{}^{(1)}(h_1h_2)^*\\&\quad=\delta_{(h_1h_2),P^{-1}}+\sum_t\sum_{P_0P_1\cdots Pt}^{P}(-1)^tC[(h_1h_2);P_0]\\&\qquad\times S_{P_1}S_{P_2}\cdots S_{P_t}.\qquad(3.26)\end{aligned}$$

By noting the relation $S_P{}^*=S_{P^{-1}}$, the above equation can be rewritten as

$$\begin{aligned}&a_P{}^{(1)}(h_1h_2)=\delta_{(h_1h_2),P}\\&\qquad+\sum_t\sum_{P_0P_1\cdots P_n}^{P}{}'(-1)^tC[(h_1h_2);P_0]^*\\&\qquad\times S_{P_1}{}^{-1}S_{P_2}{}^{-1}\cdots S_{P_t}{}^{-1},\qquad(3.27)\end{aligned}$$

where the summation $\sum_{P_0P_1\cdots P_t}{}'$ takes all possible $P_0, P_1\cdots P_t$ under the condition

$$P=P_0{}^{-1}(h_1h_2)P_1{}^{-1}P_2{}^{-1}\cdots P_t{}^{-1}.\qquad(3.28)$$

The equation (3.27), however, is less convenient than (3.26). To evaluate the electron permutation P as given by (3.28), we have to start from the last loop S_{P_t} and to count the cyclic permutations in reverse order. On the other hand, computation of $a_{P^{-1}}{}^{(1)}(h_1h_2)^*$ by (3.26) and (3.24) is exactly the same as the expansion (3.17) of $f_P[h(n)]$ and the electron permutation P can be obtained by multiplying cyclic permutations following the same order in which the loops appear. It is easily found that, after completing a diagram of $\mathbf{A}_{P^{-1}}{}^{(1)}(h_1h_2)^*$ by (3.26), a corresponding diagram for $\mathbf{A}_P{}^{(1)}(h_1h_2)$ can be obtained by reversing the direction of arrows in all solid lines as well as broken lines.

The calculation of $\mathbf{A}^{(1)}(R)$ just described can be extended to any permutation R, and it will be found that

$$\begin{aligned}a_{P^{-1}}{}^{(1)}(R^{-1})^*&=\delta_{R,P}+\sum_t\sum_{P_0P_1\cdots Pt}^{P}(-1)^tC[R;P_0]\\&\qquad\times S_{P_1}S_{P_2}\cdots S_{P_t}.\qquad(3.29)\end{aligned}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Diagrams for $a_P^{(1)}(R^{-1})$ can be constructed from those obtained by (3.29), by simply reversing directions of arrows in all solid lines and broken lines.

The only problem here is to develop $\mathbf{A}^{(1)}(R^{-1})^\dagger$ in terms of $\mathbf{F}$ and get an equation similar to (3.22), which, in return, gives explicit expressions of $C[R; P_0]$. This can also be carried out automatically by drawing diagrams of $C[R; P_0]$ as follows: Let R be a cyclic permutation $R=(h_1h_2\cdots h_s)$ and consider all possible permutations P_0 which start from a point on the loop $(h_1h_2\cdots h_s)$. The permutations P_0 may consist of many unconnected loops $P_{01}, P_{02}, \cdots, P_{0r}$, but each of the loops must have at least one common point with the original loop $(h_1h_2\cdots h_s)$. The desired coefficients $C[R; P_0]$ will be given by

$$C[R; P_0]=S_{P_{01}}S_{P_{02}}\cdots S_{P_{0r}} -S_{R^{-1}P_{01}R}S_{R^{-1}P_{02}R}\cdots S_{R^{-1}P_{0r}R}, \quad (3.30)$$

where $P_0=P_{0r}P_{0r-1}\cdots P_{02}P_{01}$.

In case R is a single interchange, we had the relation

$$C[R; P_0]=-C[R; R^{-1}P_0R], \quad (3.31)$$

which leads to factorizations of the type

$$C[R; P_0][\tilde{\mathbf{U}}(R^{-1}P_0)-\tilde{\mathbf{U}}(P_0R^{-1})], \quad (3.32)$$

as has been shown in (3.22). When R is a permutation involving more than two electrons, the relation (3.31) is no longer valid and each matrix $\tilde{\mathbf{U}}(R^{-1}P_0)$ may carry a distinct coefficient $C[R; P_0]$. Therefore $\mathbf{A}^{(1)}(R^{-1})^\dagger$ will not be written in the form (3.32).

Use of the inequality (A7) in (3.22) leads to the conclusion that the sum

$$L_b^{(2)}=\sum_P |a_P^{(1)}(h_1h_2)-\delta_{(h_1h_2),P}| \quad (3.33)$$

is also bounded and small as compared with unity as long as Δ is small. However, the quantity

$$L_b^{(s)}=\sum_P |a_P^{(1)}(R_s^{-1})-\delta_{R_s^{-1},P}| \quad (3.34)$$

will increase in proportion to the number s of electrons involved in the permutations R_s. This will be seen if we calculate some of the dominant terms in $\mathbf{A}^{(1)}(R_s^{-1})^\dagger$. For instance, let R_s be a loop $(h_1h_2\cdots h_s)$ of equally spaced s electrons in a crystal with translational symmetry. The matrix $\mathbf{A}^{(1)}(R_s^{-1})^\dagger$ will include s terms of the form

$$C[R_s; (h_ik_i)]\mathbf{U}(R_s^{-1}(h_ik_i)), \quad \text{for} \quad i=1, 2, \cdots, n,$$

whose s coefficients

$$C[R_s; (h_ik_i)]=\langle h_i|k_i\rangle\langle k_i|h_i\rangle-\langle h_{i+1}|k_i\rangle\langle k_i|h_{i+1}\rangle,$$

are equal to each other. Terms of the form

$$C[R_s; (h_ik_i)(h_jk_j)]\mathbf{U}(R_s^{-1}(h_ik_i)(h_jk_j))$$

will appear $\frac{1}{2}s(s-1)$ times in $A^{(1)}(R_s^{-1})^\dagger$, since all possible relative positions of loops (h_ik_i) and (h_jk_j) should be considered here.

This divergence of $L_b^{(s)}$ will lead to difficulties in proving the convergence of the expansion of $\mathbf{A}^{(1/2)}(R)$ as is seen in the following subsection (b). The origin of the divergence is due to the fact that diagrams in $\mathbf{A}^{(1)}(R_s^{-1})^\dagger$ are not connected with solid lines (overlaps). It is expected that, if the quantity $S_{R_s}\mathbf{A}^{(1)}(R_s)^\dagger$ is considered instead of $\mathbf{A}^{(1)}(R_s^{-1})^\dagger$, the sum of the absolute values of the expansion coefficients $S_{R_s}a_P^{(1)}(R_s^{-1})$

$$M_b^{(s)}=\sum_P |S_{R_s}[a_P^{(1)}(R_s^{-1})-\delta_{R_s^{-1}P}]| \leqslant |S_{R_s}| L_b^{(s)} \quad (3.35)$$

will converge and be very small. In fact, there is no essential difference between $\mathbf{A}^{(1)}(R_s^{-1})^\dagger$ and $\mathbf{F}[h(n)]$, and their expansion coefficients are calculated similarly by (3.17) and (3.26). Therefore the argument used in Appendix for bounding $F[h(n)]$ will be applied to $\mathbf{A}^{(1)}(R_s^{-1})^\dagger$ too.

(b) *Asymptotic Expansion of* $\mathbf{A}^{(1/2)}(B)$.

The expansion coefficients $a_P^{(1)}(R)$ obtained in the preceding subsection (a) are related to the desired ones $a_P^{(1/2)}(R)$ by

$$a_P^{(1)}(R)=\sum_Q a_Q^{(1/2)}(R)a_P^{(1/2)}(Q). \quad (3.36)$$

This relation is proved as follows. The matrix $\mathbf{A}^{(1)}(R)$ defined by (3.18) can also be expanded as

$$\begin{aligned}\mathbf{A}^{(1)}(R)&=\mathbf{D}^{-1/2}\mathbf{D}^{-1/2}\tilde{\mathbf{U}}(R)\mathbf{D}^{1/2}\mathbf{D}^{1/2}\\ &=\sum_Q a_Q^{(1/2)}(R)\mathbf{D}^{-1/2}\tilde{\mathbf{U}}(Q)\mathbf{D}^{1/2}\\ &=\sum_P\sum_Q a_Q^{(1/2)}(R)a_P^{(1/2)}(Q)\tilde{\mathbf{U}}(P). \quad (3.37)\end{aligned}$$

Comparison of (3.37) with (3.18) yields (3.36).

Let $a_P^{(1/2)}(R)$ and $a_P^{(1)}(R)$ be RP elements of matrices $\mathbf{a}^{(1/2)}$ and $\mathbf{a}^{(1)}$, respectively, and rewrite Eq. (3.36) in terms of the matrix representation as follows:

$$\mathbf{a}^{(1)}=\mathbf{a}^{(1/2)}\mathbf{a}^{(1/2)}. \quad (3.38)$$

Use of the orthogonality relation of the irreducible representation matrices $\tilde{\mathbf{U}}(P)$ in (3.2) leads to[21,22]

$$a_P^{(1/2)}(R)=\sum_{\rho km}\frac{f_\rho}{N!}(D^{-1/2})_{kk}^{(\rho)}\tilde{U}_{km}^{(\rho)}(R) \times(D^{1/2})_{mm}^{(\rho)}\tilde{U}_{km}^{(\rho)}(P)^*, \quad (3.39)$$

[21] As we shall show in (4.1) and (4.2), it is always possible to consider a representation where $\mathbf{D}$ is diagonal.

[22] The $N!$ matrices $\tilde{\mathbf{U}}(P)$ introduced by (2.8) are representation matrices of the permutation group. By choosing a suitable set of N-spin functions Θ_i as basis, $\tilde{\mathbf{U}}(P)$'s can be made irreducible. Let $\tilde{\mathbf{U}}^{(\rho)}(P)$ be the matrix in the irreducible representation ρ. The km

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where f_ρ is the dimension of the subspace (ρ). Since $(D^{-1/2})_{kk}{}^{(\rho)}$ and $(D^{1/2})_{mm}{}^{(\rho)}$ are real, we find the relation

$$a_P{}^{(1/2)}(R)=a_R{}^{(1/2)}(P)^*, \tag{3.40}$$

which shows that the matrices $\mathbf{a}^{(1/2)}$ and $\mathbf{a}^{(1)}$ are both Hermitian. Hence, there exists a unitary matrix $\mathbf{V}$ with which $\mathbf{a}^{(1/2)}$ and $\mathbf{a}^{(1)}$ are simultaneously diagonalized such that

$$\mathbf{V}^\dagger\mathbf{a}^{(1)}\mathbf{V}=\mathbf{1}+\boldsymbol{\eta}, \quad \text{diagonal}, \tag{3.41}$$

$$\mathbf{V}^\dagger\mathbf{a}^{(1/2)}\mathbf{V}=(\mathbf{1}+\boldsymbol{\eta})^{1/2}, \quad \text{diagonal}. \tag{3.42}$$

Eigenvalues $1+\eta_K$ and $(1+\eta_K)^{1/2}$ of matrices $\mathbf{a}^{(1)}$ and $\mathbf{a}^{(1/2)}$ are all positive, and there is no case where $(\mathbf{1}+\boldsymbol{\eta})^{1/2}$ on the right of (3.42) carries a minus sign. This will be proved as follows. Let us introduce matrix $\mathbf{A}^{(1/4)}(R)$ and the expansion coefficients $a_P{}^{(1/4)}(R)$ by

$$\mathbf{A}^{(1/4)}(R)\equiv\mathbf{D}^{-1/4}\tilde{\mathbf{U}}(R)\mathbf{D}^{1/4}=\sum_P a_P{}^{(1/4)}(R)\tilde{\mathbf{U}}(P). \tag{3.43}$$

As before, a Hermitian matrix $\mathbf{a}^{(1/4)}$ will be constructed from the expansion coefficients $a_P{}^{(1/4)}(R)$, and the following relation between $\mathbf{a}^{(1/4)}$ and $\mathbf{a}^{(1/2)}$ will be found

$$\mathbf{a}^{(1/2)}=\mathbf{a}^{(1/4)}\mathbf{a}^{(1/4)}. \tag{3.44}$$

This relation shows that $\mathbf{a}^{(1/4)}$ is also brought into a diagonal form by the unitary matrix $\mathbf{V}$ used in (3.41) and (3.42), and that the eigenvalues are square roots of eigenvalues of $\mathbf{a}^{(1/2)}$. This implies that, if some eigenvalues of $\mathbf{a}^{(1/2)}$ carried minus signs, the corresponding eigenvalues of $\mathbf{a}^{(1/4)}$ would have to be imaginary. This is contradictory to the theorem that the eigenvalues of a Hermitian matrix are real. Therefore, eigenvalues $1+\eta_K$ and $(1+\eta_K)^{1/2}$ in (3.41) and (3.42) must be all positive.

Since off-diagonal elements $a_P{}^{(1)}(R)$ are small, the relations (3.41) and (3.42) suggest that the perturbation technique can be applied to calculate the eigenvalues $1+\eta_K$ and the unitary matrix $\mathbf{V}$ of $\mathbf{a}^{(1)}$. The desired matrix $\mathbf{a}^{(1/2)}$ can then be obtained from

$$\mathbf{a}^{(1/2)}=\mathbf{V}(\mathbf{1}+\boldsymbol{\eta})^{1/2}\mathbf{V}^\dagger. \tag{3.45}$$

It turned out that this approach is not practical since the matrix $\mathbf{a}^{(1)}$ has an infinite order of degeneracy. For instance, diagonal elements $a_{(h_ik_i)}{}^{(1)}(h_ik_i)$, for $i=1, 2, \cdots, N$, are all equal to each other, if we consider a crystal with translational symmetry.

To eliminate this difficulty, it is more convenient to use an asymptotic expansion. Let us expand $(\mathbf{1}+\boldsymbol{\eta})^{1/2}$ in (3.45) in a power series of $\boldsymbol{\eta}$. The matrix $\mathbf{a}^{(1/2)}$ is then written formally as

$$\begin{aligned}\mathbf{a}^{(1/2)}&=\mathbf{V}(\mathbf{1}+\tfrac{1}{2}\boldsymbol{\eta}-\tfrac{1}{2}\times\tfrac{1}{4}\boldsymbol{\eta}^2+\tfrac{1}{2}\times\tfrac{1}{4}\times(3/6)\boldsymbol{\eta}^3-\cdots)\mathbf{V}^\dagger\\&=\mathbf{1}+\tfrac{1}{2}\mathbf{b}-\tfrac{1}{2}\times\tfrac{1}{4}\mathbf{b}^2+\tfrac{1}{2}\times\tfrac{1}{4}\times(3/6)\mathbf{b}^3-\cdots,\end{aligned} \tag{3.46}$$

where

$$\mathbf{b}\equiv\mathbf{V}\boldsymbol{\eta}\mathbf{V}^\dagger=\mathbf{a}^{(1)}-\mathbf{1}. \tag{3.47}$$

These equations (3.46) and (3.47) are written more explicitly as

$$a_P{}^{(1/2)}(R)=\delta_{RP}+\tfrac{1}{2}b_{RP}-\tfrac{1}{2}\times\tfrac{1}{4}\sum_Q b_{RQ}b_{QP}+\cdots, \tag{3.48}$$

and

$$b_{RP}=a_P{}^{(1)}(R)-\delta_{RP}. \tag{3.49}$$

Since b_{RP} is obtained by (3.29) and (3.49), the expansion coefficients $a_P{}^{(1/2)}(R)$ can be calculated by (3.48) provided the series converges.

In practice, there will not be any difficulty in using the expansion (3.48) for the calculation of $a_P{}^{(1/2)}(R)$. This will be explained as follows: Since it is not possible to calculate b_{RP} for all R and P exactly, we need to truncate and approximate the matrix b by neglecting permutations involving $s+1$ electrons or more. Let b^0 be the truncated matrix. The RP element $b_{RP}{}^0$ is then given by an approximate b_{RP} when R and P are both permutations of s electrons or less, while $b_{RP}{}^0=0$ if either R or P involves $s+1$ electrons or more. Here s is chosen so that $L_b{}^{(s)}$ as defined by (3.34) is less than one. This implies that

$$\sum_P|b_{RP}{}^0|\leqslant\epsilon<1, \quad \text{for all } R. \tag{3.50}$$

When all of b_{RP} in (3.48) are replaced by $b_{RP}{}^0$, the series (3.48) converges and the quantities $a_P{}^{(1/2)\,(0)}(R)$ thus calculated satisfy the following inequality:

$$\sum_P|a_P{}^{(1/2)\,(0)}(R)|\leqslant 2-(1-\epsilon)^{1/2}<(1-\epsilon)^{-1/2}. \tag{3.51}$$

The relation (3.51) will be proved in exactly the same way as (A6) has been obtained.

When the number s increases, however, the value of $L_b{}^{(s)}$ increases indefinitely, and the convergence of (3.48) will not be proved easily by an exact language of algebra.[11] Nevertheless, it is expected that the series (3.48), multiplied by S_R

$$S_Ra_P{}^{(1/2)}(R)=S_R\delta_{RP}+\tfrac{1}{2}S_Rb_{RP}-\tfrac{1}{2}\times\tfrac{1}{4}\sum_Q S_Rb_{RQ}b_{QP}+\cdots \tag{3.52}$$

converges, for the following reasons. Quantities such as S_Rb_{RP} or $\sum_Q S_Rb_{RQ}$ will be finite and small as we have discussed in (3.35). Higher terms $\sum_Q S_Rb_{RQ}b_{QP}$, $\sum_{Q_2}\sum_{Q_1}S_Rb_{RQ_1}b_{Q_1Q_2}b_{Q_2P}$, etc., consist of connected dia-

---

element of matrix $\mathbf{A}^{(1/2)}(R)$ in this representation is then written as

$$[A^{(1/2)}(R)]_{km}{}^{(\rho)}\equiv(D^{-1/2})_{kk}{}^{(\rho)}\tilde{\mathbf{U}}_{km}{}^{(\rho)}(R)(D)_{mm}{}^{(\rho)}=\sum_Q a_Q{}^{(1/2)}(R)\tilde{\mathbf{U}}_{km}{}^{(\rho)}(Q). \tag{1}$$

Because of the orthogonality relation of the irreducible representation matrices

$$\sum_{\rho km}(f_\rho/N!)\tilde{\mathbf{U}}_{km}{}^{(\rho)}(Q)\tilde{\mathbf{U}}_{km}{}^{(\rho)}(P)^*=\delta_{QP}, \tag{2}$$

we will find (3.39) when multiplying (1) by $\tilde{\mathbf{U}}_{km}{}^{(\rho)}(P)^*$ and summing over ρ, k and m.

grams, which build up over $S_R b_{RQ}$. This implies the convergence of the series provided the same diagrams do not accumulate. When a diagram appears repeatedly, we can count the number of times the diagram appears as we did for the $\mathbf{F}$ matrix in Sec. III (1b), and it will be finally found that they cancel each other in the course of the summation in (3.52), so the net contribution is a small finite number.

The calculation of $\sum_Q S_R b_{RQ} b_{QP}$ is, in fact, very similar to that of $S_{R_n}\mathbf{F}[h(n)]$ described by (3.15) or (3.9), where b_{RQ} corresponds to $\Gamma[k(n)]$ and b_{QP} to $\mathbf{F}_{h(n)}[k(m)]$. $S_{R_n}F[h(n)]$ may contain very large terms $\mathbf{F}_{h(n)}[k(m)]$ when m is large, but those are connected by $S_{R_n}\Gamma[k(m)]$. Large terms $b_{Q_m P}$ for large m are also connected by $S_R b_{RQ_m}$. To evaluate higher terms $\sum_{Q_2}\sum_{Q_1} S_R b_{RQ_1} b_{Q_1 Q_2} b_{Q_2 P}$, etc., corresponds to expanding $\mathbf{F}_{h(n)}[k(m)]$ in terms of $\mathbf{F}_{h(n)k(m)}[l(s)]$, etc. As we have discussed in the Appendix, the value of $S_{R_n}\mathbf{F}[h(n)]$ vanishes when n becomes large.

The higher order contribution, for which $L_b^{(s)} > 1$, can also be calculated by combining a perturbation

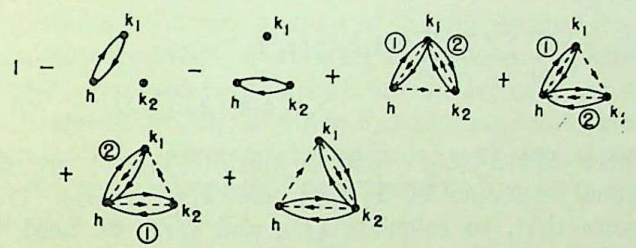

FIG. 7. The expansion of $\mathbf{F}[h|h]$.

technique with the asymptotic expansion described here. We shall not describe the details but we will again reach the same conclusion that $S_R\mathbf{A}^{(1/2)}(R)$ is expanded in terms of connected diagrams.

(c) *Role of* $\mathbf{A}^{(1/2)}(R)$

We have described the matrix $\mathbf{A}^{(1/2)}(R)$ as being very close to one and merely a correction factor of the $\mathbf{F}$ matrix. Here we shall illustrate, by an example, an essential role of $\mathbf{A}^{(1/2)}$ in our calculation.

Let us consider a Hermitian matrix

$$\mathbf{S}_N = \mathbf{D}^{-1/2}\mathbf{S}[h|h]\mathbf{D}^{-1/2},$$

which, according to (3.3), is expanded as

$$\mathbf{S}_N = \mathbf{D}^{-1/2}\mathbf{S}[h|h]\mathbf{D}^{-1/2} = \sum_P \sum_Q f_Q[h|h] a_P^{(1/2)}(Q)\tilde{\mathbf{U}}(P). \quad (3.53)$$

By using the prescription (i)–(iv) in Sec. III (1b) for drawing diagrams of matrix $\mathbf{F}[h|h]$, we find that $\mathbf{F}[h|h]$ contains among others the diagrams illustrated in Fig. 7.

If we set $\mathbf{A}^{(1/2)}(R) = 1$ and hence $a_P^{(1/2)}(R) = \delta_{RP}$, the matrix $\mathbf{S}_N$ becomes equivalent to $\mathbf{F}[h|h]$ described in Fig. 7, which is not Hermitian. For example, Hermitian

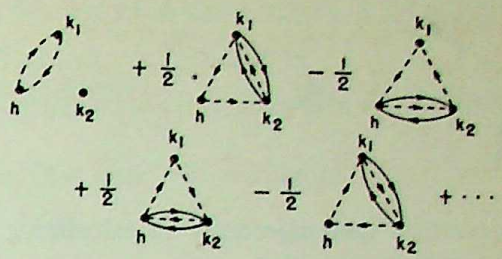

FIG. 8. The expansion of $\mathbf{A}^{(1/2)}(hk_1)$.

conjugates of the fourth and seventh diagrams become equivalent to, respectively, the second and fourth diagrams in Fig. 9. However, those diagrams cannot appear in $\mathbf{F}[h|h]$, since, to draw either of them, we have to start from loop (k_1k_2). All diagrams in $\mathbf{F}[h|h]$, however, should start from h.

On the other hand, matrix $\mathbf{A}^{(1/2)}(hk_1)$ includes the diagrams in Fig. 8. Diagrams for $\mathbf{A}^{(1/2)}(hk_2)$ are similar to those in Fig. 8 and obtained from them by interchanging k_1 and k_2. If we multiply $\mathbf{A}^{(1/2)}(hk_1)$ by the second term in Fig. 7 and $\mathbf{A}^{(1/2)}(hk_2)$ by the third, we obtain the expression for $\mathbf{S}_N$, which is similar to the series in Fig. 7, but the fourth and seventh terms are replaced by those in Fig. 9, and matrix $\mathbf{S}_N$ becomes Hermitian.

The present example clearly shows that the matrix $\mathbf{A}^{(1/2)}(R)$ is essential for retaining the Hermitian property of the energy matrix.

IV. DISCUSSION

(1) Evaluation of the Expectation Values

According to the description in Sec. III, any matrix containing an operator $f(\mathbf{r}_h)$ or $g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})$ can now be evaluated by drawing diagrams. Let us denote an integral of the form $\langle k|f(\mathbf{r}_h)|h\rangle$ by a heavy line starting from h and ending at k plus a wavy line indicating the operator $f(\mathbf{r}_h)$ as shown in Fig. 10, where the second one corresponds to $\langle h|f(\mathbf{r}_h)|h\rangle$. The integral

$$\langle k_1k_2|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle$$

is also written by diagrams as in Fig. 11. Here the second one represents a Coulomb interaction, the third one an exchange interaction.

From (3.16) and (3.17) together with the discussion at the end of Sec. III (2b), it is clear that any expectation value $\langle\mathbf{f}\rangle$ or $\langle\mathbf{g}\rangle$ given by (2.26) or (2.27) can be written as a sum of connected diagrams. This provides another indication that the nonorthogonality difficulties do not appear and that the Heitler–London

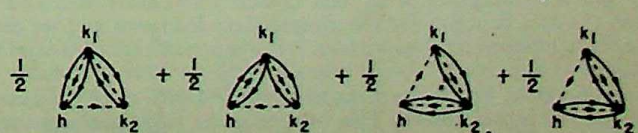

FIG. 9. Terms appearing in the expansion of $\mathbf{S}_N = \mathbf{D}^{-1/2}\mathbf{S}[h|h]\mathbf{D}^{-1/2}$.

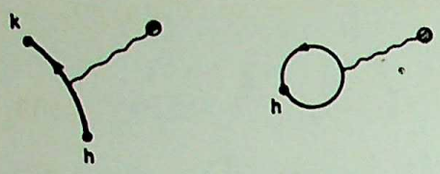

FIG. 10. Diagrams for $\langle k|f(\mathbf{r}_h)|h\rangle$ and $\langle h|f(\mathbf{r}_h)|h\rangle$.

method can be used rigorously in calculating energy spectra or other quantities.

The calculation can be carried out as follows:

(i) First, we shall write an interaction term $\langle k|f(\mathbf{r})|h\rangle$ or $\langle k_1k_2|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle$ by using notations introduced in Figs. 10 and 11.

(ii) The matrix $\mathbf{D}^{-1/2}\mathbf{S}[k|h]\mathbf{D}^{-1/2}$ or

$$\mathbf{D}^{-1/2}S[k_1k_2|h_1h_2]\mathbf{D}^{-1/2}$$

should follow the diagram just obtained in (i). These matrices are expanded in terms of $f_P[h(n)]$ and $a_P{}^{(1/2)}(R)$.

(iii) Diagrams for $f_P[h(n)]$ are all constructed according to the prescriptions (i)–(iv) in Sec. III (1b).

(iv) Before computing $a_P{}^{(1/2)}(R)$, we need to draw diagrams for $a_P{}^{(1)}(R)$. This will be accomplished according to the instructions appearing between (3.29) and (3.30).

(v) The desired coefficients $a_P{}^{(1/2)}(R)$ are computed by the asymptotic expansion (3.48) and (3.49).

(vi) Finally, the matrix $\mathbf{D}^{-1/2}\mathbf{S}[k|h]\mathbf{D}^{-1/2}$ or

$$\mathbf{D}^{-1/2}\mathbf{S}[k_1k_2|h_1h_2]\mathbf{D}^{-1/2}$$

is calculated by (3.3).

(vii) Repeat the process for all k. Thus, the calculation of $\langle\mathbf{f}\rangle$ or $\langle\mathbf{g}\rangle$, including the inverse of the overlap, is now completed.

(2) Calculation of the Ground-State Energy

So far, our aim was to calculate spin-wave spectra of the Heitler–London space. The wave function $\mathbf{\Psi}$ defined by (2.3), therefore, was a vector in the complete space G of spin waves, and the energy matrix had the dimensions of the space G. This matrix representation has introduced the matrices $\mathbf{A}^{(1/2)}(R)$, which are difficult to calculate.

If, on the other hand, we want to compute the ground state of the Heitler–London method by assuming a definite spin function Θ^0 for the system,[23] we can bypass the difficult calculation of $\mathbf{A}^{(1/2)}(R)$ and we need to compute the $\mathbf{F}$ matrices in one dimension, only.

The 2^N wave functions Ψ_i defined by (2.3) can be regarded as orthogonal and the overlap matrix $\mathbf{D}$ as diagonal. If $\mathbf{D}$ is not diagonal, there exists a unitary matrix $\mathbf{V}$ with which $\mathbf{D}$ can be brought into diagonal form such that

$$\mathbf{D}'=\mathbf{V}^\dagger\mathbf{D}\mathbf{V}=\int(\mathbf{\Psi}\mathbf{V})^\dagger(\mathbf{\Psi}\mathbf{V})d\tau. \qquad (4.1)$$

This implies that, instead of $\mathbf{\Psi}$, we should use the orthogonal wave functions $\mathbf{\Psi}\mathbf{V}$ defined by

$$\mathbf{\Psi}\mathbf{V}=(N!)^{-1/2}\sum_P(-1)^PP^\tau X(\mathbf{r}_1,\mathbf{r}_2,\cdots,\mathbf{r}_N)\times P^\sigma\mathbf{\Theta}(\sigma_1,\sigma_2,\cdots,\sigma_N)\mathbf{V}, \qquad (4.2)$$

and, instead of $\mathbf{\Theta}$, spin functions $\mathbf{\Theta}\mathbf{V}$ should be used as basis.

Use of the diagonal matrix $\mathbf{D}$ in (2.26) and (2.27) leads to

$$\langle f\rangle_{ii}=\sum_h\langle h|f(\mathbf{r}_h)|h\rangle S[h|h]_{ii}D_{ii}{}^{-1}+\sum_h\sum_k{}'\langle k|f(\mathbf{r}_h)|h\rangle S[k|h]_{ii}D_{ii}{}^{-1}, \qquad (4.3)$$

and

$$\langle g\rangle_{ii}=\tfrac{1}{2}\sum_{h_1}\sum_{h_2}{}'\sum_{k_1}\sum_{k_2}{}'\langle k_1k_2|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle\times S[k_1k_2|h_1h_2]_{ii}D_{ii}{}^{-1}, \qquad (4.4)$$

where $S[k|h]_{ii}D_{ii}{}^{-1}$ and $S[k_1k_2|h_1h_2]_{ii}D_{ii}{}^{-1}$ are diagonal elements of $\mathbf{F}[k|h]$ and $\mathbf{F}[k_1k_2|h_1h_2]$. This shows that, to calculate $\langle f\rangle_{ii}$ and $\langle g\rangle_{ii}$, we need to compute the $\mathbf{F}$ matrices only.

The overlap matrices $\mathbf{D}$ and $\mathbf{S}$ introduced by (2.7) and (2.18) can be regarded as if they are one dimensional. Hence matrices $\mathbf{F}$ and $\mathbf{X}$ introduced in Sec. III are all one dimensional and $\mathbf{U}(P)$ is a number defined by (2.6) where $i=j$. The description of drawing diagrams of the $\mathbf{F}$ matrices in Sec. III (1b) is now applied to this "one dimensional" case, and the calculation will be simplified considerably.

(3) Intra-Atomic Terms

As we have remarked in the end of Sec. I, our method can be applied to a case where each of the atoms carries more than one electron. We need to make only two short remarks for this case.

Since atomic orbitals centered at a nucleus are orthogonal to each other, overlap integrals between them vanish and we need to draw lines between those belonging to different atoms. It is convenient, therefore,

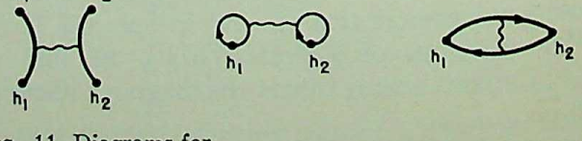

FIG. 11. Diagrams for $\langle k_1k_2|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle$, $\langle h_1h_2|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle$ and $\langle h_2h_1|g(\mathbf{r}_{h_1}\mathbf{r}_{h_2})|h_1h_2\rangle$.

[23] For a ferromagnet or an ionic crystal with closed-shell structure, the spin function for the ground state is known and we can use this simplified method without introducing further approximations. For any other type of ground state, we have to assume a model function Θ^0 for the spins to compute $\mathbf{U}(P)$, since the exact function Θ is not known. This introduces an additional approximation to the wave function Ψ defined by (2.3). In (2.3), we have specified the product Λ of atomic orbitals, but Θ can, in principle, be obtained by solving the spin Hamiltonian of the type (1.2).

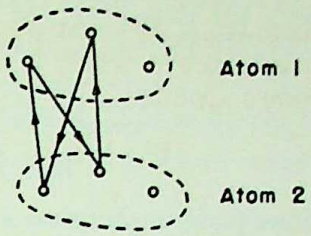

FIG. 12. An example of diagrams for arrays of many-electron atoms.

to group electrons belonging to a single atom and draw lines only between groups as is shown in Fig. 12. Of course *heavy* lines introduced in Figs. 10 and 11 representing interactions can connect electrons belonging to one atom.

The second remark concerns the case where two electrons occupy the same orbital with up and down spins. Here the overlap matrix $\mathbf{D}$ no longer has an inverse when the entire space G is considered. As we have discussed in Appendix B of paper I, however, there is a smaller space in which $\mathbf{D}^{-1}$ exists and our method can be used without any further difficulty. The smaller space is in fact a complete space of spin wave spectra for this case. We also do not need to consider $N!$ permutations but take one out of those generated from each other by simply permuting electrons in the same orbitals. For example, we need to consider only one of the diagrams in Fig. 13 when h_1 and h_2 are the same atomic orbital. Detailed discussion of such techniques will be found elsewhere[24] and therefore we shall not discuss it any further.

ACKNOWLEDGMENTS

In the course of developing the present work, the author has received great benefits from numerous communications with Dr. C. Herring. In fact, Dr. C. Herring has originally suggested the theorem described in the Appendix. Thanks are due to Dr. T. L. Gilbert for many discussions.

APPENDIX: EXPANSION OF $(1+\mathbf{X}[h(n)])^{-1}$

In this Appendix, we shall discuss the convergence of the expansion (3.14) or (3.10). First, it will be shown that, if the inequality

$$\epsilon=\sum_P |x_P[h(n)]|<1 \tag{A1}$$

is valid, the series (3.14) converges.

Both sides of (3.14) can be expanded in terms of $\tilde{\mathbf{U}}(P)$ and it will be found that

$$f_P[h(n)]=\delta_{EP}-(x[h(n)])_P+(x[h(n)]^2)_P-\cdots, \tag{A2}$$

where

$$(x[h(n)]^m)_P = \sum_{Q_1}\cdots\sum_{Q_{m-1}} x_{Q_1}[h]x_{Q_2Q_1^{-1}}[h]\cdots x_{PQ_{m-1}^{-1}}[h]. \tag{A3}$$

Taking the sum of absolute values of $(x[h(n)]^m)_P$, we find that

$$\sum_P |(x[h(n)]^m)_P| \leqslant [\sum_Q |x_Q[h(n)]|]^m=\epsilon^m. \tag{A4}$$

Inserting (A4) into (A2), we obtain

$$f_P[h(n)]\leqslant \delta_{EP}+\epsilon+\epsilon^2+\cdots=\delta_{EP}+\epsilon(1-\epsilon)^{-1}. \tag{A5}$$

and also

$$\sum_P |f_P[h(n)]| \leqslant (1-\epsilon)^{-1}. \tag{A6}$$

These results prove the original statement. If we truncate the series after the mth term of (3.14), errors in $f_P[h(n)]$ and $\mathbf{F}[h(n)]$ will both be smaller than $\epsilon^m(1-\epsilon)^{-1}$.

In the forthcoming paper, we shall introduce the theorem that the sum L_n of absolute values of the expansion coefficients $f_P[h(n)]$ is bounded as

$$[1+O(\Delta\Delta_0)]^{-n}\leq L_n\leq[1-O(\Delta\Delta_0)]^{-n}, \tag{A7}$$

where

$$L_n=\text{max on } h\text{'s of } \sum_P |f_P[h_1\cdots h_n|h_1\cdots h_n]|, \tag{A8}$$

$$\Delta=\text{max on } h \text{ of } \sum_{j\neq h} |\langle j|h\rangle|, \tag{A9}$$

$$\Delta_0=\text{max of } |\langle j|h\rangle|, \tag{A10}$$

and

$$O(\Delta\Delta_0)=\frac{\Delta\Delta_0}{1-\Delta}\left\{1+\frac{1}{4}\frac{4\Delta\Delta_0}{(1-\Delta)^2}+\frac{1.3}{4.6}\left[\frac{4\Delta\Delta_0}{(1-\Delta)^2}\right]^2+\cdots\right\}. \tag{A11}$$

Here we shall show briefly how this theorem can be proved. The expansion formula (2.23) of matrices S leads to

$$\mathbf{F}[\cdots h_n|\cdots h_n] = \mathbf{F}[\cdots h_nh_{n+1}|\cdots h_nh_{n+1}] + \sum_h{}^{(n+1)}\langle h|h_{n+1}\rangle \mathbf{F}[\cdots h_nh|\cdots h_nh_{n+1}], \tag{A12}$$

and

$$\mathbf{F}[\cdots h_{n+1}|\cdots h_n] = \langle h_n|h_{n+1}\rangle \mathbf{F}[\cdots h_{n+1}h_n|\cdots h_nh_{n+1}] + \sum_h{}^{(n+1)}\langle h|h_{n+1}\rangle \mathbf{F}[\cdots h_{n+1}h|\cdots h_nh_{n+1}], \tag{A13}$$

where $\cdots$ in the square brackets indicates $h_1h_2\cdots h_{n-1}$. When the matrices $\mathbf{F}$ in (A12) are expanded in terms of f_P and $\tilde{\mathbf{U}}(P)$, the equation is converted into a set of $N!$ equations for f_P as follows:

$$f_P[\cdots h_n|\cdots h_n] = f_P[\cdots h_nh_{n+1}|\cdots h_nh_{n+1}] + \sum_h{}^{(n+1)}\langle h|h_{n+1}\rangle f_P[\cdots h_nh|\cdots h_nh_{n+1}], \tag{A14}$$

[24] M. Kotani *et al.*, Ref. 18, also see T. Arai, J. Phys. Soc. Japan 18, 718 (1963).

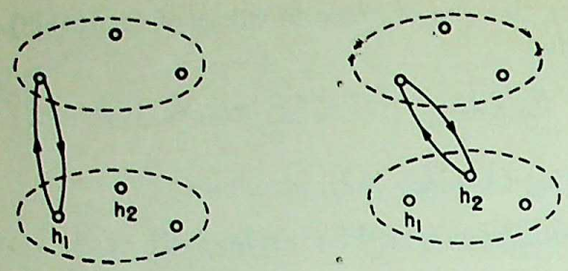

FIG. 13. An example of a case of two equivalent diagrams. Here electrons h_1 and h_2 occupy the same atomic orbital with up and down spins. We need to consider only one of them.

for all P. By taking absolute values of each term in (A14) and summing over $N!$ permutations P, we obtain that

$$\sum_P |f_P[\cdots h_n|\cdots h_n]|$$

$$\leqslant \sum_P |f_P[\cdots h_n h_{n+1}|\cdots h_n h_{n+1}]| + \sum_h{}^{(n+1)} |\langle h|h_{n+1}\rangle| \times \sum_P |f_P[\cdots h_n h|\cdots h_n h_{n+1}]| . \quad \text{(A15)}$$

Since the above inequality is valid for any h's, we find that

$$L_n \leq L_{n+1} + \Delta l_{n+1}{}^1, \quad \text{(A16)}$$

where

$$l_n{}^1 = \max \text{ on } h\text{'s of } \sum_P |f_P[\cdots h_n h|\cdots h_n h_{n+1}]| , \quad \text{(A17)}$$

and h is not involved among $h_1 \cdots h_n h_{n+1}$.

Similarly transposition of (A12) leads to

$$L_{n+1} \leq L_n + \Delta l_{n+1}{}^1, \quad \text{(A18)}$$

and, from (A13), we also find that

$$l_n{}^1 \leq \Delta_0 L_{n+1} + \Delta l_{n+1}{}^1. \quad \text{(A19)}$$

If the relation

$$l_{n+1}{}^1 \leq [O(\Delta\Delta_0)/\Delta] L_{n+1} \quad \text{(A20)}$$

is valid for any n, the present theorem will be proved. In fact, use of (A20) in (A16) and (A18) leads to

$$[1+O(\Delta\Delta_0)]^{-1} L_n \leq L_{n+1} \leq [1-O(\Delta\Delta_0)]^{-1} L_n \quad \text{(A21)}$$

for any n. If n becomes zero, the matrix $\mathbf{F}$ becomes $\mathbf{D}\mathbf{D}^{-1}=1$ and $L_0=1$. Inserting this result in (A21) when $n=0$, we find the desired bound for L_1. Repeated use of (A21), by increasing n one by one, will lead to the expression (A7).

The relation (A20) will be proved by an inductive unraveling process as follows. When $n=N-1$, Eq. (A19) becomes

$$l_{N-1}{}^1 \leq \Delta_0 L_N, \quad \text{(A22)}$$

since the second term on the right of (A13) vanishes. From (2.19), it is clear that $\mathbf{F}[\cdots h_{N-1}|\cdots h_{N-1}] = \mathbf{F}[\cdots h_{N-1}h_N|\cdots h_{N-1}h_N]$, and hence $L_{N-1}=L_N$. This implies that (A22) is written as

$$l_{N-1}{}^1 \leq \Delta_0 L_{N-1}. \quad \text{(A23)}$$

Since Δ_0 is smaller than $O(\Delta\Delta_0)/\Delta$, the above relation proves the inequality (A20) when $n=N-1$.

Let us assume that (A20) is valid for $n=n_0$. Use of (A20) in (A18) and (A19) yields

$$[1-O(\Delta\Delta_0)] L_{n_0+1} \leq L_{n_0} \quad \text{(A24)}$$

and

$$l_{n_0}{}^1 \leq [\Delta_0 + O(\Delta\Delta_0)] L_{n_0+1}. \quad \text{(A25)}$$

From (A24) and (A25), we obtain

$$l_{n_0}{}^1 \leq [\Delta_0 + O(\Delta\Delta_0)][1-O(\Delta\Delta_0)]^{-1} L_{n_0}. \quad \text{(A26)}$$

Inserting the expression (A11) for $O(\Delta\Delta_0)$ into (A26), we will find that the coefficient

$$[\Delta_0 + O(\Delta\Delta_0)][1-O(\Delta\Delta_0)]^{-1}$$

on the right of (A26) is equivalent to $O(\Delta\Delta_0)/\Delta$. Hence (A20) is also valid for $n=n_0-1$. This shows that (A20) is valid for any n. Thus the present theorem is proved.

Use of the inequality (A7) in (3.9) leads to

$$\epsilon = \sum_P |x_P[h]| < \Delta^2(1-O(\Delta\Delta_0))^{-1} + \Delta^3(1-O(\Delta\Delta_0))^{-2} + \Delta^4(1-O(\Delta\Delta_0))^{-3} + \cdots. \quad \text{(A27)}$$

Therefore, the inequality (A1) is satisfied when $n=1$ and the expansion (3.10) is valid as long as Δ is small as compared with one.

Use of the inequality (A7) in (3.13) will lead in the case $n=2$ to the same conclusion and it will be found that the series (3.12) converges. If, on the other hand, n increases, the upper bound $(1-O(\Delta\Delta_0))^{-n}$ and ϵ increase indefinitely and therefore the expansion (3.14) is no longer valid. However, it will be found that, in calculating an expectation value $\langle \mathbf{f} \rangle$ or $\langle \mathbf{g} \rangle$, the matrix $\mathbf{F}[h(n)]$ appears in the form $S_{R_n}\mathbf{F}[h(n)]$, which vanishes when n increases indefinitely since

$$S_{R_n}\mathbf{F}[h(n)] < \Delta^n(1-O(\Delta\Delta_0))^{-n} \to 0 \quad \text{(A28)}$$

as long as Δ is small as compared with unity. Here R_n is a cyclic permutation with which electrons $h_1, h_2, \cdots, h_{n-1}, h_n$ are shifted to orbitals $h_2, h_3, \cdots, h_n, h_1$ and S_{R_n} is an overlap of the type $\int R_n \Lambda^* \Lambda dv$.

PHYSICAL REVIEW VOLUME 134, NUMBER 4A 18 MAY 1964

Thomas-Fermi Theory of the Atom as a Solution of the Density-Matrix Hierarchy*†

NANDOR L. BALAZS
State University of New York at Stony Brook, Stony Brook, New York

(Received 15 July 1963; revised manuscript received 16 December 1963)

In this paper we show that the Thomas-Fermi (TF) theory for a neutral atom is the zeroth-order solution of the full N-body problem if (a) the following assignments of smallness are made: $N^{-1/3}=\epsilon$, $e=e_0\epsilon^{3/2}$, $m=m_0/\epsilon^2$, $\epsilon\to 0$; (b) the singlet density matrix in the x representation, $\rho_1(x',x)$, is a fast oscillating function of the off-diagonal elements, of the type $\sin[(x'-x)/\epsilon]$; (c) the higher-order density matrices are determinants of the singlet density matrix as $\epsilon\to 0$. The higher-order approximations, however, cannot be obtained by a simple power-series expansion in ϵ, since the solutions contain ϵ in a nonanalytical fashion. Taking into account the exclusion principle to zeroth order in ϵ, and solving the equations of motion for the singlet density matrix to the next-higher-(second-) order approximation, we obtain the equations found by Kompaneets and Pavlovskii, and Baraff and Borowitz. These contain the Dirac and Weizsäcker corrections. Finally, we offer some conjectures about possible improvements of the approximation scheme.

1. INTRODUCTION

THE Thomas-Fermi (TF) model of the atom is the most successful attempt to account in simple terms for the characteristic features of complex atoms.

Many papers deal with the application of this theory to different systems, and with its heuristic improvements.[1] However, relatively little attention has been paid to the *systematic construction* of a statistical theory of complex atoms. The original derivation of the TF model was heuristic, and it is hard to tell what are the approximations involved, and how one can improve upon them. Such a more systematic treatment can be obtained in two different ways: expansion in terms of a small parameter, or a variational treatment.

There were three major efforts utilizing an expansion technique, all starting essentially from the Hartree-Fock (HF) scheme, expanding (1) in Planck's constant, $\hbar$[2]; (2) in inverse powers of the number of electrons (N) in the atom[3]; (3) in the off-diagonal elements of the density matrix.[4]

There are, however, two major difficulties associated with any of these attempts. First, it is not clear in what sense one should take h, $1/N$, or the magnitude of the off-diagonal elements of the density matrix as small. It cannot mean that in the limit when the chosen parameter tends to zero we obtain a rigorous solution, since if h goes to zero the exclusion principle must become inoperative, and if N goes to infinity the atom acquires an infinite radius. Clearly, a coupled limiting process is involved and one has to determine which parameters tend to zero and at what rate. Second, starting with the HF scheme the following objections are left unanswered. (A) One can show at most in this way that in some limit the TF model is as good as the HF scheme; actually it might turn out to be better. (B) We may indeed find that in some limit we obtain from the HF scheme the TF solutions; it also may happen that in this limit the HF scheme itself is a very poor approximation to the actual N-body problem. (C) If we intend to improve systematically the TF model starting with the HF scheme we have no assurance that the correction terms found are not of the same order of magnitude as the error committed by starting with the HF scheme in the first place.

Another very popular approach makes use of the fact that the HF scheme can be obtained as the Euler equations of a variational principle.[5] Write out the energy of the atom as a functional of the one-particle density matrix. Stipulate as auxiliary conditions that the one-particle density matrix or singlet density matrix normalized to N has a fixed trace and is idempotent. The Euler equations of this variational problem give the HF scheme. One is then tempted to go into this variational problem with a suitable trial function and determine its best form in the usual manner. However, a very serious trouble occurs (apart from the fact that the accuracy of the approximation cannot be assessed). The one-particle density matrix and hence the trial function has to obey an additional condition which cannot be given a simple mathematical form without solving the whole N-body problem: The singlet density matrix is to be of the form which can be obtained by integrating $N-1$ times the N-particle density matrix. While it is obvious that for the trial function this implies "smoothness" in some sense, it is by no means clear how to formalize this condition. Without satisfying it, however, the variational approximations obtained can be void of any physical meaning.

For this reason we decided to investigate the possibility of an expansion in terms of a small parameter. Of course, it is possible that the wisest approach will eventually combine both methods. Throughout this paper we confine our interest to neutral atoms.

2. OUTLINE

Our plan will be as follows: First, we find the small parameter involved; then we show heuristically that in the limit when this parameter goes to zero the TF model is to be expected to give a rigorous solution of the N-body problem in question, and we assess the orders of magnitude of the different correction terms usually appended to the original TF theory (see Ref. 1). Then we start from first principles, set up the appropriate equations and symmetry conditions and show that indeed to zeroth order in this parameter we *rigorously* obtain the conventional TF theory. Next we shall show that the actual solutions are nonanalytical in the small parameter, hence the next approximation cannot be obtained by a simple power-series expansion. If, notwithstanding we attempt to do this in an inconsistent fashion, by improving the solutions of the differential equations to the next order, while satisfying the exclusion principle only to zeroth order, we obtain the usual exchange (Dirac) and inhomogeneity (Weizsäcker) correction. This will demonstrate, then, that these correction terms are probably not quite correct, and that for a consistent improvement over the original TF results it is necessary to devise an approximation method which can be used if the solution is nonanalytical in the small parameter.

3. THE SMALL PARAMETER

Characteristic Quantities

To construct the small parameter we shall first need the characteristic quantities involved in the TF theory. A short, dimensional analysis will accomplish this. Assume that the electron cloud around the nucleus is confined to a volume L^3; let this be accomplished entirely by an electrostatic potential U in cooperation with the exclusion principle. (This, of course, may not be possible, but if it is, the argument runs as follows.) Let there be N electrons confined; denote the maximum momentum at a given point inside L^3 by p_0, the mass and charge of an electron by m and e. Then, from Poisson's equation

$$U/L^2 \approx e^2 N/L^3, \tag{1}$$

since the density is $\approx N/L^3$. The condition that p_0 is the maximum momentum reads

$$p_0^2/2m \approx U. \tag{2}$$

The exclusion principle stipulates that each phase cell should contain at most one electron with a given spin; the condition that the atom be in its lowest energy state requires that no phase cell having momentum less than p_0 be empty. The two conditions together give

$$p_0^3/h^3 \approx N/L^3. \tag{3}$$

From (1) and (2) it follows that

$$U \approx Ne^2/L \approx p_0^2/2m, \tag{4}$$

while (2) and (3) give

$$p_0 L \approx hN^{1/3}, \quad L \approx a/N^{1/3}; \quad (a = \text{Bohr radius}).$$

Thus, we obtained the three characteristic quantities p_0, U, and L as functions of N. (Observe that the $1/N^{1/3}$ dependence is connected with the three-dimensional nature of the problem. One- and two-dimensional atoms, composed of charged sheets, or charged filaments, respectively, would have characteristic quantities with a different N dependence.)

Assessment of the TF Approximation

Suppose you have solved the TF differential equations. How can you tell whether the answer is, or is not, a correct solution of the full N-body problem? The problem is not trivial since the TF solutions do not furnish immediately the wave function or the density matrix of the N-body problem. There are two avenues open. First, the TF solution gives the number of electrons with given positions and momenta; from this we may construct in the well-known manner the singlet density matrix. In turn, from this we may construct the density matrix of the whole system, provided further assumptions are made about the relation of the singlet density matrix to the complete density matrix. Once this is obtained, we may verify how far this matrix obeys the equations of motion and the exclusion principle. This method has the advantage that both the satisfaction of the equations of motion and the exclusion principle can be tested. However, from the TF theory it is not immediately clear what are those further assumptions necessary to construct the density matrix from the singlet density matrix. For this reason we choose the second approach. This will test to a certain degree the satisfaction of the equations of motion, but not that of the exclusion principle. The TF theory is semiclassical theory, consequently it assumes that the local de Broglie wavelength varies slowly from point to point. Is this assumption satisfied everywhere by the solution? If we plot according to the TF theory the number of electrons contained in a spherical shell of radius r and unit-thickness around the nucleus, $n(r)4\pi r^2$, where $n(r)$ is the density at the point r, we find a function as shown in Fig. 1. For small values of r the function starts as $\sqrt{r}$, it has a single maximum at about $a/N^{1/3} = L$, where a is the Bohr radius and N is the number of electrons in the neutral atom; for large values of r the function goes to zero as $r^{-3/2}$. Associated with this density there is an electric potential energy $U(r)$ which goes as Ne^2/r if $r \ll L$, and as e^2a^3/r^4 for $r \gg L$. Finally we can define a local momentum

Digitized by Arya Samaj Foundation Chennai and eGangotri

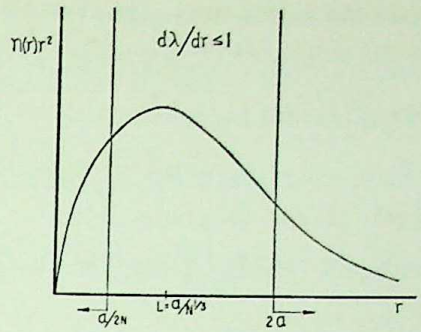

FIG. 1. Qualitative graph showing number of electrons on a shell of radius r as given by the Thomas-Fermi theory. Approximation good within region where the rate of change of the local de Broglie wavelength is small.

$p(r)=[2m(U-E)]^{1/2}$. The validity of the semiclassical approximation requires that $d\lambda\!\!\!^{-}/dr\ll 1$, with $\lambda\!\!\!^{-}=\hbar/p$. Write $d\lambda\!\!\!^{-}/dr=\lambda\!\!\!^{-}d\ln p/dr$; put approximately $\ln p\sim\frac{1}{2}\ln U$ +const with $U\sim r^{-n}$; $n=1$, $r\ll L$, $n=4$, $r\gg L$. This gives $\lambda\!\!\!^{-}n/2r\ll 1$ as our condition. The latter is certainly violated if $\frac{1}{2}n(\lambda\!\!\!^{-}/r)\equiv\frac{1}{2}n(\hbar/pr)$ is equal to 1. There are two roots to this equation: $a/2N$ and $2a$. Between then lies the maximum of the charge distribution (see Fig. 1). Hence we may say that for the majority of the electrons the TF solution is a good approximation to the Schrödinger equation.

Is the exclusion principle satisfied? Seemingly yes, since the solution was so constructed that one, or no, electrons of a given spin occupy each phase cell. However, this elementary form of the exclusion principle does not hold any longer if density gradients are present within the system and a more complicated condition has to be satisfied in its place. The derivation of this condition requires more preparation. In Sec. 7 we will show what this condition is, and how well the TF solutions satisfy it.

Construction of the Small Parameter

Now let us find the small parameter of the problem. Obviously we seek a limiting process such that in this limit the equations and the exclusion principle should be satisfied everywhere, while keeping the characteristic features of the solution unchanged. The usual solution is believed to be correct for $a/2N<r<2a$. The characteristic features of the atom represented by this solution are the radius of the atom L, and the energy per electron Ne^2/L. (According to the virial theorem for charged particles the kinetic and the potential energies, hence the total energy have the same order of magnitude.) Thus we seek a limiting process where a/N goes to zero, a goes to infinity, while L and Ne^2/L is being kept fixed. If we keep h fixed, this can only be accomplished by letting N go to infinity, e going to zero as $N^{-1/2}$, and m going to infinity as $N^{2/3}$, thus $N\to\infty$, $e=e_0N^{-1/2}$, $m=m^0N^{2/3}$, e_0, m_0 being the original values of e and m. In this limit then the equations are satisfied everywhere, and, as we shall show, so is the exclusion principle. Formally, we may consider h as variable, instead of m. Then the same result can be obtained by letting h go to zero as $N^{-1/3}$, i.e., $N\to\infty$, $e=e_0N^{-1/2}$, $\hbar=\hbar_0N^{-1/3}$. Since we are employing a limiting process in which N tends to infinity, the question arises as to the computation of extensive quantities. The rule is as follows. First, compute the value of the associated intensive quantity in the limit as N tends to infinity. (E.g., if you are interested in the total energy, compute first the energy per particle as N tends to infinity.) Next, multiply this quantity by the actual number of particles.

Finally, we would like to stress that this selection of a small parameter was specifically designed for the purposes of the TF problem in such a manner as to make the semiclassical approximation valid for the entire atom in the zeroth order. For this reason it has less generality than the usual method where one treats the difference between the actual and the self-consistent potential as small; on the other hand, because of the more specific nature of the choice it tells us more about the approximation.

Orders of Magnitude of the Correction Terms

The usual exchange correction to the energy per electron is given by $\approx e^2p_0/h$, i.e., the Coulomb interaction between two electrons at a de Broglie wavelength h/p_0 apart. The ratio of this quantity to p_0^2/m is of the order $1/N^{2/3}=\epsilon^2$. The inhomogeneity correction to the energy per electron is given by $\approx e^2a[\text{grad}\log n]^2$; its ratio to p_0^2/m is again ϵ^2. Thus, if we accept ϵ as a relevant small parameter, these terms are correction terms of second-order smallness. The Fermi-Amaldi correction, replacing N with $N-1$, gives obviously a correction of order $1/N=\epsilon^3$, a term of third-order smallness. Finally, the correlation correction, introduced by Gombás, $\sim e^2n^{1/3}/(an^{1/3}+10^{-1})$ is of the order $\epsilon^4p_0^2/m$.

4. THE BASIC EQUATIONS

In this section we derive the basic equations of the theory, the equations of motion for the reduced density matrices. We shall work with density matrices for the following reason. The basic aim is to set up expressions in which the coordinates of one or two electrons appear only, the coordinates of the other electrons being integrated out. However, the state of one electron interacting with the others cannot be described by a wave function (not being a pure state) while it can be described by a density matrix; hence the latter is the proper tool.

Envisage a neutral atom with N electrons, and a fixed nucleus with charge number N. The Hamiltonian of the system is given by

$$H=\sum_{r=1}^{N}(K_r+V_r)+\sum_{1\leqslant i<j\leqslant N}\Phi(x_i-x_j),$$

$$K_r=-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x_r\partial x_r};\quad \Phi(x)=e^2/|x|;\qquad (5)$$

$$V_r=-N\Phi(x_r).$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The state of the system is described by the antisymmetrical wave function $\Psi(x_1,\cdots,x_N,t)$. (In principle the spin coordinates should also be included; however, the absence of spin variables in the Hamiltonian has the effect that the existence of the spin coordinates changes only certain factors in the equations. These can be put in any time, practically by inspection. Hence, for simplicity, we omit them throughout the paper, and shall point out when necessary which terms acquire different factors.) The density matrix for the whole atom in a pure state is defined as

$$\rho_N(x_1',\cdots,x_N';\,x_1,\cdots,x_N,t) = \Psi^*(x_1',\cdots,x_N',t)\Psi(x_1,\cdots,x_N,t). \quad (6)$$

Differentiate (6) with respect to t and express the time derivative of Ψ through the Schrödinger equation. We obtain

$$i\hbar\partial\rho_N/\partial t=(H-H')\rho_N, \quad (7)$$

where H' acts only on the x' variables. (This equation holds true even if ρ_N does *not* represent a pure state.)

Define now the reduced density matrices ρ_s by

$$\rho_s(x_1',\cdots,x_s',x_1,\cdots,x_s,t)=\int d^3x_{s+1}\cdots \times\int d^3x_N\rho_N(x_1',\cdots,x_s',x_{s+1},\cdots,x_N;\,x_1,\cdots,x_s,\cdots,x_{s+1},\cdots,x_N,t). \quad (8)$$

Contrary to the usual definition we do not include any combinatorial factors in the definition of the ρ_s. Consequently, all the density matrices $\rho_s(s=1, 2, \cdots, N)$ are normalized to unity. The reason for this departure is due to the fact that an N-dependent normalization would make a limiting process $N\to\infty$ more unpleasant. In Eq. (7) put $x_{s+1}'=x_{s+1}$, $x_{s+2}'=x_{s+2}$, $\cdots$, $x_N'=x_N$, and integrate over these variables. We get

$$i\hbar\frac{\partial\rho_s}{\partial t}=\sum_{r=1}^{s}[(K_r-K_r')+(V_r-V_r')]\rho_s + \sum_{1\leqslant i<j\leqslant s}[\Phi(x_i-x_j)-\Phi(x_i'-x_j')]\rho_s+(N-s) \times\sum_{1\leqslant i\leqslant s}\int d^3x_{s+1}[\Phi(x_i-x_{s+1})-\Phi(x_i'-x_{s+1})] \times\rho_{s+1}(x_1',\cdots,x_s',x_{s+1};\,x_1,\cdots,x_s,x_{s+1}). \quad (9)$$

If the atom is in a stationary state, the time derivative is equal to zero. The exclusion principle is incorporated in the symmetry conditions on the ρ_s; an interchange of any two primed coordinates, reproduces the function with the opposite sign. (Since we shall discuss stationary states we may choose, if we so desire, all density matrices real.)

Define now the new dimensionless variables

$$y_k=(x_k'+x_k)/2L,\ z_k=(x_k'-x_k)/L,\ (k=1,\ 2,\ \cdots,\ N),$$

and the new dimensionless functions of these variables

$$\rho_s(x_1',\cdots,x_s';\,x_1,\cdots,x_s)=R_s(y_1,\cdots,y_s;\,z_1,\cdots,z_s)/L^{3s}.$$

Equation (8) becomes

$$R_s(y_1,\cdots,y_s;\,z_1,\cdots,z_s) =\int d^3y_{s+1}R_{s+1}(y_1,\cdots,y_s,y_{s+1};\,z_1,\cdots,z_s,0).$$

Write $\Phi(x)=e^2\phi/L$ and observe that $K_r(x)-K_r(x')=h^2/mL^2(\partial^2/\partial y_r\partial z_r)$. Substitute all these back in Eq. (9), and divide by Ne^2/L; we obtain (putting $\partial\rho_s/\partial t=0$)

$$\sum_{1\leqslant i\leqslant s}\{(a/LN)(\partial^2/\partial y_i\partial z_i) +[\phi(y_i+z_i/2)-\phi(y_i-z_i/2)]\}R_s -1/N\sum_{1\leqslant i<j\leqslant s}\{\phi[y_i-y_j+(z_i-z_j)/2] -\phi[y_i-y_j-(z_i-z_j)/2]\}R_s-(1-s/N) \times\sum_{1\leqslant i\leqslant s}\int d^3y_{s+1}[\phi(y_i-y_{s+1}+z_i/2) -\phi(y_i-y_{s+1}-z_i/2)]R_{s+1}(y_1,\cdots,y_s,y_{s+1};\,z_1,\cdots,z_s,0)=0.$$

Introduce $N=\epsilon^{-3}$ and $L/a=\epsilon$ according to the previous section. The first term acquires the factor ϵ^2. Absorb one ϵ in the new variable $\zeta=z/\epsilon$, and divide with the other ϵ. This way finally we obtain the set of equations, ϵ^{-3} in number, we shall work with:

$$\sum_{1\leqslant i\leqslant s}\left\{\frac{\partial^2}{\partial y_i\partial\zeta_i}+(1/\epsilon)[\phi(y_i+\epsilon\zeta_i/2)-\phi(y_i-\epsilon\zeta_i/2)]\right\} \times R_s(y_1,\cdots,y_s;\,\epsilon\zeta_1,\cdots,\epsilon\zeta_s|\,\epsilon) -\epsilon^3\sum_{1\leqslant i<j\leqslant s}(1/\epsilon)\{\phi[y_i-y_j+\epsilon(\zeta_i-\zeta_j)/2] -\phi[y_i-y_j-\epsilon(\zeta_i-\zeta_j)/2]\}R_s(y_1,\cdots,y_s;\, \epsilon\zeta_1,\cdots,\epsilon\zeta_s|\,\epsilon)-(1-\epsilon^3s)\sum_{1\leqslant i\leqslant s}\int d^3y_{s+1}(1/\epsilon) \times[\phi(y_i-y_{s+1}+\epsilon\zeta_i/2)-\phi(y_i-y_{s+1}-\epsilon\zeta_i/2)] \times R_{s+1}(y_1,\cdots,y_s,y_{s+1};\,\epsilon\zeta_1,\cdots,\epsilon\zeta_s,0|\,\epsilon)=0, \quad (s=1,\ 2,\ \cdots,\ 1/\epsilon^3). \quad (10)$$

Here we have explicitly indicated the fact that the R functions now can depend on ϵ in two different ways; first, due to the change of variables from z to ζ, and second, on account of the fact that originally ρ_s, and hence R_s, involved $N(=1/\epsilon^3)$ parametrically (since they were obtained from ρ_N or R_N by integration). We

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

rewrite Eq. (10) in a more transparent form. Introduce the difference operator D_r; it acts on the argument y_r of a function F to which it is applied;

$$D_rF(y_1,y_2,\cdots,y_r,\cdots) \\ -(1/\epsilon)[F(y_1,y_2,\cdots,y_r+\epsilon\zeta_r/2,\cdots) \\ -F(y_1,y_2,\cdots,y_r-\epsilon\zeta_r/2,\cdots)].$$

Thus in the limit $\epsilon\to 0$ it gives $\zeta_r\cdot\partial F/\partial y$. Equation (10) reads now as

$$\sum_{1\leqslant i\leqslant s}\left[\frac{\partial^2}{\partial y_i\partial\zeta_i}+D_i\phi(y_i)\right]f_s \\ -\epsilon^3\sum_{1\leqslant i<j\leqslant s}[(D_i+D_j)\phi(y_i-y_j)]f_s \\ -(1-\epsilon^3 s)\sum_{1\leqslant i\leqslant s}\int d^3y_{s+1}\int d^3\zeta_{s+1}\delta(\zeta_{s+1}) \\ \times[(D_i+D_{s+1})\phi(y_i-y_{s+1})]f_{s+1}=0. \quad (11)$$

For sake of symmetry we introduced the delta function $\delta(\zeta_{s+1})$ and an additional integration over ζ_{s+1}. The functions f_s are defined as:

$$R_s(y_1,\cdots,y_s;\,\epsilon\zeta_1,\cdots,\epsilon\zeta_s|\,\epsilon)=f_s(y_1,\cdots,y_s;\,\zeta_1,\cdots,\zeta_s|\,\epsilon).$$

These equations must be supplemented by conditions on the f_s functions. These are the recursion relations:

$$f_s(y_1,\cdots,y_s;\,\zeta_1,\cdots,\zeta_s|\,\epsilon)=\int d^3y_{s+1}f_{s+1} \\ \times(y_1,\cdots,y_s,y_{s+1};\,\zeta_1,\cdots,\zeta_s,0|\,\epsilon); \quad (12)$$

the normalization conditions:

$$\int d^3y_1\cdots\int d^3y_s f_s(y_1,\cdots,y_s;\,0,\cdots,0|\,\epsilon)=1; \quad (13)$$

the symmetry conditions:

$$f_s\left(\frac{x_1'+x_1}{2L},\cdots,\frac{x_s'+x_s}{2L};\frac{x_1'-x_1}{\epsilon L},\cdots,\frac{x_s'-x_s}{\epsilon L}\middle|\,\epsilon\right) \quad (14)$$

must change its sign upon interchange of x_k and x_r, or x_k' and x_r', $k\neq r$.

We wrote out the latter in terms of the variables x, x', to simplify the conditions. Equations (12) and (13) are not independent. If we define $f_0=1$, the normalization conditions are the consequence of (12) for $s=0$. Hence, in the future we need not mention (13) explicitly.

Then our aim is to solve the equation-system (11) for the set of f_s functions satisfying conditions (12), (13), and (14) in the limit $\epsilon\to 0$; moreover, if possible, to devise a scheme of successive approximations for small, nonzero ϵ. In addition we may require that the solution should give the lowest possible value for the mean energy per electron. In that case we seek the solution for the lowest energy state of the neutral atom. If the atom is at temperature $T=0$, we must require that ρ_N, or the associated f_N should represent a pure state as indicated by (6). [For nonzero temperatures all equations remain unchanged except for (6).] The purpose of the new variables y, z, and ζ is the following: Envisage $\rho_1(x',x)$ defined at the lattice points in the (x',x) plane, then the y, z labeling of these points corresponds to a 45° rotation, and a change in scales (see Fig. 2); y labels a distance along lines parallel to the diagonal, z the perpendicular distance from the diagonal. Since our limiting process shifts the problem in the semiclassical region, *the off-diagonal elements must decrease in size and oscillate fast*; thus only small values of z become of importance. For this reason we introduce the new variable $\zeta=z/\epsilon$, which amounts to introducing a new unit of length along the z axis, which is ϵ times the previous one, using thereby a yardstick more adapted to the problem. This is also evident from the fact that in terms of these variables the coefficients in the equation-system (11) *contain positive powers of* ϵ, *and as* $\epsilon\to 0$ *the coefficients become independent of* ϵ. (At this stage one could take the Fourier transform with respect to z or ζ, a natural step to do for oscillatory functions; this introduces the so-called Wigner functions. However, the general treatment seems to be simpler without this step, and consequently we shall formulate the theory in terms of the f functions, and will use Fourier transforms only as a tool to solve the resulting equations.)

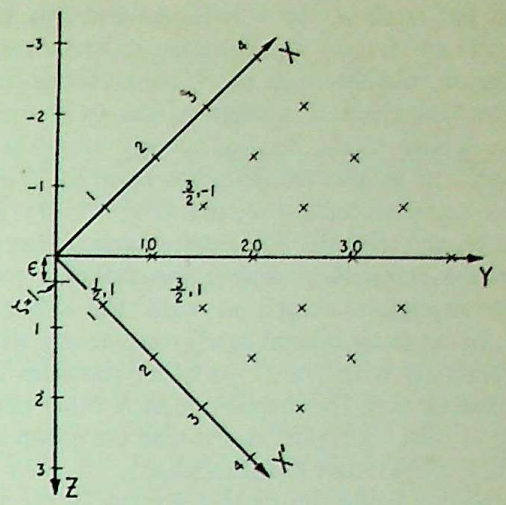

FIG. 2. Relation between old (x',x) and new (y,z) labeling of elements of singlet density matrix $\rho_1(x',x)$.

5. CHARACTERISTIC FEATURES OF THE EQUATION SYSTEM AND THE SUPPLEMENTARY CONDITIONS; NONANALYTICITY DIFFICULTIES

The solution of (11) subject to conditions (12), (13), and (14) is equivalent to the full, correct solution of the problem; in order to obtain an approximate solution we must study the characteristic features of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

problem for small ϵ. As ϵ tends to zero, in (11) all coefficients of f_s and f_{s+1} become independent of ϵ; moreover, we observe that there are no terms linear in ϵ, and two of the terms proportional to ϵ^3 disappear entirely. These terms have a simply physical interpretation. The set of s particles described by f_s interact with the external field [second term of (11)], with each other, and with the $N-s$ other particles; as ϵ tends to zero the interaction *within* the set of s particles becomes negligible compared with the other interactions, being proportional to ϵ^3; consistently with this the interaction with the $N-s$ other particles can be approximated with the interaction of N other particles. Because of this, the s particles within the group behave as if they would move independently of each other, their behavior being determined by the interaction of each with the particles outside the group. Thus we expect that up to and including order ϵ^2 the f_s functions should be expressible in terms of f_1. Thus the structure of the Eqs. (11) suggests that (a) using the variables y and ζ, f_s will depend only on positive powers of ϵ (this, of course, was just reason to introduce these variables); (b) there shall be no terms linear in ϵ; (c) up to ϵ^2, f_s shall be expressible in terms of f_1. Introduce now functions $f_s^{(k)}(y_1,\cdots,y_s,\zeta_1,\cdots,\zeta_s)$ *independent* of ϵ, where k denotes the order of the approximation. Then our expectations can be formulated in the expression

$$f_s(y_1,\cdots,y_s;\zeta_1,\cdots,\zeta_s|\,\epsilon)=\sum_{k=0}\epsilon^k f_s^{(k)}, \qquad (15)$$

with $f_s^{(0)}=F[f_1^{(0)}]$, $f_s^{(1)}\equiv 0$, $f_s^{(2)}=G[f_1^{(2)}]$; F and G are unknown functionals, independent of ϵ.

The following questions are to be faced: (a) Does (11) have solutions of this form at all; (b) if so, are these solutions compatible with the supplementary conditions; (c) if so, how to determine F and G together with $f_1^{(0)}$, $f_1^{(2)}$ from the equations and supplementary conditions? The difficulty we encounter in answering these questions is due to the fact that the introduction of the small parameter gives no clue as to the construction of the functions F and G, while the existence of the solutions will depend on this construction. Omitting in (11) the term containing the double sum on i and j, which is proportional to ϵ^3, we see that the equation contains only a sum of operators each acting on one set of y, ζ variables with a given index. This, then suggests that the functionals should simply be the product of their argument functions each carrying variables with a given index. Indeed, it is easy to show that one can find such solutions to (11) [see next section, Eq. (27)], however, they violate the symmetry conditions (4) for $s>1$, since they correspond to solutions which obey Boltzmann statistics.[6] It is natural that the symmetry condition will cause trouble if we use the variables y, ζ. In term of these variables it is *impossible to express the exclusion principle in an ϵ-independent way*. Thus the variables most suited for the discussion of the equations of motion are not so useful when it comes to express the conditions implied by the exclusion principle. Indeed the command: exchange x_1' and x_2', keep x_1, x_2 fixed, amounts to replacing y_1 with $\frac{1}{2}(y_1+y_2)+\frac{1}{4}\epsilon(\zeta_1-\zeta_2)$; y_2 with $\frac{1}{2}(y_1+y_2)-\frac{1}{4}\epsilon(\zeta_1-\zeta_2)$; ζ_1 with $(y_2-y_1)/\epsilon+\frac{1}{2}(\zeta_1+\zeta_2)$; ζ_2 with $-(y_2-y_1)/\epsilon+\frac{1}{2}(\zeta_1+\zeta_2)$. This explicit appearance of ϵ casts doubt on the possibility of expressing $f_s(|\,\epsilon)$ as a power series in ϵ with only positive powers, if the symmetry condition is to be satisfied. Indeed, for $s=2$ the symmetry condition reads

$$\begin{aligned}f_2(y_1,y_2;\zeta_1,\zeta_2|\,\epsilon)&\\ =-f_2[&\tfrac{1}{2}(y_1+y_2)+(\epsilon/4)(\zeta_1-\zeta_2),\ \tfrac{1}{2}(y_1+y_2)\\ &-(\epsilon/4)(\zeta_1-\zeta_2);\ (1/\epsilon)(y_2-y_1)+\tfrac{1}{2}(\zeta_1+\zeta_2),\\ &-(1/\epsilon)(y_2-y_1)+\tfrac{1}{2}(\zeta_1+\zeta_2)]. \qquad (16)\end{aligned}$$

Now we see why f_2 cannot be a power series involving only positive powers of ϵ, with coefficients which are functions of y and ζ only. f_2 will be oscillatory in ζ_1, and ζ_2, i.e., in the third and fourth variables. On account of (16), this means that it must also be oscillatory in $(y_1-y_2)/\epsilon$ thus it will have to contain, in general, arbitrarily high negative powers of ϵ. This does not preclude the possibility that there should be a solution of $\epsilon\to 0$; it only asserts that the ϵ dependence of the solution cannot be analytic around $\epsilon=0$ if it also satisfies the exclusion principle. This squashes our hopes of finding a solution of the form (15), and we must go about the solution differently. First, let us see whether there *is* a solution for $\epsilon=0$; next, investigate the possibility of an approximation scheme which is not a simple power-series expansion in ϵ. In the remainder of the paper we will discuss the $\epsilon=0$ approximation and only touch upon the more difficult problem of the approximation scheme.

6. THE ZEROTH-ORDER APPROXIMATION

The Reduction of the Hierarchy

For $\epsilon\to 0$, $D_r\to\zeta_r(\partial/\partial y_r)$, and the equations read

$$\left\{\frac{\partial^2}{\partial y_1\partial\zeta_1}+\zeta_1\frac{\partial\phi(y_1)}{\partial y_1}\right\}f_1(y_1,\zeta_1)$$
$$-\int d^3y\left[\zeta_1\frac{\partial}{\partial y_1}\phi(y_1-y_2)\right]f_2(y_1,y_2;\zeta_1,0)=0, \qquad (17a)$$

$$\sum_{1\leqslant i\leqslant s}\left\{\frac{\partial^2}{\partial y_i\partial\zeta_i}+\zeta_i\frac{\partial\phi(y_i)}{\partial y_i}\right\}f_s(y_1,\cdots,y_s;\zeta_1;\cdots,\zeta_s)$$
$$\times\sum_{1\leqslant i\leqslant s}\int d^3y_{s+1}\left[\zeta_i\frac{\partial\phi(y_i-y_{s+1})}{\partial y_i}\right]$$
$$\times f_{s+1}(y_1,\cdots,y_s,y_{s+1};\zeta_1,\cdots,\zeta_s,0)=0,$$
$$(s=2,3,\cdots); \qquad (17b)$$

[6] It is rather interesting that such a solution should still exist, since in constructing the small parameter ϵ we made already explicit use of the exclusion principle.

with

$$f_s(y_1,\cdots y_s;\zeta_1,\cdots,\zeta_s)=\int d^3y_{s+1}f_{s+1}$$

$$\times(y_1,\cdots,y_s,y_{s+1};\zeta_1,\cdots,\zeta_s,0); \quad (18a)$$

where

$$f_s\left(\frac{x_1'+x_1}{2L},\cdots,\frac{x_s'+x_s}{2L};\frac{x_1'-x_1}{\epsilon L},\cdots,\frac{x_s'-x_s}{\epsilon L}\right) \quad (18b)$$

must change its sign if we interchange any two primed variables, x_i', x_j', say $(i=1,\cdots,s;\ j=1,\cdots,s;\ i\neq j)$, or any two unprimed variables, x_i, x_j, say; all f_s must be normalized to unity, the f_s must describe a pure state, the energy must be a minimum.

Now we construct the functional F, guided by the Hartree-Fock scheme. To do this we temporarily return to the density matrices ρ_s. Let $f_1^{(0)}(y_1,\zeta_1)$ be independent of ϵ, *qua* function of y and ζ; a $\rho_1(x',x)$ is now defined by

$$L^3\rho_1(x_1',x_1)=f_1^{(0)}\left(\frac{x_1'+x_1}{2L},\frac{x_1'-x_1}{\epsilon L}\right).$$

ρ_1, of course, will depend on ϵ in a complicated way. We proceed to f_s and ρ_s, $(s>1)$ in a similar manner. With $f_s(y_1,\cdots,y_s;\zeta_1,\cdots,\zeta_s|\,\epsilon)$ a $\rho_s(x_1',\cdots,x_s';x_1,\cdots,x_s)$ is associated by

$$f_s(y_1,\cdots,y_s;\zeta_1,\cdots,\zeta_s|\,\epsilon)=L^{3s}\rho_s(x_1',\cdots,x_s';x_1,\cdots,x_s),$$

where

$$x_k'/L=y_k+\tfrac{1}{2}\epsilon\zeta_k,\quad x_k=y_k-\tfrac{1}{2}\epsilon\zeta_k.$$

The functional relation is now obtained as follows:

First, construct ρ_s as a determinant,

$$\rho_s(x_1',\cdots,x_s';x_1,\cdots,x_s)$$

$$=\frac{N^s(N-s)!}{N!}\begin{vmatrix}\rho_1(x_1',x_1)&\cdots&\rho_1(x_1',x_s)\\ \vdots&&\vdots\\ \rho_1(x_s',x_1)&\cdots&\rho_1(x_s',x_s)\end{vmatrix}. \quad (19)$$

Next, express all the x's through y and ζ, and put $N=\epsilon^{-3}$. Finally, let $\epsilon\to 0$ wherever it still appears, after everything is expressed in terms of y and ζ (not x!). The resulting $f_s^{(0)}$ will be our zeroth approximation. (The appearance of the N^s factor in addition to the more usual combinational term is due to the fact that here ρ_1 is normalized to unity and not to N. This way, as $N\to\infty$ the combinatorial factor goes to one.) These functions should satisfy the supplementary conditions and the equations of motion. Let us start with the supplementary conditions. The recursion relation between ρ_2 and ρ_1 reads as

$$\int\rho_2(x_1',x_2;x_1,x_2)d^3x_2=\rho_1(x_1',x_1).$$

According to (19), ρ_2 is given by

$$\rho_2(x_1',x_2';x_1,x_2)=[N/(N-1)][\rho_1(x_1',x_1)\rho_1(x_2',x_2)-\rho_1(x_1',x_2)\rho_1(x_2',x_1)].$$

Substituting this in the previous equation we obtain the integral condition

$$N\int d^3x''\rho_1(x',x'')\rho_1(x'',x)=\rho_1(x',x). \quad (20)$$

Now we show that if (20) is fulfilled, the other recursion relations for $s\geqslant 2$ are also satisfied. Take ρ_s with $x_s'=x_s$ and expand the determinant according to elements in the sth column; multiply the coefficients into the last row and integrate over x_s. The integration can be performed using (20) and we indeed obtain ρ_{s-1} as defined by (19). This shows that all recursion relations are fulfilled if (20) is satisfied. Let us demonstrate now that if (20) is satisfied the system is in a pure state, i.e., it is at the temperature zero. The system is in a pure state if ρ_N is idempotent, i.e., if

$$\int d^3x_1''\cdots d^3x_N''\rho_N(x_1',\cdots,x_N';x_1'',\cdots,x_N'')\times\rho_N(x_1'',\cdots,x_N'';x_1,\cdots,x_N)=\rho_N(x_1',\cdots,x_N';x_1,\cdots,x_N).$$

Again, we can perform the integrations using (20) and we find that ρ_N *is* idempotent. Thus, the only conditions not yet satisfied through (20) are the normalization condition on f_1, and the minimal condition on the energy. We now express (20) and the normalization condition in terms of $f_1^{(0)}$. Substitute in (20) $\rho_1=f_1^{(0)}(y,\zeta)/L^3$ with $x'/L=y+\frac{1}{2}\epsilon\zeta$, $x/L=y-\frac{1}{2}\epsilon\zeta$ and put $N=\epsilon^{-3}$. Change the integration variables from x'' to s by $(x''-x)/\epsilon L=s$; one gets

$$\int d^3s f_1^{(0)}(y+\tfrac{1}{2}\epsilon s,\zeta-s)f_1^{(0)}[y-\tfrac{1}{2}\epsilon(\zeta-s),s]=f_1^{(0)}(y,\zeta). \quad (21)$$

Letting $\epsilon\to 0$, we obtain

$$\int d^3s f_1^{(0)}(y,\zeta-s)f_1^{(0)}(y_1,s)=f_1^{(0)}(y,\zeta). \quad (22)$$

The normalization condition reads

$$\int f_1^{(0)}(y,0)d^3y=1. \quad (23)$$

Thus, our problem is reduced to show that the so constructed $f_s^{(0)}$ functions satisfy (17), (22), (23), and the minimal condition on the energy. We shall accomplish this in two steps. First, we show that the $f_s^{(0)}$ functions for $s>1$ satisfy (17b) if $f_1^{(0)}$ satisfies (17a); next, we show that the set of equations (17b), (22), and (23) for

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$f_1^{(0)}$, coupled with the minimum condition is nothing else but the TF theory. To accomplish the first step we need the $f_s^{(0)}$ functions in terms of $f_1^{(0)}$. Let us start with $f_2^{(0)}$. Before going to the limit $\epsilon=0$, we get from (19)

$$f_2(y_1,y_2;\zeta_1,\zeta_2|\epsilon)=\frac{1}{1-\epsilon^3}\Big\{f_1^{(0)}(y_1,\zeta_1)f_1^{(0)}(y_2,\zeta_2)$$
$$-f_1^{(0)}\Big(\frac{1}{2}(y_1+y_2)+\frac{\epsilon}{4}(\zeta_1-\zeta_2),\ \frac{y_1-y_2}{\epsilon}+\frac{1}{2}(\zeta_1+\zeta_2)\Big)$$
$$\times f_1^{(0)}\Big(\frac{y_1+y_2}{2}-\frac{\epsilon}{4}(\zeta_1-\zeta_2);$$
$$-\frac{(y_1-y_2)}{\epsilon}+\frac{1}{2}(\zeta_1+\zeta_2)\Big)\Big\}. \quad (24)$$

In the semiclassical region the off-diagonal elements of ρ_1 decrease in size and oscillate fast. In terms of f_1 this means that f_1 for a fixed value of y must tend to zero and oscillate fast as ζ tends to infinity. Thus we seek solutions for which $f_1(y,\infty)=0$. Now let ϵ tend to zero. The second term is then always zero, unless $y_1=y_2$ in which case it has the *finite* value

$$f_1^{(0)}[y_1,\tfrac{1}{2}(\zeta_1+\zeta_2)]f_1^{(0)}[y_2,\tfrac{1}{2}(\zeta_1+\zeta_2)].$$

Hence,

$$f_2^{(0)}(y_1,y_2;\zeta_1,\zeta_2)\underset{\epsilon=0}{=}f_1^{(0)}(y_1,\zeta_1)f_1^{(0)}(y_2,\zeta_2)$$
$$-\delta_{y_1-y_2,0}f_1^{(0)}[y_1,\tfrac{1}{2}(\zeta_1+\zeta_2)]f_1^{(0)}[y_2,\tfrac{1}{2}(\zeta_1+\zeta_2)], \quad (25)$$

where $\delta_{k,0}$ is a Kronecker δ and not a Dirac δ. [We must add the stipulation $\epsilon\to 0$ since the symmetry properties required by the exclusion principle are expressed through the variables x', x and their relation to y, ζ involves ϵ. This makes ϵ appear each time explicitly in the right-hand side of (25) whenever we interchange x' and x.] This result can be easily generalized for the higher $f_s^{(0)}$ functions. The rule is as follows. Think of the expanded determinant in (19); each term in the sum will contain $s\rho_1$ factors; of these, some ρ_1 factors will have the same index on both the primed and unprimed x variables, e.g., $\rho_1(x_k',x_k)$; the others will carry variables where the two indices differ, e.g., $\rho_1(x_k',x_l)$. To get the corresponding $f_s^{(0)}$, replace each ρ_1 where the indices are the same, say k, by $f_1^{(0)}(y_k,\zeta_k)$, and replace each $\rho_1(x_k',x_l)$, where the indices on the two variables are different (k and l, say) by $\delta_{y_k-y_l,0}f_1^{(0)}\times(y_k,\frac{1}{2}(\zeta_k+\zeta_l))$. Now we are prepared to solve (17) in the limit $\epsilon\to 0$. Write (17a) as

$$A_1f_1(1)+J_{1,2}[f_2(1,2)]=0 \quad (26)$$

where A_1 is the operator $\partial^2/\partial y_1\partial\zeta_1+\zeta_1(\partial\phi/\partial y_1)$, and $J_{1,2}$ is the operator $(-1)\int d^3y_2\int d^3\zeta_2\delta(\zeta_2)\zeta_1[\partial\phi(y_1-y_2)/\partial y_1]$. The arguments in the f functions are indicated by the index of the argument, e.g.,

$$f_2(1,2)=f_2(y_1,y_2;\zeta_1,\zeta_2).$$

The set (17b) reads then

$$\sum_{r=1}^{s}A_rf_s(1,\cdots,s)$$
$$+\sum_{r=1}^{s}J_{r,s+1}[f_{s+1}(1,\cdots,s+1)]=0. \quad (27)$$

We first show that (27) is satisfied if f_s is a product of $f_1^{(0)}$'s, provided $f_1^{(0)}$ satisfies (26). [By (25) f_s *is* this product if all y's are different.] Then $f_s(1,\cdots,s)=f_1^{(0)}(1)\cdots f_1^{(0)}(s)$, and $J_{r,s+1}[f_{s+1}(1,\cdots,s+1)]=f_1^{(0)}(1)\cdots f_1^{(0)}(s)J_{r,s+1}[f_1^{(0)}(s+1)]$. Equations (26) and (27) become

$$A_1f_1^{(0)}(1)+f_1^{(0)}(1)J_{1,2}[f_1^{(0)}(2)]=0; \quad (28)$$

$$1f_1^{(0)}(2)\cdots f_1^{(0)}(s)\{A_1f_1^{(0)}(1)$$
$$+f_1^{(0)}(1)J_{1,s+1}[f_1^{(0)}(s+1)]\}$$
$$+f_1^{(0)}(1)1f_1^{(0)}(3)\cdots f_1^{(0)}(s)\{A_2f_1^{(0)}(2)$$
$$+f_1^{(0)}(2)J_{2,s+1}[f_1^{(0)}(s+1)]\}$$
$$+\text{same for index } 3+\cdots$$
$$+\text{same for index } s=0. \quad (29)$$

Thus, if $f_1^{(0)}(1)$ satisfies (28), then (29) is automatically satisfied for any s. If the y's are not all different, we proceed as follows. First, we observe that in (26) the second term in f_2 [see (25)] does contribute nothing, since we integrate a function, which is zero everywhere except at a point, where it is finite.[7] Next, we observe that for the same reason the integral in (27) contributes nothing as long as in the integrand there is a Kronecker δ present which carries a y_{s+1}. All such terms must carry a factor $f_1^{(0)}(s+1)$ according to the construction; thus they must be $\rho_1(x_{s+1}',x_{s+1})$ times the minor of $\rho_1(x_{s+1}',x_{s+1})$ in the determinant. Consequently, *under the operator* $J_{r,s+1}$ *we can write* $f_{s+1}(1,\cdots,s+1)=f_s(1,\cdots,s)f_1^{(0)}(s+1)$, and (27) becomes

$$\sum_{r=1}^{s}A_rf_s(1,\cdots,s)+f_s(1,\cdots,s)$$
$$\times\sum_{r=1}^{s}J_{r,s+1}[f_1^{(0)}(s+1)]=0, \quad (s=1,2\cdots). \quad (30)$$

[This expression also contains the product of all the diagonal elements, for which we have already shown the truth of (30).] Now interpret $\delta_{y,0}$ as an even function of y, then its derivative is zero, and A_r does not act on the deltas in the product; this makes all deltas a multiplicative factor in (30). If all the y's are not equal to each other, this factor is zero, and the equation is satisfied; if all the y's have the same value, cancel the δ factors, and we are to satisfy the set (30) with the

[7] It is easy to see that the $(y_1-y_2)^{-2}$ type of singularity due to $\partial\phi(y_1-y_2)/\partial y_1$ does not affect this argument.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

stipulation $y_1=y_2=\cdots=y_s$. Now again, as before, the equation breaks up into a sum of terms, each of which vanishes, if (30) is satisfied for $s=1$. This is, however, satisfied if we require (28) to be true. Thus, in the limit $\epsilon=0$ we have solved the whole hierarchy of equations if we can solve (28) for $\epsilon=0$.

The Reduced Hierarchy and the Dirac Scheme

The problem is then solved if we find a solution of (28), (22), and (23) which minimizes the energy. Equation (28) is the equation of motion of the singlet density matrix; (22) expresses the two auxiliary conditions that the exclusion principle should be satisfied, and that the system should be in a pure state; (23) is a normalization condition. This set of equations are related to the set which formed the starting point of Dirac's investigations.[2] Dirac introduces a singlet density matrix, normalized to N, and stipulates that this density matrix should be a solution of the Hartree-Fock scheme with the subsidiary condition that the singlet density matrix should be idempotent, and that the energy be a minimum. Then he proceeds to solve this set of equations in the limit as Planck's constant tends to zero. Equation (28) is related to the equation of motion in the Hartree-Fock scheme, (22) to the idempotency condition, (23) to the normalization condition. However, in the further development there appears a disparity. Dirac solves in this limit the idempotency condition by an heuristic assumption on the form of the singlet density matrix; using the so resulting density matrix in the equations of motion he finds the TF solution, *amended by exchange terms, but with no other corrections*. This is astonishing for two reasons. First, according to our estimates in Sec. 3, the exchange terms are second-order corrections. Second, there is another second-order correction, the Weizsäcker correction. Thus, either no correction term should appear, or both. (Indeed, one of the more mysterious features of the Weizsäcker correction has always been that it somehow failed to appear in Dirac's approximation.) The inconsistency arises through the heuristic assumption used in solving the idempotency condition. This is a correct lower-order approximation; however, to this approximation the exchange terms in the equations of motion do also vanish [see (25)], the same way as the terms containing the Weizsäcker correction, and which indeed were tacitly put equal to zero by Dirac, when he equated the kinetic-energy term with its classical limit, $p^2/2m$.

For this reason in the next section we shall analyze the solution of our set of equations with somewhat greater care as usual, to demonstrate that in zeroth order the TF solutions are only obtained. To accomplish this aim we solve the equations in a manner which exhibits the similarities with the usual TF derivation as much as possible, instead of striking out along the path suggested by Dirac.

7. THE THOMAS-FERMI SOLUTION

We seek the solution of (28), (22), (23) which makes the energy a minimum. Let us start with (22) and (23). Fourier analyze $f_1^{(0)}$ in ζ:

$$f_1^{(0)}(y,\zeta)=(2\pi)^{-3}\int d^3k w(y,k)e^{ik\cdot\zeta}. \tag{31}$$

Equation (22) asserts that

$$w(y,k)^2=w(y,k), \tag{32}$$

or

$$w(y,k)=1, \quad \text{or} \quad 0. \tag{33}$$

The location of the boundary $h(y,k)=0$ separating the $w=1$ and $w=0$ domains (which can be multiply connected) is left undetermined by (22), while the normalization condition (23) merely requires that the volume of the $w=1$ region be $(2\pi)^3$. Observe that the determination of the boundary $h=0$ completes the solution of the problem. This is furnished by Eq. (28) and the minimal condition. Equation (28) written out in full reads:

$$\left\{\frac{\partial^2}{\partial y\partial\zeta}+\zeta\frac{\partial\phi(y)}{\partial y}\right\}f_1^{(0)}(y,\zeta)$$

$$-f_1^{(0)}(y,\zeta)\int d^3y_2\zeta\frac{\partial\phi(y-y_2)}{\partial y}f_1^{(0)}(y_2,0)=0. \tag{34}$$

Substitute (31) into (34) and observe that $w\zeta e^{ik\cdot\zeta}\equiv -iw(\partial e^{ik\cdot\zeta}/\partial k)\rightarrow i(\partial w/\partial k)e^{ik\cdot\zeta}$ by partial integration. We obtain:

$$k(\partial w/\partial y)-(\partial\Psi/\partial y)(\partial w/\partial k)=0, \tag{35a}$$

$$\Psi(y)=-\phi(y)+\int d^3y_2\phi(y-y_2)\int d^3k_2 w(y_2,k_2);$$

$$w(y,k)=1, \text{ or } 0. \tag{35b}$$

Equation (35) is the same as the classical Liouville equation for a one-particle distribution function $w(y,k)$, k being a dimensionless momentum variable, y a dimensionless position variable, and Ψ a dimensionless potential energy. The latter is a self-consistent potential since it depends on $\int d^3k w(y,k)$, which is proportional to the (yet unknown) density: thus (32) is the self-consistent field problem of Thomas and Fermi. Equation (35a) gives the equation of motion, (35b) the exclusion principle at T equal to zero. This is to be solved with the auxiliary condition that the total energy $\int d^3k \times\int d^3y(\frac{1}{2}k^2+\Psi)w$ be a minimum. What restrictions are placed by (35a) on the location of the boundary $h=0$? A straightforward substitution shows that $w(y,k)$ can only be a function of the combination $\frac{1}{2}k^2+\Psi(y)$. (In a stationary state the distribution function can only be a function of the constants of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

motion; the angular momentum being by hypothesis zero, only the energy $E=\frac{1}{2}k^2+\Psi$ remains.) Hence, the boundary $h=0$ must be a $E=$const surface, or several different energy surfaces pieced together.

To determine the boundary we must know (a) which energy surface, or surfaces, will be used, i.e., the determination of the constants in the $E=$const equation; (b) the potential energy Ψ.

We first answer (a). In the 6-dimensional (y,k) space (Fig. 3) one constructs the $E=$const surfaces; they will be spherically symmetrical in both the k three-space, and y three-space. The former is a consequence of E containing k^2 only; the latter is due to the fact that Ψ can only depend on $|y|$, since ϕ is a function of $|y|$, and so is $\int d^3k w(y,k)$ by symmetry. Were the angular momentum of the atom different from zero, a preferred plane would exist. (In the one-dimensional situation depicted in Fig. 3. This symmetry means that the $E=$const surfaces are symmetrical with respect to both the y and k axis.) By assumption only bound states should exist; thus $w(k,)y=W(E)$ must be zero if $E>0$; for $E<0$ $W(E)$ must be zero or one. In other words, we could have a W which consists of layers of 0 and 1, each layer bounded by $E=$const surfaces. (E.g., we could have on Fig. 2 $W=1$ between the $E=0$, $E=E'$ surfaces, $W=0$ between the $E=E'$ and $E=E''$ surfaces, etc.)

Now, it is possible to show that (a) the minimum energy obtains if there are no gaps, thus $W(E)=1$ if $E\leqslant E_c\leqslant 0$, where E_c is a critical energy; (b) the equations have no solution unless $E_c=0$. (The layered distributions correspond to excited states.) Thus

$$\begin{aligned} &W(E)=1 \quad E\leqslant 0,\\ &W(E)=0 \quad E>0,\\ &E=\tfrac{1}{2}k^2+\Psi(y). \end{aligned} \tag{36}$$

To answer (b) we proceed as follows: Take the Laplacian of Ψ with respect to y. We obtain

$$\Delta\Psi=4\pi\delta(y)-4\pi\int w(y,k)d^3k\,, \tag{37}$$

since $\Delta\phi=\Delta(1/|y|)=-4\pi\delta(y)$. The integral over w can be simply performed. Fix y; for each y, k can range over all values less than or equal to $k_m(y)$ defined by $\frac{1}{2}k_m^2+\Psi=0$; for all these values of k, w is equal to one; hence the integral is $(4\pi/3)k_m^3$. (The shaded area is Fig. 2.) Thus we get the two equations

$$\begin{aligned} &\Delta\Psi=-4\pi\delta(y)-4\pi(4\pi/3)k_m^3(y)\,,\\ &\tfrac{1}{2}k_m^2+\Psi=0. \end{aligned} \tag{38}$$

Equation (38) constitutes the standard set of Thomas-Fermi equations in dimensionless variables. The numerical factors are different. This is due to two trivial causes. First, we did not scale out 4π's and other numbers with our choice of L; second, as we mentioned, we omitted the factor 2 arising from the additional summation to be performed over the spin states. This then shows that in the limit $\epsilon\to 0$ the TF theory is a rigorous solution of the N-body problem.

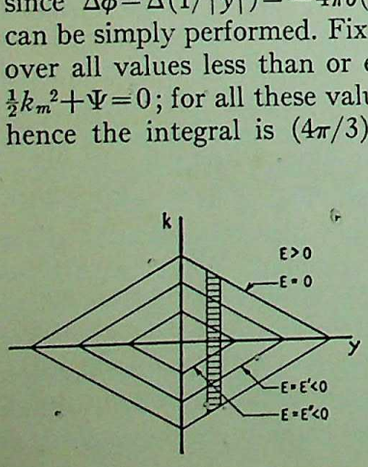

FIG. 3. Qualitative picture of (k,y) space, reduced μ space of electron, k-reduced momentum, y-reduced position; several constant-energy surfaces are shown.

8. THE INCONSISTENT NEXT APPROXIMATION

We have seen that the simple power-series expansion (15) does not exist. In spite of this it may be worthwhile to pretend temporarily its existence, in order to observe through what anomalies the equations inform us that we are attempting the impossible.

The pattern is clear. First, we have to assume a functional G which connects the f_s with f_1 to the next order in ϵ, still satisfying the exclusion principle. This, with the recursion relations gives a condition on f_1 which must be solved together with the equations of motion for the f_s. Let us assume that G is of the same form as F; thus, we extend to second order in ϵ the determinantal construction of the f_s from f_1. Then the recursion relations give again Eq. (21) as a condition, with $f_1(y,\zeta)=f_1^{(0)}(y,\zeta)+\epsilon^2 f_1^{(2)}(y,\zeta)$ in place of $f_1^{(0)}$, and with $y+\frac{1}{2}\epsilon\zeta$, $y-\frac{1}{2}\epsilon\zeta$ appearing in the arguments. Expanding it to second order in ϵ and equating the coefficient of ϵ^2 to zero, we get an inhomogeneous linear integral equation for $f^{(2)}$, where the homogeneous equation has only zero as its solution. Hence the inhomogeneous equation has, at most, one solution. This means that if a solution exists *we have found f_1 to second order* without ever investigating the equations of motion to second order. It is clear, however, that such a solution must be incompatible with the equations of motion for the following reason. We can modify the functional G in an infinite number of ways to give the same relation between f_1 and f_2, but different relations between f_1 and f_3, f_4, etc. This leaves the hypothetical solution unchanged but will modify the equations of motion. Thus, this specification of G is too restrictive. The solution, however, does not exist. If we formally solve the equation we find that the solution diverges. An inconsistent solution can be obtained, however. Assume that f_2 *is* a determinant, put

$$f_1(y,\zeta\,|\,\epsilon)=f_1^{(0)}(y,\zeta)+\epsilon^2 f_1^{(2)}(y,\zeta)$$

and expand it to second order in ϵ^2. Insert it in the equation of motion for f_1, and equate to zero separately the coefficient of ϵ^2. This way we obtain the previous zeroth-order equations for $f_1^{(0)}$, and an inhomogeneous equation for $f_1^{(2)}$. This equation is the one found by

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Kompaneets and Pavlovskii, and Baraff and Borowitz, containing the correction terms introduced earlier in a more heuristic way by Dirac (exchange correction) and by Weizsäcker (inhomogeneity correction). As we see, this result is then inconsistent in the sense that the exclusion principle is satisfied to zeroth order, while the equation of motion for f_1 is satisfied to second order; moreover it is left open how far the other equations of motion for f_s with $s>1$ are satisfied, since this involves a decision about the functional dependence of f_s on f_1.

9. CONJECTURES

As we see, the solution of the hierarchy of equations for the reduced density matrices involves three steps: the discovery of the proper small parameter; the establishment of a functional relation between the singlet density matrix and the higher density matrices; the invention of a calculational scheme to improve the approximations. We shall now comment on each step, bearing in mind what we have shown before. First, we observe the general difficulty that there is no general, all embracing postulate from which all three steps would necessarily follow. We first picked a small parameter such that in zeroth order we should recover the TF model; this of course does not make the small parameter unique. However, the parameter of smallness gives no clue as to the construction of the functional connecting the higher density matrices with the singlet density matrix. Moreover, this functional relation (chosen in such a way as to satisfy the exclusion principle) forces the small parameter already picked to appear in a nonanalytical manner. What we are missing is a postulate which connects the two separate assumptions about the small parameter and the functional relation. The basic feature of the TF model is that the energy is a functional of the density only. This unique feature should be incorporated from the beginning in some manner, as for example to seek those solutions of the hierarchy for which the singlet density matrix is a functional of the density (its diagonal elements) only, the pair density matrix a functional of the singlet density matrix, etc., and trying to determine the unknown functionals through the expansion in terms of a small parameter. Sidestepping this basic predicament, the present treatment suggests two basic improvements. We observe that the present small parameter essentially expresses the smallness of the off-diagonal elements of the singlet density matrix, but it does so in a very crude way. Think of the singlet density matrix in the x representation; our expansion says that only those elements are of importance which lie along the diagonal in a strip of *uniform* width ϵ. In reality this strip will be far from being uniform. As we go (in the x representation) along the diagonal, the diagonal elements $\rho(x,x)$ give the density as a function of the radial distance from the nucleus. The heuristic considerations in Sec. 3 show that the TF approximation is good around a distance L from the nucleus but poor everywhere else. Close to the nucleus the field is changing too rapidly; far away the density is insufficient. Thus, this strip is rather wide at both ends, becoming narrow in between. Thus, it is unwise to assign the small parameter ϵ uniformly in the (y,ζ) space; most likely there will be different asymptotic regions in this space with different correct assignment of smallness. One way to accomplish this is to introduce the unknown density distribution in the scale, and hence in the small parameter. Thus the small parameter must be specified implicitly. This already may make the nonanalyticity difficulties disappear. However, it seems to us that another remedy may also be required. In the present scheme, as it is usual, we insisted that the temperature of the atom is absolute zero. This may be too restrictive a stipulation. For, is it not rather preposterous to state, that you wish to determine the energy of the atom within an accuracy of, say, 20%, and at the same time to insist that you know its temperature exactly and not only to the same accuracy as you know the energy? It is likely that a coupled limiting process is required, in which the temperature is treated as an additional small parameter. Preliminary work suggests that this does indeed eliminate some of the difficulties, since at finite temperatures Eq. (22) acquires an additional term $kT\partial f/\partial\mu$ (μ being the chemical potential). Thus, we have essentially a "boundary layer" problem in μ around the Fermi surface, kT being the thickness of the boundary layer. It is a well-known fact of asymptotic analysis that one must *not* treat such cases by putting simply the boundary thickness equal to zero, since this obliterates the highest derivative in the equation.

10. SUMMARY AND CONCLUSIONS

We have shown then, that there exists a small parameter and a functional relation between the singlet and higher density matrices such that in the limit as this small parameter tends to zero, the TF solutions are exact solutions of the full N-body problem, for neutral atoms at absolute zero temperature. One surmises that the same would hold for ions as well, if under ionization we mean that a fraction of the total number of electrons are removed (and not a given number). The problem, however, involves the small parameter in question in a nonanalytical fashion and for this reason a simple power-series expansion cannot be used to go to the next approximation. If we are content to satisfy the exclusion principle to zeroth order, and the equations of motion of the singlet density matrix to next order, we obtain the equations found by Kompaneets and Pavlovskii, and Baraff and Borowitz, which contain the exchange and inhomogeneity correction terms. Finally, we suggest possible steps one could take to get rid of the difficulty generated by the nonanalyticities.

Theory of Core-Electron Contributions to Hyperfine Interactions*

G. D. GASPARI, WEI-MEI SHYU, AND T. P. DAS

(Received 5 August 1963; revised manuscript received 16 January 1964)

A convenient method is devised for the calculation of magnetic hyperfine constants in atoms, molecules, and metals taking into consideration the exchange interaction between the core electrons and the unpaired valence electrons. In this method, the core-electron wave functions are perturbed by the nuclear magnetic moment via the Fermi contact term, and the energy of the system is then calculated in the Hartree-Fock approximation using the perturbed core wave functions. The present method is closely related to the exchange perturbation method of Cohen, Goodings, and Heine. However, the former has the advantage of being more flexible in the sense that the same perturbed core-electron functions may be used for the ground and excited states of the atom and for metals without significant error. For lithium atom $1s^2 2s$ and $1s^2 2p$ states, we obtained values for the core contribution to the hyperfine constant a (in $a\mathbf{I}\cdot\mathbf{S}$) of 83.76 Mc/sec and -8.9 Mc/sec in good agreement with the earlier values of Cohen, Goodings, and Heine. We have applied this method to a calculation of the core-polarization correction to the Knight shift in lithium metal using recent wave functions of Kohn and Callaway. The core-polarization corrections produced by the s and p parts of the conduction-electron wave function are nearly equal but opposite in sign, while that produced by the d part is an order of magnitude smaller. This results in a net correction of about -5.3% of the direct contribution to the Knight shift from the conduction electrons.

I. INTRODUCTION

A NUMBER of recent detailed and careful investigations[1–10] of the magnetic hyperfine interaction in atoms and paramagnetic ions have clearly demonstrated the important role of exchange polarization of the core electrons in contributing to the magnetic hyperfine interaction constant. In all these investigations, the method that has been employed has come to be known generally as the unrestricted Hartree-Fock (UHF) method. In keeping with the recent attempt of standardization of nomenclature,[11] we shall call the unrestricted Hartree-Fock method the spin polarized method (SP). Similarly, the projected unrestricted Hartree-Fock method will be denoted as the projected spin polarized method (PSP).[12] Some of the investigators[2–4,6,9] have handled the SP method self-consistently, while others have used a perturbation approach. To avoid confusion we shall refer to the method of treating the exchange potential as a perturbation, the exchange perturbation method (EP). In recent papers, Nesbet,[7] Marshall,[8] and Heine[13] have discussed possible errors that can occur in the results of calculation by the SP method, because the many-electron wave function used in the SP method is not an eigenfunction of $\mathbf{S}^2$, where $\mathbf{S}$ is the total spin of the atom. From the investigations of these authors, one arrives at the conclusion, that for paramagnetic ions and atoms, this limitation of the SP method is not a serious source of error; but in extending the SP method to metals and molecules, one has to be more careful about the influence of this source of error.

In this paper we are interested in a perturbation method which has the advantage of flexibility over the EP method while not sacrificing accuracy. The accuracy

of the method can be easily compared with other perturbation calculations, which we shall show to be exactly equivalent in principle to our method. Specifically, what one does is to perturb the core electrons with the nuclear magnetic moment (μ) via the Fermi contact interaction; and with these perturbed functions, one then computes the energy to first order in μ, which is directly related to the hyperfine coupling constant. This method, which we shall call the moment perturbation method (MP), differs from the EP approach only in the order of application of the perturbations, since there the core electrons are perturbed by the exchange potential rather than the nuclear magnetic moment. The flexibility of the method arises by letting the nucleus perturb the core functions and approximating (which we demonstrate by our lithium atom calculations to be a good approximation) these perturbed functions as being independent of the configuration of the outer valence electrons. Thus, we assume that the interaction between the magnetic moment of the nucleus and the core electrons of the atom is not greatly altered when one goes from the atomic ground state to an excited state, or to molecular and metallic states. This has the advantage of enabling one to calculate exchange-polarization effects when the system is in a variety of environments without having to solve separate differential equations in each case. In order to demonstrate the practicality and flexibility of the MP method, we have calculated the hyperfine interaction constants for atomic lithium in the $1s^22s$ and $1s^22p$ configurations, and compared them with the results of earlier calculations. We then apply the MP method to calculate the contribution of exchange polarization to Knight shift in metallic lithium. In all these calculations, the perturbed core wave functions used were those calculated for atomic lithium $1s^22p$ configuration. This procedure[14] is analogous to similar cross perturbation methods that have been used for the quadrupole antishielding factors for ions,[15] and for the calculation of nuclear magnetic shielding coefficients in molecules.[16]

In Sec. II we describe the details of our method and its correspondence with the EP method. In Sec. III the method is applied to lithium atom $1s^22s$ and $1s^22p$ states, and the results are compared with earlier EP calculations. In Sec. IV we calculate the core-polarization correction to the Knight shift in lithium metal using the recent Wigner-Seitz wave functions obtained by Kohn and Callaway.[17] In Sec. V we shall discuss the limitations of the MP method and the problem of self-consistency.

THEORY OF THE MP METHOD

The general procedure followed here is similar to that employed in some other perturbation problems. However, for the sake of completeness, we have presented here an adaptation pertinent to our problem at hand. Let us consider a general system whose unperturbed Hamiltonian is $\mathcal{H}_0$ and whose ground-state wave function is Ψ_0.

$$\mathcal{H}_0\Psi_0=E_0\Psi_0. \tag{1}$$

Let the system be perturbed by two general first-order perturbing forces described by Hamiltonians $\mathcal{H}_E$ and $\mathcal{H}_N$. If $\delta\Psi_E$ and $\delta\Psi_N$ represent the first-order changes in the wave function of the system due to $\mathcal{H}_E$ and $\mathcal{H}_N$, respectively, then the energy of the system correct to the second order is

$$E=\frac{\langle\Psi_0+\delta\Psi_E+\delta\Psi_N|\mathcal{H}_0+\mathcal{H}_E+\mathcal{H}_N|\Psi_0+\delta\Psi_E+\delta\Psi_N\rangle}{\langle\Psi_0+\delta\Psi_E+\delta\Psi_N|\Psi_0+\delta\Psi_E+\delta\Psi_N\rangle}. \tag{2}$$

On simplication, after making a binomial expansion of the denomintaor, one gets

$$\begin{aligned}E=\{&E_0+E_e+E_N+2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_E\rangle+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_E\rangle\\&+2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_N\rangle+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_N\rangle+\langle\delta\Psi_E|\mathcal{H}|\delta\Psi_E\rangle\\&+\langle\delta\Psi_N|\mathcal{H}|\delta\Psi_N\rangle+2\langle\delta\Psi_E|\mathcal{H}_0|\delta\Psi_N\rangle\}\\&-\{\langle\delta\Psi_E|\delta\Psi_E\rangle-\langle\delta\Psi_N|\delta\Psi_N\rangle-2\langle\delta\Psi_E|\delta\Psi_N\rangle\}.\end{aligned} \tag{3}$$

After omitting terms higher than second order, Eq. (3) becomes

$$\begin{aligned}E=&E_0+E_e+E_N+\langle\delta\Psi_N|\mathcal{H}_0-E_0|\delta\Psi_N\rangle\\&+\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_E\rangle+2\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_N\rangle\\&+2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_E\rangle+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_E\rangle\\&+2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_N\rangle+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_N\rangle,\end{aligned} \tag{4}$$

where we have assumed that the perturbed wave function is normalized to first order. That is,

$$\langle\Psi_0|\delta\Psi_E\rangle=\langle\Psi_0|\delta\Psi_N\rangle=0, \tag{5}$$

and the first-order changes in energy are given by

$$\begin{aligned}E_e&=\langle\Psi_0|\mathcal{H}_E|\Psi_0\rangle,\\E_N&=\langle\Psi_0|\mathcal{H}_N|\Psi_0\rangle.\end{aligned} \tag{6}$$

The second-order change in energy is given by

$$\begin{aligned}E^{(2)}=&2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_E\rangle+\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_E\rangle\\&+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_N\rangle+\langle\delta\Psi_N|\mathcal{H}_0-E_0|\delta\Psi_N\rangle\\&+2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_N\rangle+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_E\rangle\\&+2\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_N\rangle.\end{aligned} \tag{7}$$

[14] While this work was in progress, we received a preprint of a paper by Heine (Ref. 13) in which he mentioned that E. Šimánek had independently proposed a similar method to Heine to avoid some of the inaccuracies of the SP method that were discussed in Ref. 13.

The terms in the second-order change in energy can be regrouped[18] as

$$E_e^{(2)}=2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_E\rangle+\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_E\rangle,$$
$$E_N^{(2)}=2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_N\rangle+\langle\delta\Psi_N|\mathcal{H}_0-E_0|\delta\Psi_N\rangle,$$
$$E_{eN}^{(2)}=2\langle\Psi_0|\mathcal{H}_E|\delta\Psi_N\rangle+2\langle\Psi_0|\mathcal{H}_N|\delta\Psi_E\rangle+2\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_N\rangle. \quad (8)$$

The quantity $E_e^{(2)}$ is the second-order change in energy due to $\mathcal{H}_E$ alone; $E_N^{(2)}$ is the second-order change in energy due to $\mathcal{H}_N$ alone; and $E_{eN}^{(2)}$ is the second-order change in energy due to the interaction of $\mathcal{H}_E$ and $\mathcal{H}_N$.

The first-order equations for $\delta\Psi_E$ and $\delta\Psi_N$ are

$$(\mathcal{H}_0-E_0)\delta\Psi_E=-(\mathcal{H}_E-E_e)\Psi_0, \quad (9)$$

$$(\mathcal{H}_0-E_0)\delta\Psi_N=-(\mathcal{H}_N-E_N)\Psi_0, \quad (10)$$

which may also be derived by minimizing $E_e^{(2)}$ and $E_N^{(2)}$ with respect to $\delta\Psi_E$ and $\delta\Psi_N$, respectively. From Eqs. (9) and (10) it is easily seen that

$$\langle\delta\Psi_N|\mathcal{H}_E|\Psi_0\rangle=\langle\delta\Psi_E|\mathcal{H}_N|\Psi_0\rangle=-\langle\delta\Psi_E|\mathcal{H}_0-E_0|\delta\Psi_N\rangle. \quad (11)$$

Hence, using Eq. (11), $E_{eN}^{(2)}$ reduces to

$$E_{eN}^{(2)}=2\langle\delta\Psi_E|\mathcal{H}_N|\Psi_0\rangle, \quad (12)$$

$$E_{eN}^{(2)}=2\langle\delta\Psi_N|\mathcal{H}_E|\Psi_0\rangle. \quad (13)$$

One could now apply this result to our problem of core polarization. For the perturbing Hamiltonian $\mathcal{H}_E$, we take the exchange potential at the position of the core electron due to the unpaired valence electron and for $\mathcal{H}_N$, the Fermi contact interaction due to the nuclear magnetic moment.

$$\mathcal{H}_E=-\frac{\psi_{\text{val}}(1)}{\psi_{\text{core}}(1)}\int\psi_{\text{val}}(2)\frac{e^2}{r_{12}}\psi_{\text{core}}(2)d\tau_2, \quad (14)$$

$$\mathcal{H}_N=\frac{16\pi}{3}\gamma_e\gamma_N\hbar^2\mathbf{I}\cdot\mathbf{S}\delta(\mathbf{r}). \quad (15)$$

In Eq. (15), γ_e is the magnetogyric ratio ($e/2$ Mc/sec) of the electron, γ_N is the magnetogyric ratio of the nucleus, and $\mathbf{I}$ and $\mathbf{S}$ are the respective spins of the nucleus and electron. Equation (14) requires some explanation[5]:

In the presence of an unpaired valence electron, with spin "up," Eq. (14) represents the difference in exchange potential seen by the up and down core electrons. If the restricted Hartree-Fock Hamiltonian for the core states were used as $\mathcal{H}_0$ in Eq. (9), we should consider two first-order equations of the type of Eq. (9), one for the up core state and one for the down. The equation for the up state would involve $+\mathcal{H}_E/2$ on the right and that for the down state $-\mathcal{H}_E/2$. For those effects which involve $\mathcal{H}_E$ to first order, one can consider the down state to remain unperturbed and the up state to be perturbed by $\mathcal{H}_E$ as given in Eq. (14).

Besides $E_{eN}^{(2)}$, the various higher order terms that could contribute to the hyperfine interaction are $\mathcal{H}_E^2\mathcal{H}_N$, $\mathcal{H}_E^3\mathcal{H}_N$, $\mathcal{H}_E^4\mathcal{H}_N$, $\cdots$. These terms are expected to be negligible in heavy atoms where $\mathcal{H}_E$ is a small perturbation compared to $\mathcal{H}_0$. For light atoms there may be a non-negligible contribution from such terms. We have not investigated its effect in lithium atom since our major interest is in Knight shift calculations. It will be shown in Sec. IV that these higher order terms in $\mathcal{H}_E$ do not have to be considered in core-polarization contributions to Knight shift. Higher order terms like $\mathcal{H}_N^2\mathcal{H}_E$, $\mathcal{H}_N^3\mathcal{H}_E$, $\cdots$, lead to terms in the energy non-linear in nuclear spin and are of no interest to us.

For metal ψ_{val} becomes ψ_{cond}, the wave function for a conduction electron which extends over the entire crystal and therefore, involves more than one center. The perturbation equation for $\delta\Psi_E$ [Eq. (9)] cannot, therefore, be separated into radial and angular parts. Cohen, Goodings, and Heine[5] attempted to meet this limitation by expressing ψ_{cond} around the nucleus in question as a linear combination of spherical harmonics and used the linear independence of spherical harmonics of different orders to separate Eq. (9) into a number of independent differential equations. This procedure is rather cumbersome because one now has to solve a set of differential equations in place of Eq. (9). In the MP procedure, one considers the perturbations in the reverse order. This is justified because of the two alternative expressions (12) and (13) for $E_{eN}^{(2)}$. Instead of first considering the perturbation $\delta\Psi_E$ due to $\mathcal{H}_E$, let us consider the perturbation of the wave function $\delta\Psi_N$ due to $\mathcal{H}_N$. Thus, we can determine $\delta\Psi_N$ by solving Eq. (10) and obtain $E_{eN}^{(2)}$ from Eq. (13). Since $\mathcal{H}_N$ is a localized perturbation by a point source and ψ_0 refers to ψ_{core} (the wave function of the core electrons) which is, to a very good approximation, localized and centrosymmetric, Eq. (10) can be separated into radial and angular parts. It should be noted that when the wave function for the conduction electron is expanded as a sum of spherical harmonics, the MP method obviates the necessity of having to solve a set of differential equations; but instead, one has to evaluate a set of integrals arising out of Eq. (13). In principle, the two procedures for calculating $E_{eN}^{(2)}$ should lead to identical results; but in practice, this will not be exactly true. In the process of obtaining numerical solutions of the differential Eqs. (9) and (10), one weights various regions of space differently because of the different natures of the two perturbations $\mathcal{H}_E$ and $\mathcal{H}_N$. This point will become clear in Sec. III, where we compare our results with those of Cohen, Goodings, and Heine's EP calculations on lithium atom. We shall also show in Sec. III that for a model, where analytic solutions are obtainable with both EP and MP methods, the two methods do, in fact, lead to identical results.

With these general remarks, we now proceed to the detailed forms of the equations that one has to solve for the MP method. Since, in a general case, one may have more than one core state to perturb, a formulation such as Dalgarno's for the perturbation of many-electron systems[19] is helpful. We will follow Dalgarno's method II (i.e., non-self-consistent perturbation) and obtain the first-order perturbation equations for $\delta\psi_N$ by minimizing the second-order energy [Eq. (59) in Dalgarno's paper] with respect to $\delta\psi_N$.

The first-order perturbation equations are then given by

$$(\mathcal{H}_i-\epsilon_i)\delta\psi_{i,N}-\sum_j(\epsilon_j-\epsilon_i)\langle\psi_j|\delta\psi_{i,N}\rangle\psi_j = -\mathcal{H}_N\psi_i+\sum_j\langle\psi_j|\mathcal{H}_N|\psi_i\rangle\psi_j, \quad (16)$$

where $\mathcal{H}_i$ is the one-electron Hamiltonian, and ψ_i, ψ_j are the one-electron wave functions in the Hartree-Fock approximation, and ϵ_i and ϵ_j are the corresponding eigenvalues. The first-order change in the wave function for the ith one-electron state due to $\mathcal{H}_N$ is $\delta\psi_{i,N}$. For a core ns state, Eq. (16) for $\delta\psi_{ns,N}$ takes the form

$$(\mathcal{H}_{ns}-\epsilon_{ns})\delta\psi_{ns,N}=\sum_{n's}(\epsilon_{n's}-\epsilon_{ns})\langle\psi_{n's}|\delta\psi_{ns,N}\rangle\psi_{n's} -\mathcal{H}_N\psi_{ns}+\sum_{n's}\langle\psi_{n's}|\mathcal{H}_N|\psi_{ns}\rangle\psi_{n's}. \quad (17)$$

One has to solve Eq. (17) for all occupied core ns states, since the s states are the only ones which do not have nodes at the origin and, hence, can contribute to the hyperfine interaction through the Fermi contact term. The summation terms on the right-hand side extend over all the core s states.

The zero-order one-electron wave function ψ_{ns} satisfies the equation

$$(\mathcal{H}_{ns}-\epsilon_{ns})\psi_{ns}=0. \quad (18)$$

That is, in atomic units

$$(-\nabla^2+V_{ns}-\epsilon_{ns})\psi_{ns}=0, \quad (19)$$

where V_{ns} is the one-electron potential seen by an electron in the ns state in the Hartree-Fock approximation. Therefore,

$$(V_{ns}-\epsilon_{ns})=\nabla^2\psi_{ns}/\psi_{ns}. \quad (20)$$

Substituting this in Eq. (17), we get

$$\left(-\nabla^2+\frac{\nabla^2\psi_{ns}}{\psi_{ns}}\right)\delta\psi_{ns,N} =\sum_{n's}(\epsilon_{n's}-\epsilon_{ns})\langle\psi_{n's}|\delta\psi_{ns,N}\rangle\psi_{n's} -\mathcal{H}_N\psi_{ns}+\sum_{n's}\langle\psi_{n's}|\mathcal{H}_N|\psi_{ns}\rangle\psi_{n's}. \quad (21)$$

[19] A. Dalgarno, Proc. Roy. Soc. (London) **A251**, 282 (1959).

If we now introduce the new function $\phi_{ns,N}$, defined by

$$\delta\psi_{ns,N}=-\frac{A}{4\pi}\frac{\psi_{ns}}{r}+\frac{\phi_{ns,N}}{r}Y_0^0(\theta,\phi), \quad (22)$$

where

$$A=\frac{16\pi}{3}\gamma_e\gamma_N\hbar^2 I_z\frac{m}{a_0\hbar^2},$$

and remembering that $\nabla^2(1/r)=-4\pi\delta(\mathbf{r})$, Eq. (21) reduces to

$$-\frac{d^2\phi_{ns,N}}{dr^2}+\frac{A}{2\pi r^3}u_{ns}-\frac{A}{2\pi r^2}\frac{du_{ns}}{dr}+\frac{\phi_{ns,N}}{u_{ns}}\frac{d^2u_{ns}}{dr^2} =\sum_{n's}(\epsilon_{n's}-\epsilon_{ns})\{\langle u_{n's}|\phi_{ns,N}\rangle u_{n's}\} +A\sum_{n's}\psi_{n's}(0)\psi_{ns}(0)u_{n's}, \quad (23)$$

where we have used the notation

$$\psi_{ns}=[u_{ns}(r)/r]Y_0^0(\theta,\phi).$$

Because of the first term on the right-hand side, Eq. (23) is an integrodifferential equation and must be solved self-consistently. This term represents the influence of Pauli principle on the perturbed core states.

After determining $\delta\psi_{ns,N}$ by solving Eq. (23), one can get the second-order energy $E_{eN}^{(2)}$ using Eq. (13). Thus, substituting for the determinantal function $\delta\Psi_N$ in terms of the one-electron functions $\delta\psi_{ns,N}$ and using Eq. (14) for $\mathcal{H}_E$, we get

$$E_{eN}^{(2)}=2\sum_n\left\{\int\psi_{\rm val}(1)\delta\psi_{ns,N}(1)\psi_{\rm val}(2)\psi_{ns}(2) \times\frac{1}{r_{12}}d\tau_1d\tau_2-\sum_{n'}\int\psi_{\rm val}(1)\psi_{ns}(1)\psi_{\rm val}(2)\psi_{n's}(2) \times\frac{1}{r_{12}}d\tau_1d\tau_2\int\psi_{n's}\delta\psi_{ns,N}d\tau\right\}. \quad (24)$$

From this equation the correction a_c to the hyperfine constant a from core polarization is obtained by the equation

$$a_c=E_{eN}^{(2)}/IJ2\pi\hbar. \quad (25)$$

In solids and molecules, **J** is equal to the total spin **S**; whereas, for atoms, **J** is the total angular momentum of the valence electrons.

III. RESULTS FOR LITHIUM ATOM $1s^22p$ AND $1s^22s$ STATES

For the lithium atom $1s^22p$ ($J=\frac{3}{2}$) state Eq. (23) for $\phi_{1s,N}$ takes the form

$$-\frac{d^2\phi_{1s,N}}{dr^2}+\frac{A}{2\pi r^3}u_{1s}-\frac{A}{2\pi r^2}\frac{du_{1s}}{dr}+\frac{\phi_{1s,N}}{u_{1s}}\frac{d^2u_{1s}}{dr^2} =A|\psi_{1s}(0)|^2u_{1s}. \quad (26)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

To illustrate the nature of the solution of Eq. (26), we first assume a hydrogenic form for u_{1s} for which an exact solution of Eq. (23) can be obtained. The Coulson-Duncanson functions[20] represent such a choice.

$$\psi_{1s}=\left(\frac{z^3}{\pi}\right)^{1/2}e^{-zr},\quad \psi_{2p_0}=\left(\frac{\xi^5}{\pi}\right)^{1/2}re^{-\xi r}\cos\theta \tag{27}$$

and

$$z=2.69,\quad \xi=0.525.$$

The solution of Eq. (21) is then found to be[21]

$$\phi_{1s,N}=\frac{A}{4\pi}(2z\ln r+2z^2r)u_{1s}(r). \tag{28}$$

To find a solution $\delta\psi_{1s,N}$ which satisfies Eq. (5), we use the Schmidt orthogonalization procedure and obtain from Eqs. (22) and (28)

$$\delta\psi_{1s,N}=\frac{A}{4\pi}[F_{1s}-\langle\psi_{1s}|F_{1s}|\psi_{1s}\rangle]\psi_{1s},$$

where (29)

$$F_{1s}=-\frac{1}{r}+2z\ln r+2z^2r.$$

From Eq. (14), the exchange perturbation $\mathcal{K}_E$ due to the $2p_0$ electron is given by

$$\mathcal{K}_E=-\frac{u_{2p}(r)}{3u_{1s}(r)}\left[\frac{1}{r^2}\int_0^r u_{2p}(s)u_{1s}(s)sds+r\int_r^\infty u_{2p}(s)u_{1s}(s)\frac{1}{s^2}ds\right]. \tag{30}$$

Hence, from Eqs. (24) and (30) it follows that

$$E_{eN}^{(2)}=-\tfrac{2}{3}B\left\{\int_0^\infty u_{2p}(r)\delta u_{1s,N}(r)dr\times\left[\frac{1}{r^2}\int_0^r u_{1s}(s)u_{2p}(s)sds+r\int_r^\infty u_{1s}(s)u_{2p}(s)\frac{1}{s^2}ds\right]\right\}, \tag{31}$$

where

$$B=\frac{A}{4\pi}\times\frac{e^2}{a_0}=\frac{4}{3}\frac{\gamma_N\gamma_e\hbar^2I_z}{a_0^3},$$

and

$$\delta u_{1s,N}=\frac{4\pi}{A}r\delta\psi_{1s,N}. \tag{32}$$

For the Coulson-Duncanson functions using Eqs. (27), (28), and (31), and performing the necessary integrations, we get

$$E_{eN}^{(2)}=-\frac{32}{9}B\xi^5z^3\left[\frac{147z^2}{4(z+\xi)^8}-\frac{15}{8(z+\xi)^6}-\frac{273z}{8(z+\xi)^7}-\frac{21z\ln(z+\xi)}{2(z+\xi)^7}+\frac{48z\ln 2}{(z+\xi)^7}+\frac{21z\ln z}{2(z+\xi)^7}\right]. \tag{33}$$

Substituting the values of z and ξ, one gets

$$E_{eN}^{(2)}=-0.0540B. \tag{34}$$

From Eqs. (25) and (32), remembering $I=J=\frac{3}{2}$, it then follows that

$$a_c=\frac{4\mu_N\mu_0E_{eN}^{(2)}}{3a_0^3IJ(2\pi\hbar)B}=-5.24\ \text{Mc/sec}, \tag{35}$$

where $\mu_N=\gamma_NI\hbar$ is the magnetic moment of the Li^7 nucleus and μ_0 is the Bohr magneton.

Since $u_{1s}(r)$ involves a single exponential for the Coulson-Duncanson function, one can obtain an exact analytic solution for the perturbation equation (16) for the EP method, with $\delta\psi_{iN}$ and $\mathcal{K}_N$ replaced by $\delta\psi_{iE}$ and $\mathcal{K}_E$, respectively.

$$\delta\psi_{1s,E}=-\frac{8}{9}\left(\frac{z^3}{\pi}\right)^{1/2}\frac{\xi^5e^{-zr}}{(z+\xi)^7}\left\{\frac{3(z+\xi)^4r^2e^{-2\xi r}}{4\xi}+\left[\frac{3(z+\xi)^4}{4\xi^2}+\frac{9(z+\xi)^3}{2\xi}\right]re^{-2\xi r}+\left[\frac{3(z+\xi)^4}{8\xi^3}+\frac{9(z+\xi)^3}{4\xi^2}+\frac{51(z+\xi)^2}{4\xi}\right]e^{-2\xi r}+\frac{75e^{-2\xi r}}{4r}-\frac{24e^{(z-\xi)r}}{r}-\frac{75z}{2}\int\frac{e^{-2\xi r}}{r}dr+48z\int\frac{e^{(z-\xi)r}}{r}dr\right\}-\frac{28}{3}\left(\frac{z^3}{\pi}\right)^{1/2}\frac{z^2\xi^5e^{-zr}}{(z+\xi)^7}\left(r+\frac{1}{z}\ln r-\frac{1}{2z^2r}\right). \tag{36}$$

Substituting $\delta\psi_{1s,E}$ from Eq. (36) into Eq. (12), one obtains, after some manipulation, exactly the same expression for $E_{eN}^{(2)}$ as in Eq. (33).

The value of a_c in Eq. (35) is about one-half of Goodings'[4] calculated value (−10.7 Mc/sec) by the SP method and is in somewhat better agreement with Cohen, Goodings, and Heine's[5] value (−8.5 Mc/sec) by the EP method. However, one does not expect very good agreement with these earlier results because the single-exponential hydrogen functions are not good approximations to the Hartree-Fock wave functions.[22]

To get a result by the MP method which could be properly compared in terms of accuracy with Cohen,

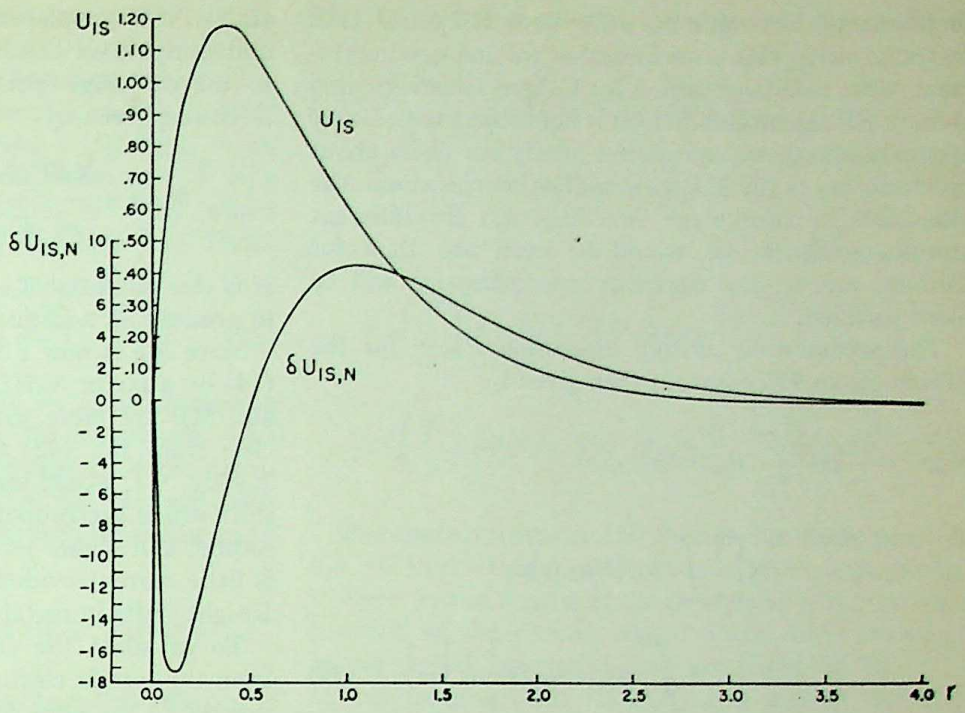

FIG. 1. Plot of unperturbed (u_{1s}) wave function and first-order perturbation $\delta u_{1s,N}$ as function of r for lithium atom $1s^22p$ configuration.

Goodings, and Heine's EP calculation and Goodings' SP calculation, we next solved Eq. (23) using Hartree-Fock wave functions. The solution has now to be obtained by numerical integration of Eq. (23). In Fig. 1, the function $\delta u_{1s,N}$ [defined in Eq. (32)] is plotted, together with Goodings' Hartree-Fock wave function[20] u_{1s}, which was employed in our calculations. The function $\delta u_{1s,N}$ resembles a $2s$ type function, in that, it has a node, but $\delta\psi_{1s,N}=(A/4\pi)(\delta u_{1s,N}/r)$ goes to negative infinity at the origin.

Using Eq. (31), together with Goodings' HF wave functions u_{1s}, u_{2p}, and $\delta u_{1s,N}$ of Fig. 1, it follows that

$$E_{cN}^{(2)}=-\tfrac{2}{3}B(0.137). \tag{37}$$

From Eq. (25) this leads to

$$a_c=-8.9 \text{ Mc/sec}. \tag{38}$$

This value compares very favorably with Cohen, Goodings, and Heine's EP value (Table I). This is satisfying in light of our Eqs. (12) and (13) and our earlier demonstration that EP and MP methods lead to identical results whenever exact solutions of Eqs. (9) and (10) are obtainable.

Both ours and Cohen, Goodings, and Heine's values for a_c are in slight disagreement with Goodings' value (Table I) obtained by the SP method. However, no measured value of a_c is available, so it is rather difficult to assess the importance of this small disagreement between the values obtained by MP (and EP) and SP methods.

The feasibility and accuracy of the MP method has now been demonstrated by its favorable comparison with the results of the EP method for the lithium atom $1s^22p$ state. We would next like to show the flexibility of the MP method by a consideration of core polarization effects for the $1s^22s$ state of lithium atom. The perturbation equation to be solved to get $\delta\psi_{1s,N}$ (or $\phi_{1s,N}$) in this case is exactly the same as in Eq. (26) except that u_{1s} may be different from its value for the $1s^22p$ state. Available tables[23] of u_{1s} for $1s^22s$ and $1s^22p$ states show that there is only a very slight difference between the values of u_{1s} in the two cases. One could

To illustrate the nature of the solution of Eq. (26), we first assume a hydrogenic form for u_{1s} for which an exact solution of Eq. (23) can be obtained. The Coulson-Duncanson functions[20] represent such a choice.

$$\psi_{1s}=\left(\frac{z^3}{\pi}\right)^{1/2}e^{-zr},\quad \psi_{2p_0}=\left(\frac{\xi^5}{\pi}\right)^{1/2}re^{-\xi r}\cos\theta \qquad (27)$$

and

$$z=2.69,\quad \xi=0.525.$$

The solution of Eq. (21) is then found to be[21]

$$\phi_{1s,N}=\frac{A}{4\pi}(2z\ln r+2z^2r)u_{1s}(r). \qquad (28)$$

To find a solution $\delta\psi_{1s,N}$ which satisfies Eq. (5), we use the Schmidt orthogonalization procedure and obtain from Eqs. (22) and (28)

$$\delta\psi_{1s,N}=\frac{A}{4\pi}[F_{1s}-\langle\psi_{1s}|F_{1s}|\psi_{1s}\rangle]\psi_{1s},$$

where (29)

$$F_{1s}=-\frac{1}{r}+2z\ln r+2z^2r.$$

From Eq. (14), the exchange perturbation $\mathcal{K}_E$ due to the $2p_0$ electron is given by

$$\mathcal{K}_E=-\frac{u_{2p}(r)}{3u_{1s}(r)}\left[\frac{1}{r^2}\int_0^r u_{2p}(s)u_{1s}(s)sds+r\int_r^\infty u_{2p}(s)u_{1s}(s)\frac{1}{s^2}ds\right]. \qquad (30)$$

Hence, from Eqs. (24) and (30) it follows that

$$E_{eN}^{(2)}=-\tfrac{2}{3}B\left\{\int_0^\infty u_{2p}(r)\delta u_{1s,N}(r)dr\times\left[\frac{1}{r^2}\int_0^r u_{1s}(s)u_{2p}(s)sds+r\int_r^\infty u_{1s}(s)u_{2p}(s)\frac{1}{s^2}ds\right]\right\}, \qquad (31)$$

where

$$B=\frac{A}{4\pi}\times\frac{e^2}{a_0}=\frac{4}{3}\frac{\gamma_N\gamma_e\hbar^2I_z}{a_0^3},$$

and

$$\delta u_{1s,N}=\frac{4\pi}{A}r\delta\psi_{1s,N}. \qquad (32)$$

For the Coulson-Duncanson functions using Eqs. (27), (28), and (31), and performing the necessary integrations, we get

$$E_{eN}^{(2)}=-\frac{32}{9}B\xi^5z^3\left[\frac{147z^2}{4(z+\xi)^8}-\frac{15}{8(z+\xi)^6}-\frac{273z}{8(z+\xi)^7}-\frac{21z\ln(z+\xi)}{2(z+\xi)^7}+\frac{48z\ln 2}{(z+\xi)^7}+\frac{21z\ln z}{2(z+\xi)^7}\right]. \qquad (33)$$

Substituting the values of z and ξ, one gets

$$E_{eN}^{(2)}=-0.0540B. \qquad (34)$$

From Eqs. (25) and (32), remembering $I=J=\frac{3}{2}$, it then follows that

$$a_c=\frac{4\mu_N\mu_0E_{eN}^{(2)}}{3a_0^3IJ(2\pi\hbar)B}=-5.24\ \text{Mc/sec}, \qquad (35)$$

where $\mu_N=\gamma_NIh$ is the magnetic moment of the Li^7 nucleus and μ_0 is the Bohr magneton.

Since $u_{1s}(r)$ involves a single exponential for the Coulson-Duncanson function, one can obtain an exact analytic solution for the perturbation equation (16) for the EP method, with $\delta\psi_{iN}$ and $\mathcal{K}_N$ replaced by $\delta\psi_{iE}$ and $\mathcal{K}_E$, respectively.

$$\delta\psi_{1s,E}=\frac{8}{9}\left(\frac{z^3}{\pi}\right)^{1/2}\frac{\xi^5e^{-zr}}{(z+\xi)^7}\left\{\frac{3(z+\xi)^4r^2e^{-2\xi r}}{4\xi}+\left[\frac{3(z+\xi)^4}{4\xi^2}+\frac{9(z+\xi)^3}{2\xi}\right]re^{-2\xi r}+\left[\frac{3(z+\xi)^4}{8\xi^3}+\frac{9(z+\xi)^3}{4\xi^2}+\frac{51(z+\xi)^2}{4\xi}\right]e^{-2\xi r}+\frac{75e^{-2\xi r}}{4r}-\frac{24e^{(z-\xi)r}}{r}-\frac{75z}{2}\int\frac{e^{-2\xi r}}{r}dr+48z\int\frac{e^{(z-\xi)r}}{r}dr\right\}-\frac{28}{3}\left(\frac{z^3}{\pi}\right)^{1/2}\frac{z^2\xi^5e^{-zr}}{(z+\xi)^7}\left(r+\frac{1}{z}\ln r-\frac{1}{2z^2r}\right). \qquad (36)$$

Substituting $\delta\psi_{1s,E}$ from Eq. (36) into Eq. (12), one obtains, after some manipulation, exactly the same expression for $E_{eN}^{(2)}$ as in Eq. (33).

The value of a_c in Eq. (35) is about one-half of Goodings'[4] calculated value (−10.7 Mc/sec) by the SP method and is in somewhat better agreement with Cohen, Goodings, and Heine's[5] value (−8.5 Mc/sec) by the EP method. However, one does not expect very good agreement with these earlier results because the single-exponential hydrogen functions are not good approximations to the Hartree-Fock wave functions.[22]

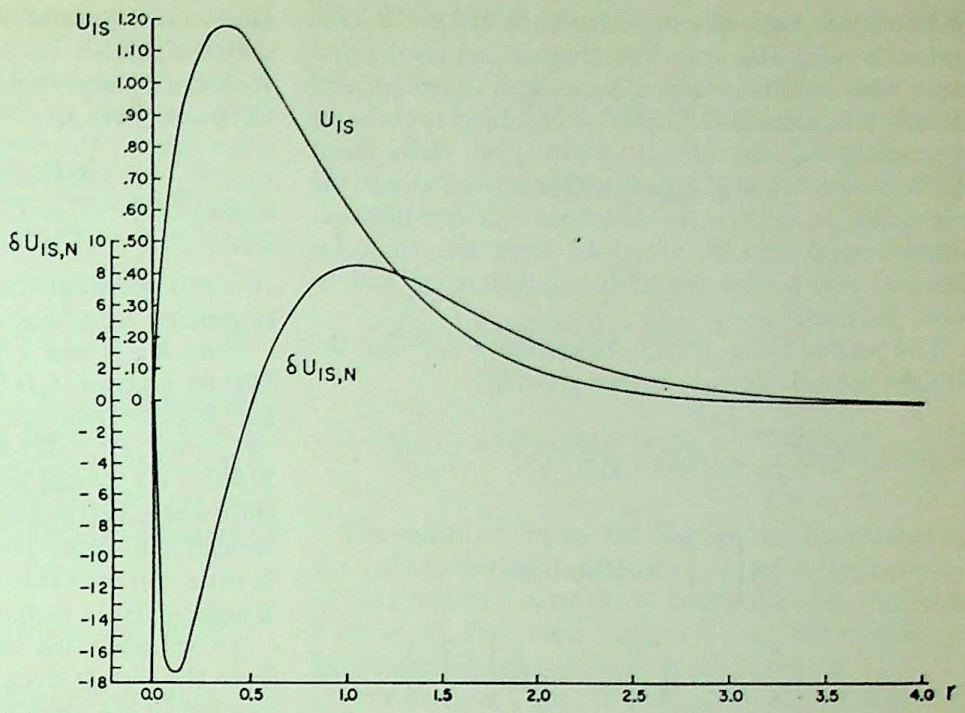

FIG. 1. Plot of unperturbed (u_{1s}) wave function and first-order perturbation $\delta u_{1s,N}$ as function of r for lithium atom $1s^22p$ configuration.

Goodings, and Heine's EP calculation and Goodings' SP calculation, we next solved Eq. (23) using Hartree-Fock wave functions. The solution has now to be obtained by numerical integration of Eq. (23). In Fig. 1, the function $\delta u_{1s,N}$ [defined in Eq. (32)] is plotted, together with Goodings' Hartree-Fock wave function[20] u_{1s}, which was employed in our calculations. The function $\delta u_{1s,N}$ resembles a $2s$ type function, in that, it has a node, but $\delta\psi_{1s,N}=(A/4\pi)(\delta u_{1s,N}/r)$ goes to negative infinity at the origin.

Using Eq. (31), together with Goodings' HF wave functions u_{1s}, u_{2p}, and $\delta u_{1s,N}$ of Fig. 1, it follows that

$$E_{eN}^{(2)}=-\tfrac{2}{3}B(0.137). \tag{37}$$

From Eq. (25) this leads to

$$a_c=-8.9 \text{ Mc/sec}. \tag{38}$$

This value compares very favorably with Cohen, Goodings, and Heine's EP value (Table I). This is satisfying in light of our Eqs. (12) and (13) and our earlier demonstration that EP and MP methods lead to identical results whenever exact solutions of Eqs. (9) and (10) are obtainable.

Both ours and Cohen, Goodings, and Heine's values for a_c are in slight disagreement with Goodings' value (Table I) obtained by the SP method. However, no measured value of a_c is available, so it is rather difficult to assess the importance of this small disagreement between the values obtained by MP (and EP) and SP methods.

The feasibility and accuracy of the MP method has now been demonstrated by its favorable comparison with the results of the EP method for the lithium atom $1s^22p$ state. We would next like to show the flexibility of the MP method by a consideration of core polarization effects for the $1s^22s$ state of lithium atom. The perturbation equation to be solved to get $\delta\psi_{1s,N}$ (or $\phi_{1s,N}$) in this case is exactly the same as in Eq. (26) except that u_{1s} may be different from its value for the $1s^22p$ state. Available tables[23] of u_{1s} for $1s^22s$ and $1s^22p$ states show that there is only a very slight difference between the values of u_{1s} in the two cases. One could

TABLE I. List of contributions to hyperfine constants in Mc/sec for lithium atom $1s^22s$ and $1s^22p$ states.

	$1s^22s$			$1s^22p$		
	Core polarization	Direct $2s$ contribution	Total	Core polarization	Direct $2p$ contribution	Total
Goodings	106	284	390	−10.7	0	−10.7

therefore use the same $\phi_{1s,N}$ for both $1s^22p$ and $1s^22s$ states. If using this approximation we find good agreement with results obtained by Cohen, Goodings, and Heine's EP calculation (which is not subject to the same approximation), we can indeed justify our claim about the flexibility of the MP method. For heavier atoms, the alteration in core wave functions u_{ns} for different atomic configurations would be even less than for lithium; and so the flexibility approximation will be more justified.

The second-order energy expression $E_{eN}^{(2)}$ for the lithium atom $1s^22s$ state is then given by

$$E_{eN}^{(2)}=-2B\left\{\int_0^\infty u_{2s}(r)\delta u_{1s,N}(r)\times\left[\frac{1}{r}\int_0^r u_{1s}(s)u_{2s}(s)ds+\int_r^\infty u_{1s}(s)u_{2s}(s)\frac{1}{s}ds\right]dr\right\}. \quad (39)$$

On evaluating the integrals in Eq. (39), one gets $E_{eN}^{(2)}=2B(0.1434)$. The hyperfine constant is therefore

$$a_c=83.76 \text{ Mc/sec}. \quad (40)$$

The comparison of this value with Cohen, Goodings, and Heine's and Goodings' values (Table I) is very satisfying.

IV. CORE CONTRIBUTION TO KNIGHT SHIFT IN LITHIUM METAL

As another important application of the MP method, we shall consider the magnetic field produced at the Li^7 nucleus in lithium metal as a result of the exchange polarization of the core $1s$ electrons when the conduction electrons are polarized by the external magnetic field. The usual expression for the Knight shift due to the conduction electrons is given by[24]

$$\frac{\Delta H}{H}=\frac{8\pi}{3}\chi_p\langle|\psi_F(0)|^2\rangle_{\text{av}}, \quad (41)$$

where χ_p is the spin susceptibility per atom, and $\langle|\psi_F(0)|^2\rangle_{\text{av}}$ is the average electron density at the nucleus from electrons at the Fermi surface. Equation (41) can be interpreted in the following way: Of the conduction electrons near the Fermi surface, a fraction $(\frac{1}{2}+\chi_pH/2\mu_0)$ have their spins parallel to the field, and a fraction $(\frac{1}{2}-\chi_pH/2\mu_0)$ have their spins antiparallel to the field. When these electrons interact with the nuclear moment through the interaction term $\mathcal{H}_N$, we get the effective field ΔH in Eq. (41) out of the difference in populations in the parallel and antiparallel spin states. This population difference between the parallel and antiparallel conduction electron states also leads to an exchange polarization potential to the core electrons, given by

$$\mathcal{H}_E=-\frac{\chi_pH}{\mu_0}\frac{\psi_k(1)}{\psi_{\text{core}}(1)}\int\psi_k(2)\frac{1}{r_{12}}\psi_{\text{core}}(2)d\tau_2. \quad (42)$$

It is this potential $\mathcal{H}_E$ which enables the core electrons to produce an additional field at the nucleus.

Since $\mathcal{H}_E$ is now a weaker perturbation than in Eq. (14) by a factor χ_pH/μ_0, the perturbation methods EP and MP are more justified than in atoms. Also, it is clear from Eq. (42) that terms of the order $\mathcal{H}_E^2\mathcal{H}_N$, $\mathcal{H}_E^3\mathcal{H}_N$, $\cdots$, would lead to contributions to the Knight shift which are proportional, respectively, to the first, second, and higher powers of the field. However, there is little current evidence for such contributions to the Knight shifts in metals.

To calculate the contribution to the Knight shift from the core $1s$ electrons by the MP method, we then proceed in the same manner as in Sec. III to calculate $E_{eN}^{(2)}$ as given by Eq. (13). For the perturbed core wave function, the function $\delta u_{1s,N}$ (Fig. 1) for the atomic lithium $1s^22p$ state was used. This is again an approximation because there may be a small difference between the wave functions u_{1s} for the metal, and for the atomic $1s^22p$ state. However, our experience with the lithium atom $1s^22s$ state in Sec. III indicates that the error due to this approximation has little effect on $E_{eN}^{(2)}$. We would also like to point out that this error would be expected to be smaller for the metal than for the $1s^22s$ atomic state because the conduction electron wave functions appear to have predominantly p character at the Fermi surface.[17]

Making use of Eqs. (13), (25), and (42), and remembering that we have to average over the Fermi surface in calculating Knight shifts, we get

$$\frac{\Delta H}{H}=\frac{8\pi}{3}\chi_p\frac{2}{A_F}\left\langle\int_0^{r_s}\psi_{kF}(1)\delta\psi_{1s,N}(1)\times\psi_{kF}^*(2)\psi_{1s}(2)\frac{1}{r_{12}}d\tau_1d\tau_2\right\rangle_{\text{Fermi surface}}, \quad (43)$$

where ψ_{kF} is the wave function for a conduction electron at the Fermi surface, r_s is the radius of the Wigner-Seitz sphere, and A_F is the area of the Fermi surface. Equation (43) can be evaluated using available wave functions ψ_{kF} for lithium metal. Of the published wave functions for lithium, those which are available in a readily usable form are the recent ones by Kohn and Callaway.[17]

$$\psi_k=\frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{(N)^{1/2}}[u_0(r)+iku_1(r)P_1(\cos\theta_{kr})+k^2(u_2(r)P_2(\cos\theta_{kr})+\phi(r))]. \quad (44)$$

[24] W. D. Knight, in *Solid State Physics*, edited by F. Seitz and D. Turnbull (Academic Press Inc., New York, 1956), Vol. 2.

The potential used in obtaining these results was an empirical potential which is expected to be more accurate than a calculated potential based on some model. In Eq. (44), θ_{kr} is the angle between a radius vector $\mathbf{r}$ and wave vector $\mathbf{k}$. The functions $u_0(r)$, $\phi(r)$, $u_1(r)$, and $u_2(r)$ were given in tabulated form and N is a normalization factor calculated up to k_F^2 term (where k_F is the Fermi momentum in the spherical Fermi surface approximation).

$$N=4\pi(1+2.79333k_F^2). \tag{45}$$

Since the Fermi surface in lithium approximates a sphere quite closely, we can take the magnitude of $\mathbf{k}_F$ in all directions as the same. The details of the calculations for evaluating the integral in Eq. (43) are given in the Appendix. It is shown there that including up to terms of order k_F^2 [Eq. (A4)]

$$\begin{aligned}
\psi_{k_F}(r)&=As(k_F,r)P_0(\cos\theta_{kr})+Ap(k_F,r)P_1(\cos\theta_{kr})\\
&\quad+Ad(k_F,r)P_2(\cos\theta_{kr}),\\
As(k_F,r)&=\frac{1}{(4\pi)^{1/2}}\Big[j_0(k_F,r)u_0(r)-k_Fj_1(k_F,r)u_1(r)\\
&\quad+k_F^2\Big(j_0(k_F,r)\phi(r)-j_2(k_F,r)u_2(r)\\
&\quad-\frac{2.79333}{2}j_0(k_F,r)u_0(r)\Big)\Big],\\
Ap(k_F,r)&=\frac{1}{(4\pi)^{1/2}}\Big[3u_0j_1+k_F(j_0u_1-2j_2u_1)\\
&\quad+k_F^2\Big(1.2j_1u_2+3j_1\phi-1.8j_3u_2\\
&\quad-\frac{3(2.79333)}{2}u_0j_1\Big)\Big],\\
Ad(k_F,r)&=\frac{1}{(4\pi)^{1/2}}\Big[-5j_2u_0+k_F(3j_3u_1-2j_1u_1)\\
&\quad+k_F^2\Big(j_0u_2-\frac{10}{7}j_2u_2-5j_2\phi+\frac{18}{7}j_4u_2\\
&\quad+\frac{5(2.79333)}{2}j_2u_0\Big)\Big],
\end{aligned}\tag{46}$$

where $j_n(k_F,r)$ is the spherical Bessel function of the order n. Using Eq. (46), it is shown in the Appendix [Eq. (A15)], that one obtains after some manipulation

$$\begin{aligned}
\frac{\Delta H}{H}&=\frac{8\pi\chi_p}{3}\frac{1}{2\pi}\int\delta\psi_{1s,N}(r_1)\psi_{1s}(r_2)\\
&\quad\times\Big\{(4\pi)^3\frac{As(k_F,r_1)As^*(k_F,r_2)}{r_>}\\
&\quad+3\Big(\frac{4\pi}{3}\Big)^3Ap(k_F,r_1)Ap^*(k_F,r_2)\frac{r_<}{r_>^2}\\
&\quad+5\Big(\frac{4\pi}{5}\Big)^3Ad(k_F,r_1)Ad^*(k_F,r_2)\frac{r_<^2}{r_>^3}\Big\}r_2^2dr_2r_1^2dr_1.
\end{aligned}\tag{47}$$

The contributions to $\Delta H/H$ from the three terms in Eq. (47) involving As, Ap, and Ad refer, respectively, to the s, p, and d parts of the conduction electron wave function at the Fermi surface. These were evaluated by numerical integration and are listed in Table II. It can be seen that $(\Delta H/H)_{cp}$ is almost equal to $(\Delta H/H)_{cs}$ but opposite in sign. In contrast, $(\Delta H/H)_{cd}$ is about a factor of 25 smaller than both $(\Delta H/H)_{cp}$ and $(\Delta H/H)_{cs}$. This leads us to expect that the contributions to the core polarization from f and higher angular momentum parts of the conduction electron wave function would be negligible. Unfortunately, it is not possible to test this point using Callaway and Kohn's wave function, because they did not give higher angular momentum components beyond d. The value of the total core contribution, $(\Delta H/H)_c$ in units of $(647.5\ \chi_p)$, namely -0.00544, is to be compared with the value of 0.10280 in the same units, for $(\Delta H/H)_{\text{direct}}$ that one gets using Kohn and Callaway's wave functions and Eq. (41). So we find that the core polarization contributes about -5.3% correction to the Knight shift. Also it is to be noted that, while the s character of the conduction electron wave function is alone important, for the direct contribution to the Knight shift as given by Eq. (41), the core polarization depends sensitively on the s and p parts of the wave function, since there is a near cancellation between $(\Delta H/H)_{cs}$ and $(\Delta H/H)_{cp}$. It is therefore imperative to know accurately the relative amounts of s and p characters in the wave functions for other metals, since the core-polarization contribution may be a more significant fraction of the direct contribution. This point has also been noted by Cohen, Goodings, and Heine.[5] These authors assumed that the conduction electron wave function can be well approximated by a combination of $2s$ and $2p$ atomic functions. In such a case, the core polarization can be calculated by taking a weighted combination of the core polarizations for atomic $1s^22s$ and $1s^22p$ configurations. However, in Figs. 2 and 3, we have compared As and Ap with the $2s$ and $2p$ atomic wave functions, respectively, obtained by Goodings.[4] It is seen that, while there is a reasonable

similarity in shapes between the metallic and atomic wave functions, the correspondence is far from exact. To make a quantitative application of the EP method comparable to our MP calculations, one would have to solve two equations of the type of Eq. (9) using Eq. (42) for $\mathcal{H}_E$ and then calculate $(\Delta H/H)_c$ using Eq. (12). With the MP method, however, because of the flexibility in using $\delta\psi_{1s,N}$ as long as the core wave functions do not vary substantially, we did not have to solve any new differential equations to obtain $(\Delta H/H)_c$. This is an illustration of the computational advantage of the MP method.

In our numerical calculations leading to the results in Table II, we had to make use of the expressions in Eq. (46) correct to k_F^2. This was necessary because of the form of Eq. (44) in which Callaway and Kohn's wave function was available. However, Eq. (47) can be used for any general wave function (such as orthogonalized plane wave and augmented plane wave), since one can obtain As, Ap, and Ad by expanding the conduction electron wave function in spherical harmonics.

TABLE II. List of contributions to Knight shift in lithium metal.

Contributions[a] to $\Delta H/H$	Value
Core-polarization s part, $(\Delta H/H)_{cs}$	0.02355
Core-polarization p part, $(\Delta H/H)_{cp}$	−0.02813
Core-polarization d part, $(\Delta H/H)_{cd}$	−0.00085
Total core polarization $(\Delta H/H)_c$	−0.00544
Direct contribution[b] $(\Delta H/H)_{\text{direct}}$	0.10280
Grand total $(\Delta H/H)_{\text{total}}$	0.09736
Experiment[c]	0.101

[a] The tabulated numbers are in units of a_0^{-3} (atomic units). To correct to the usual dimensionless manner (%) that Knight shift data are obtained, multiply by 647.5 χ_p, where χ_p is the spin susceptibility per gram.
[b] Calculated using Kohn and Callaway's wave function (Ref. 17).
[c] Taken from Table IV, Ref. 24.

CONCLUSION

As we mentioned at the outset, our motivation in developing the MP method was to find a procedure for investigating the contribution from exchange polarization to Knight shifts in metals and alloys. While the EP method as developed by Cohen, Goodings, and and Heine can, in principle, be applied in any situation, one would like to have a method that is computationally simpler and flexible enough to apply for a nucleus in a variety of environments. Our experience with lithium nucleus in the three situations discussed here leads us to believe that the MP method can be extended to give reliable results in other cases. The necessity for careful investigations of core polarizations is strongly felt at the present time, because a variety of Knight shift data in metals, alloys, and internal fields in ferromagnets, are now available; and it appears that direct contributions from conduction electrons cannot quantitatively explain such data.

We would like to conclude by making a few comments on the self-consistency problem in core-polarization calculations in general and specifically as pertinent to the MP method. In an atom containing an unpaired electron, the many-electron wave function has to be

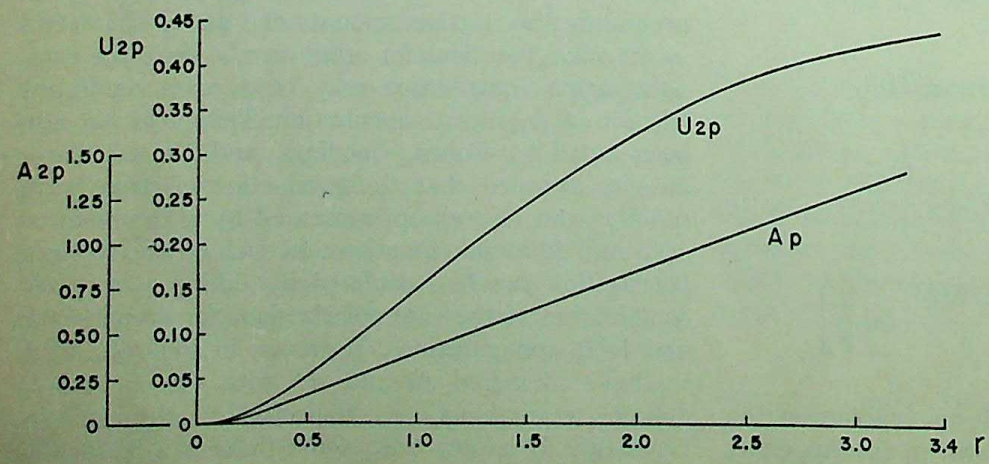

FIG. 3. Comparison of the p part of the conduction electron wave function (at Fermi surface) with Goodings' $2p$ wave function (u_{2p}) for lithium atom $1s^22p$ configuration.

an eigenfunction of S^2. As has been pointed out by a number of authors, in a correct application of the Hartree-Fock method, this condition must be built in as a constraint. This is the case with the PSP method. The SP method, however, does not have this constraint, and the results from both SP or SPP methods are therefore somewhat suspect. Heine has pointed out that it is the self-consistency procedure in the SP method which is responsible for its dangers because it leads to an uncertain admixture of correlation and exchange effects and may in fact overemphasize the correlation unduly. The EP method, which considers the exchange polarization as a perturbation and has no self-consistency built in, is free from this danger although it is evidently less accurate than PSP. In the MP method, however, the perturbed state is not an eigenfunction of S^2 because of the nature of $\mathcal{H}_N$; hence, there is no condition of constraint regarding the total spin. Self-consistency can therefore be used in the MP method without any fear of spurious contributions from correlation. However, our aim was to extend this method to metals where self-consistency is rather difficult to apply even for restricted Hartree-Fock calculations. We have therefore not explored the effects of self-consistency (Dalgarnos' method I) here.

ACKNOWLEDGMENTS

The authors are grateful to Professor J. Callaway and Dr. G. Burns for helpful discussions. We would also like to acknowledge the help we received from Dr. M. J. Garber, Director of the Computing Services at the University of California, Riverside.

APPENDIX

From Eq. (24), the second-order change in energy due to the exchange polarization of the core electrons by the conduction electrons at the Fermi surface is

$$E_{eN}^{(2)}=-\frac{2}{4\pi k_F^2}\left\langle\int_0^{r_s}\psi_{k_F}(1)\delta\psi_{1s,N}(1)\times\psi_{k_F}^*(2)\psi_{1s}(2)\frac{1}{r_{12}}d\tau_1 d\tau_2\right\rangle_{\text{Fermi surface}},\quad\text{(A1)}$$

where r_s is the radius of the Wigner, Seitz sphere $=3.21\,a_0$, k_F is the Fermi momentum $=0.59788/a_0$, and

$$\psi_{k_F}=\frac{e^{i\mathbf{k}_F\cdot\mathbf{r}}}{(N)^{1/2}}[u_0(r)+ik_Fu_1(r)P_1(\theta_{kr})+k_F^2(u_2(r)P_2(\theta_{kr})+\phi(r))],\quad\text{(A2)}$$

θ_{kr} being the angle between $\mathbf{k}_F$ and $\mathbf{r}$, and N the normalization factor, $4\pi(1+2.79333k_F^2)$ and for abbreviation we denote $P_l(\cos\theta_{kr})$ by $P_{l(\theta_{kr})}$ where θ_{kr} is the angle between $\mathbf{k}_F$ and $\mathbf{r}$. On expanding $e^{i\mathbf{k}_F\cdot\mathbf{r}}$ and N, and keeping terms up to k_F^2, ψ_{k_F} can be written as

$$\psi_{k_F}(r)=As(k_F,r)P_0(\theta_{kr})+Ap(k_F,r)P_1(\theta_{kr})+Ad(k_F,r)P_2(\theta_{kr}),\quad\text{(A3)}$$

where

$$As(k_F,r)=\frac{1}{(4\pi)^{1/2}}\Big[j_0(k_F,r)u_0(r)-k_Fj_1(k_F,r)u_1(r)+k_F^2\Big(j_0(k_F,r)\phi(r)-j_2(k_F,r)u_2(r)-\frac{2.79333}{2}j_0(k_F,r)u_0(r)\Big)\Big],$$

$$Ap(k_F,r)=\frac{1}{(4\pi)^{1/2}}\Big[3j_1u_0+k_F(j_0u_1-2j_2u_1)+k_F^2\Big(1.2j_1u_2+3j_1\phi-1.8j_3u_2-\tfrac{3}{2}(2.79333)u_0j_1\Big)\Big],\quad\text{(A4)}$$

$$Ad(k_F,r)=\frac{1}{(4\pi)^{1/2}}\Big[-5j_2u_0+k_F(3j_3u_1-2j_1u_1)+k_F^2\Big(j_0u_2-\frac{10}{7}j_2u_2-5j_2\phi+\frac{18}{7}j_4u_2+\tfrac{5}{2}(2.79333)u_0j_2\Big)\Big],$$

where $j_n(k_F,r)$ is the spherical Bessel function of order n. Using Eqs. (A3) and (A4), Eq. (A1) takes the form

$$E_{eN}^{(2)}=-\frac{1}{2\pi}\int\delta\psi_{1s,N}(r_1)\psi_{1s}(r_2)\frac{1}{r_{12}}\{[As(k_F,r_1)+Ap(k_F,r_1)P_1(\theta_{k1})+Ad(k_F,r_1)P_2(\theta_{k1})]\times[As^*(k_F,r_2)+Ap^*(k_F,r_2)P_1(\theta_{k2})+Ad^*(k_F,r_2)P_2(\theta_{k2})]\}d\tau_1d\tau_2\sin^2\theta_{k_F}d\theta_{k_F}d\phi_{k_F},\quad\text{(A5)}$$

θ_{k1} representing the angle between $\mathbf{k}_F$ and $\mathbf{r}_1$ and θ_{k2} the angle between $\mathbf{k}_F$ and $\mathbf{r}_2$. We perform the integration over the spherical Fermi surface first, and then integrate out the angular parts of $d\tau_1$ and $d\tau_2$.

Since the directions of $\mathbf{r}_1$ and $\mathbf{r}_2$ are arbitrary, let $\mathbf{r}_1$ be directed along $\mathbf{k}_z$ for convenience. Using the addition theorem for spherical harmonics

$$P_2(\theta_{k2})=\frac{4\pi}{5}\sum_{m=-2}^{2}Y_2^{m*}(\theta_{k1},\phi_{k1})Y_2^m(\theta_{12},\phi_{12}),$$
$$P_1(\theta_{k2})=\frac{4\pi}{3}\sum_{m=-1}^{1}Y_1^{m*}(\theta_{k1},\phi_{k1})Y_1^m(\theta_{12},\phi_{12}),\quad\text{(A6)}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

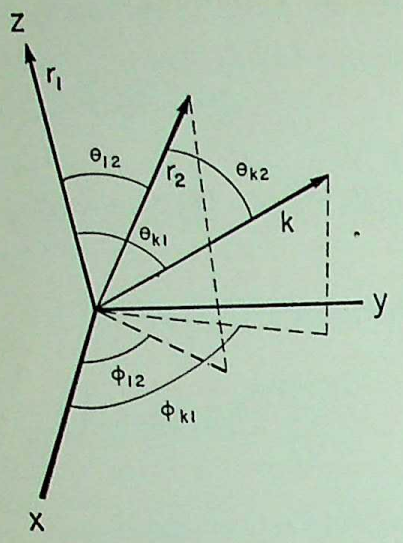

FIG. 4. Relative orientations of $\mathbf{k}$, $\mathbf{r}_1$, and $\mathbf{r}_2$.

one can evaluate the following integrals over the Fermi surface:

$$\frac{4\pi}{3}\int P_1(\theta_{k1})\sum_{m=-1}^{1} Y_1{}^{m*}(\theta_{k1},\phi_{k1})Y_1{}^{m}(\theta_{12},\phi_{12})d\Omega_k = \frac{4\pi}{3}P_1(\theta_{12})\delta_{m0}, \quad \text{(A7)}$$

$$\frac{4\pi}{5}\int P_2(\theta_{k1})\sum_{m=-2}^{2} Y_2{}^{m*}(\theta_{k1},\phi_{k1})Y_2{}^{m}(\theta_{12},\phi_{12})d\Omega_k = \frac{4\pi}{5}P_2(\theta_{12})\delta_{m0}, \quad \text{(A8)}$$

$$\int P_j(\theta_{k1})P_i(\theta_{k2})d\Omega_k = 0, \quad i\neq j.$$

Equation (A5) then reduces to

$$E_{eN}{}^{(2)} = -\frac{1}{2\pi}\int \delta\psi_{1s,N}(r_1)\psi_{1s}(r_2)\frac{1}{r_{12}}\Big[4\pi As(k_F,r_1)\times As^*(k_F,r_2)+\frac{4\pi}{3}Ap(k_F,r_1)Ap^*(k_F,r_2)P_1(\theta_{12}) +\frac{4\pi}{5}Ad(k_F,r_1)Ad^*(k_F,r_2)P_2(\theta_{12})\Big]d\tau_1 d\tau_2. \quad \text{(A9)}$$

In order to perform the angular integration involved in Eq. (A9) the following relationships will be used:

$$\frac{1}{r_{12}} = 4\pi\sum_{l=0}^{\infty}\frac{1}{(2l+1)}\frac{r_<{}^l}{r_>{}^{l+1}}\sum_{m=-l}^{l} Y_l{}^{m*}(\theta_1,\phi_1)\times Y_l{}^{m}(\theta_2,\phi_2), \quad \text{(A10)}$$

$$P_1(\theta_{12}) = \frac{4\pi}{3}\sum_{m=-1}^{1} Y_1{}^{m*}(\theta_1,\phi_1)Y_1{}^{m}(\theta_2,\phi_2), \quad \text{(A11)}$$

$$P_2(\theta_{12}) = \frac{4\pi}{5}\sum_{m=-2}^{2} Y_2{}^{m*}(\theta_1,\phi_1)Y_2{}^{m}(\theta_2,\phi_2),$$

where (A11) again follows from the spherical harmonic addition theorem. Thus,

$$\int\frac{1}{r_{12}}P_1(\theta_{12})d\Omega_1 d\Omega_2 = \frac{(4\pi)^2}{3}\sum_{l=0}^{\infty}\frac{1}{(2l+1)}\frac{r_<{}^l}{r_>{}^{l+1}} \times\sum_{m'=-l}^{l}\int Y_l{}^{m'*}(\theta_1,\phi_1)Y_l{}^{m'}(\theta_2,\phi_2) \times\sum_{m=-1}^{1} Y_1{}^{m}(\theta_1,\phi_1)Y_1{}^{m*}(\theta_2,\phi_2)d\Omega_1 d\Omega_2 = \left(\frac{4\pi}{3}\right)^2\frac{r_<}{r_>{}^2}\times 3. \quad \text{(A12)}$$

$$\int\frac{1}{r_{12}}P_2(\theta_{12})d\Omega_1 d\Omega_2 = \left(\frac{4\pi}{5}\right)^2\frac{r_<{}^2}{r_>{}^3}\times 5, \quad \text{(A13)}$$

$$\int\frac{1}{r_{12}}P_0(\theta_{12})d\Omega_1 d\Omega_2 = (4\pi)^2\frac{1}{r_>}. \quad \text{(A14)}$$

The final expression for $E_{eN}{}^{(2)}$ is then

$$E_{eN}{}^{(2)} = -\frac{1}{2\pi}\int \delta\psi_{1s,N}(r_1)\psi_{1s}(r_2) \times\{(4\pi)^2As(k_F,r_1)As^*(k_F,r_2)(1/r_>) +3(4\pi/3)^3Ap^*(k_F,r_2)Ap(k_F,r_1)(r_</r_>{}^2) +5(4\pi/5)^3Ad(k_F,r_1)Ad^*(k_F,r_2)(r_<{}^2/r_>{}^3)\} \times r_2{}^2dr_2 r_1{}^2dr_2, \quad \text{(A15)}$$

which involves only radial integrations over r_1 and r_2.

Millimeter-Wave Molecular-Beam Spectroscopy: Alkali Chlorides*

PAUL L. CLOUSER† AND WALTER GORDY
Department of Physics, Duke University, Durham, North Carolina
(Received 20 December 1963)

The pure rotational spectra of the alkali chlorides were investigated in the 0.96- to 3-mm range of the microwave region with the molecular-beam spectrometer earlier developed at Duke University. Introduction of Teflon microwave lenses and high-pass microwave filters improved this spectrometer so that measurements into the submillimeter region were possible, to an accuracy of better than one part in 10^6. Dunham's solution for the diatomic molecule was applied in interpretation of data. Improved values for B_e, α_e, and γ_e were obtained for most molecules studied. The centrifugal distortion constants D_e and β_e were obtained from the rotational spectra for the first time for all molecules measured. From the latter two constants, accurate values of ω_e and $\omega_e x_e$ were derived. Other derived quantities are: potential coefficients, isotopic mass ratios, moments of inertia, and internuclear distances. For most of these quantities, the accuracies obtained surpass those from previous measurements.

INTRODUCTION

An earlier designed, high-temperature, molecular-beam, microwave spectrometer[1,2] for operation in the shorter millimeter-wave range of the spectrum has been improved and extended in frequency coverage and has been used for extensive measurements of the alkali chlorides. Unlike the rf molecular-beam spectrometers,[3–5] which detect deflected molecules, this spectrometer detects the loss in radiation which results from the absorption of radiation by a beam of molecules simply sprayed across the radiation path. Since no deflection of the beam is necessary, this spectrometer can be used at the very high millimeter- or submillimeter-wave frequencies, at which molecules generally become insensitive to the deflection fields required for operation of the molecular-beam electric-resonance spectrometers. It has the advantage over the latter of employing a microwave detector which does not depend on the type of molecules being investigated. Because of the weak absorption of molecules in the centimeter or longer wave rf region, the present instrument, which we shall designate as a molecular-beam absorption spectrometer, is not generally applicable at these frequencies. It becomes applicable and effective in the shorter millimeter- and submillimeter-wave regions, where the absorption coefficients of most molecules become large. Because molecules generally become less sensitive to electric and magnetic fields with increase of rotational frequency, the molecular-beam resonance methods become ineffective in the millimeter-wave region, where the present spectrometer operates best. Thus, the molecular-beam absorption spectrometer is complementary to the electric- and magnetic-resonance spectrometers.

Before development of our molecular-beam spectrometer, the microwave group at Columbia University designed a hot-cell microwave spectrometer[6,7] which, like ours and like the conventional microwave spectrometer for gases, employs a microwave radiation detector. With it, they measured rotational transitions in the centimeter wave region for most of the alkali halides. More recently, Lide, Cahill, and Gold[8] have improved the hot-cell spectrometer and have extended its range to 45 kMc/sec for the measurement of the $J=0\rightarrow 1$ transition of LiCl. The principal disadvantage of the hot-cell spectrometer is the pronounced pressure and Doppler broadening of the spectral lines in a gas heated to high temperature. Also, the microwave-transmission losses in a hot cell are large for the high millimeter-wave frequencies. The molecular-beam spectrometer used here eliminates most of the pressure and Doppler broadening, and its microwave-transmission losses are sufficiently low that it can be used in the submillimeter-wave region. Introduction of dielectric lenses for the focusing of the millimeter waves through the absorption cell has significantly reduced its transmission losses over those of the earlier design.

As was demonstrated in the study of alkali bromides and iodides[2] and as is evident from this study of the alkali chlorides, a precise measurement of the millimeter-wave rotational spectra allows a more complete and more accurate evaluation of the molecular constants of these molecules than is possible from either infrared or centimeter-wave measurements. The millimeter-wave measurements are needed because the effects of centrifugal distortion on the molecular structure can be significant and because these effects of distortion may be

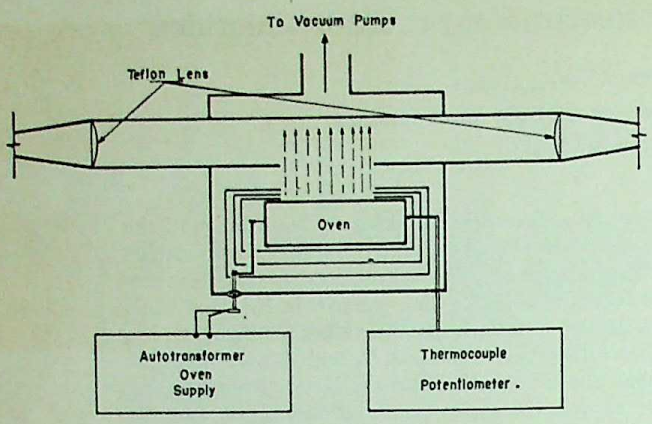

FIG. 1. Schematic diagram of molecular beam absorption cell.

accurately evaluated only by measurements at the higher microwave frequencies, at which frequencies this distortion significantly alters the rotational spectra.

EXPERIMENTAL CONSIDERATIONS

In its systems for microwave-power generation, detection, control, and measurement, the spectrometer used in this study is similar to most of those employed for video detection in the Duke microwave laboratory.[9] The principal difference between this spectrometer and conventional microwave spectrometers is in the absorption cell itself, which is specialized for the generation and utilization of high-temperature molecular beams.

Since the molecular-beam spectrometer has been described in earlier papers of this series,[1,2] only the present modifications of it will be described here. The absorption cell is shown in schematic arrangement in Fig. 1. It consists of a 60-cm section of *S*-band waveguide (3- $\times 1\frac{1}{2}$-in. cross section), into which the output of a harmonic generator operating from a 32–39 kMc/sec reflex klystron is matched by means of a 30-cm *G*- to *S*-band transition section.[9] The power is matched to the *G*-band waveguide of the detector by an identical *S*- to *G*-band transition section. A 6-in. slit is cut in the bottom of the *S*-band waveguide which is the absorption cell so that a beam of molecules can pass into it from a separate oven located just below the slit. The spectrometer has been modified from the earlier design[2] by the addition of high-pass microwave filters which reduce detector-crystal noise in order to give higher harmonics and the addition of Teflon lenses which increase the efficiency of transmission through the slotted waveguide section. These modifications have made possible detection into the submillimeter region. The filters, which operate by means of a short constriction in the *E*-field direction in an otherwise straight section of rectangular waveguide, are located at the output guide of the harmonic generator. Three high-pass microwave filters were made with cutoff wavelengths corresponding to the fourth, fifth, and sixth harmonics of the klystron frequency at the low end of its frequency band. These cutoff wavelengths were 1.87 mm, 1.56 mm, and 1.17 mm, respectively.

The lenses were placed at the large ends of the *G*- to *S*-band transition sections, as shown in Fig. 1. They are identical, planoconvex types designed upon assumption of a point source of radiation about one centimeter from the apex of the input transition section. Y. Y. Hu[10] shows that for sectoral *E*- or *H*-plane horns of less than a five-degree half-angle, the formula $d/\lambda = 5$ gives the location of the phase center or "equivalent point source" of the horn for the design of parabolic reflectors. That the theory should follow for transmission lenses is evident. The distance d into the horn from its apex for the wavelength for which the lenses were designed ($\lambda = 2$ mm) was approximately a centimeter and was not at all critical. The "equivalent point source" appears to be actually a sphere with a radius of about 1 cm for the small-angle horn used here, as is noted in Hu's work. However, with the lens 29 cm from the equivalent source, the point-source approximation is a good one.

By use of the equivalent point source, two lenses were designed by means of the thin-lens equation normally employed in the design of optical lenses. Since the wavelength of 2 mm is small as compared with the 76-$\times$38-mm lenses, the thin-lens equation is a reasonable approximation from consideration of diffraction effects. Teflon was used for fabrication of the lenses because of its high softening temperature. Its index of refraction was taken to be 1.35. A focal length of 29 cm causes the lens to collimate the output beam of the horn. This collimated beam of microwave power is refocused by its mate at the receiving horn so that it matches this power into the *G*-band waveguide of the detector. Brown's monograph on microwave lenses[11] offers further information on this subject.

The errors in measurement with the present spectrometer compare favorably with those obtained with the methods of molecular-beam resonance. The accuracy of measurement is limited only by the observer's ability to ascertain the center of an absorption line. Six measurements were made on each line, with directions of the electronic sweep of the klystron alternated so that time delays in the amplifier are canceled. This gives three measurements for which the dispersion usually lies between 1 and 5 parts in 10^7.

No very difficult problems were encountered in the measurement of the rotational transitions in the more abundant chlorides of Na, K, Rb, and Cs. Difficulties with line strength in most of the less abundant chlorine and rubidium isotopes precluded measurements over the three vibrational states necessary for resolution of B_v into the three structural constants Y_{01}, α_e, and γ_e.

The spectra of LiCl were not observed because of the high degree of dimerization in the molecular beam. Lide, Cahill, and Gold[8] have reported measurements of the $J=0\rightarrow 1$ transition of LiCl made with a heated Stark modulation cell.

Cesium chloride, the heaviest molecule investigated in this study has significant populations in the first four vibrational states. This division of population among vibrational states causes the rotational absorption lines for the ground vibrational state of this molecule to be weaker than those of the lighter chlorides, but allows measurement of rotational transitions in four of the vibrational states for $CsCl^{35}$.

All the isotopes of rubidium chloride studied have significant nuclear quadrupole couplings and at the lower J values show an absorption line splitting of several megacycles per second. Nevertheless, for the high J transitions measured in this work, the nuclear quadrupole splitting is negligible. For example, the line splitting is less than a tenth of a megacycle at 190 kMc/sec and is thus within the experimental error of our measurements. The rotational absorption lines in the third vibrational state were very weak; only one was measurable.

The spectral frequencies of $NaCl^{35}$ were measured over a wide range extending into the submillimeter-wavelength region. A cathode-ray oscilloscopic display of one of the submillimeter lines obtained for $NaCl^{35}$ is shown in Fig. 2. The signal is weak because it is near the upper frequency end of the operating range of the present spectrometer. Much stronger signals were, of course, observed in the one- to three-mm range.

Approximate oven temperatures at which the spectral lines appeared for each molecule are shown in Table I.

TABLE I. Oven temperatures.

Molecule	Temperature (°K)
NaCl	1022
KCl	1010
RbCl	970
CsCl	889

No attempt was made to measure these temperatures with strict accuracy. Care was taken only to obtain reproducible temperature measurements, since these measurements were used to predict the temperature at which spectral lines should appear at subsequent observations.

THEORETICAL CONSIDERATIONS

Dunham's theory[12] for the diatomic molecule has been applied in the analysis of the data obtained for the alkali halides. The part of this treatment which is required to make the derived results meaningful is outlined below.

[12] J. L. Dunham, Phys. Rev. 41, 713 (1932); 41, 721 (1932).

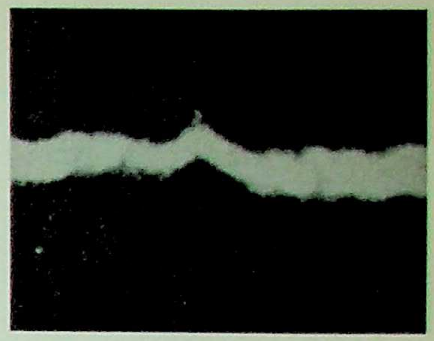

FIG. 2. Cathode-ray oscilloscopic display of the $J=23\rightarrow 24$, $v=0$, transition of $NaCl^{35}$ occurring at 312 109.88 Mc/sec (wavelength 0.97 mm). The width of the line is approximately 100 kc/sec.

The time-dependent, Schrödinger equation for the diatomic vibrating rotor may be written as

$$d^2\psi/d\xi^2+(2\mu r_e^2/h^2)\times[(E-U)-J(J+1)/(1+\xi)^2]\psi=0, \quad (1)$$

where $\xi=(r-r_e)/r_e$, where E is the energy value, and J is the rotational quantum number. The term $J(J+1)/(1+\xi)^2$ may be considered as a "centrifugal potential" and μ as a reduced mass in the equivalent, one-dimensional problem. The term U is dependent on the separation distance of the nuclei and represents the interatomic potential caused by the nuclear and electronic charges. For solution of this equation, the form of the potential function U must be known.

Many potential functions of the closed formula type have been examined by Varshni[13] and by other investigators.[14–16] Probably the most successfully and widely used of these functions is the Morse potential.[14] However, the best fit to the microwave data is obtained by use of a potential function expressed as a power series in ξ, valid only near a minimum and used first by Dunham.[12] This potential is

$$U(\xi)=hca_0^2\xi^2(1+a_1\xi+a_2\xi^2+a_3\xi^3+\cdots), \quad (2)$$

where the a's are constant coefficients.

Dunham applied this power series expansion of the potential in Eq. (1), expanded the centrifugal term as a power series, and solved the resulting equation about a minimum by the Wentzel-Kramers-Brillouin method.[12] The formula which he thus obtained for the energy levels is

$$F_{v,j}=\sum_{lj} Y_{lj}(v+1/2)^l J^j(J+1)^j, \quad (3)$$

where the Y_{lj} are the spectral constants to be obtained from the frequency measurements, J is the rotational quantum number, and v is the vibrational quantum number. If the units of the Y_{lj} are defined as Mc/sec, $F_{v,j}$ becomes a power series for the energy levels in the same units.

Dunham's approach has been reviewed by Sandeman[15] and has been extended slightly to include those Y_{lj}

expressions which would be needed if measurements of the present accuracy could be made on vibrational transitions as well. Kilpatrick,[16] using a perturbation approach different from that of Dunham, has arrived at the same results as Sandeman and Dunham, in different form, except for his equation for Y_{00}, which includes D, a term for the dissociation energy. The term for the dissociation energy does not appear in the Dunham solution because this solution considers only the form of the potential in a restricted region near the minimum of the potential function. Sandeman has pointed out that the Dunham potential can be valid only over a limited region because of difficulty with convergence of the series potential for large ξ. Dunham's formulation, or Kilpatrick's, seems to be the only one, however, which can be used with the precise spectral data obtainable in the microwave region. It is satisfactory for the microwave measurements probably because the energy levels accessible to our microwave spectrometer lie sufficiently near the minimum of the potential curve for the formulation to apply. This theory was applied by Honig *et al.*[7] to their centimeter-wave measurements of the alkali halides made with their hot-cell spectrometer and by Rusk and Gordy[2] to their measurements of the alkali bromides and iodides made with their high-temperature molecular-beam spectrometer.

By applying the Bohr frequency condition,

$$\nu=(W_2-W_1)/h,$$

and the pure rotational absorption selection rules, $\Delta J=+1$, $\Delta v=0$, to the energy-level formula, one obtains the equation relating frequency ν, quantum numbers v, J, and structural constants Y_{ij}. The equation given below expresses this frequency in terms of those Dunham constants which have a measurable effect on the energy levels. The rotational quantum number for the lower level of the transition is represented by J.

$$\begin{aligned}\nu=&2Y_{01}(J+1)+2Y_{11}(v+\tfrac{1}{2})(J+1)\\&+2Y_{21}(v+\tfrac{1}{2})^2(J+1)+4Y_{02}(J+1)^3\\&+4Y_{12}(v+\tfrac{1}{2})(J+1)^3+Y_{03}(J+1)^3(J+2)^3.\end{aligned}\quad(4)$$

The relation of Y_{03} to other well-known structural constants is given by

$$Y_{03}=(2D_2/3\omega_e^2)(12B_e^2-\alpha_e\omega_e).\quad(5)$$

Subtraction of this term, in frequency units, from each measured line frequency ν, gives a corrected frequency ν'. The corrected frequencies ν_i' are used in the calculation of the five remaining constants with a least-square technique. The derived constants are calculated from the Y values with the following relations given by Dunham[12]:

$$Y_{10}=\omega_e=2(B_e^3/Y_{02})^{1/2},\quad(6)$$

$$a_0=\omega_e^2/4B_eC,\quad(7)$$

$$a_1=Y_{11}\omega_e/6B_e^2-1,\quad(8)$$

$$a_2=Y_{12}\omega_e^3/48B_e^4+2.375+2.25a_1+1.125a_1^2,\quad(9)$$

$$a_3=\omega_e^2Y_{21}/30B_e^3-1-2a_1+6a_2+2.6a_1a_2-1.5(a_1^2+a_1^3),\quad(10)$$

$$Y_{20}=-\omega_ex_e=-1.5B_e(a_2-1.25a_1^2),\quad(11)$$

$$Y_{00}=B_e(3a_2-1.75a_1^2)/8,\quad(12)$$

$$Y_{03}=16B_e^5(3+a_1)/\omega_e^4,\quad(13)$$

$$Y_{04}=-(64B_e^7/\omega_e^6)(13+9a_1-a_2+2.25a_1^2),\quad(14)$$

$$\beta_{01}=7.5+7a_1-4.5a_2+7.5a_3-11.5a_1a_2+5.25(a_1^2+a_1^3),\quad(15)$$

$$B_e=Y_{01}/(1+B_e^2\beta_{01}/\omega_e^2).\quad(16)$$

$$I_e=h/8\pi^2B_e,\quad(17)$$

$$\mu=M_1M_2/(M_1+M_2),\quad(18)$$

$$r_e=(I_e/\mu)^{1/2},\quad(19)$$

where B_e is set as equal to Y_{01} on the right-hand side of all equations except Eq. (16).

The probable error limits in the evaluated Y values were obtained by use of a statistical method[2] designed to produce a 99% confidence in the stated errors. The limits of error for the derived constants are based on these errors and have a 99% confidence level or better. The bulk of the data analysis was performed on the IBM-7072 digital computor available in the Duke University Digital Computing Laboratory.

Except for Y_{01}, the observed Dunham constants Y are related to the more familiar spectral constants for diatomic molecules, as follows:

$$\begin{aligned}&Y_{01}\simeq B_e \quad Y_{21}=\gamma_e \quad Y_{12}=-\beta_e\\&Y_{11}=-\alpha_e \quad Y_{02}=-D_e \quad Y_{03}=H_e.\end{aligned}\quad(20)$$

Similarly,

$$Y_{10}=\omega_e \quad Y_{20}=-\omega_ex_e.\quad(21)$$

The first of these relations, $Y_{01}\simeq B_e$, is only approximate, but the other relationships hold with sufficient accuracy for the results described here. For a further description of these spectral constants, see Herzberg's monograph.[17]

Because of the high J values involved in the transitions observed in the present work, no nuclear hyperfine structure was resolved. A negligible broadening of some of the lines by nuclear quadrupole interactions were the only hyperfine effects which could be observed. Thus we shall not outline the theory of nuclear interactions here. A treatment of these effects, which are resolvable at lower frequencies, is given by Honig *et al.*[7]

ROTATIONAL CONSTANTS

The measured frequencies for each of the alkali chlorides studied are listed in Table II. In the same table are given for comparison the theoretical values of the frequencies as calculated with the spectral constants given in Table III.

The six constants (Y_{01}, α_e, γ_e, D_e, β_e, and H_e) were calculated directly from the measurements for the isotopic species $CsCl^{35}$, $RbCl^{35}$, KCl^{35}, $NaCl^{35}$, and $Rb^{85}Cl^{37}$. For the species $CsCl^{37}$, KCl^{37}, $NaCl^{37}$, and $Rb^{87}Cl^{37}$, these measurements yielded only four constants (B_0, B_1, D_e, β_e) because observations of rotational transitions for only two vibrational states were made. For the latter, Y_{01} and α_e were derived from B_0 and B_1 by use of a value of γ_e calculated with the isotopic mass ratio formulas. These six structural constants for each molecule are shown in Table III.

Comparison of the RbCl and KCl data with previous results[4] obtained with molecular-beam electric resonance shows that the three constants making up $B_v(Y_{01},\alpha_e,\gamma_e)$ have comparably small errors for the two types of measurement and that they agree well within these errors. This experiment shows no improvement in B_v over that obtained from low J transitions accurately measured with molecular-beam, electric-resonance techniques because the fractional error in the measured frequencies for both experiments is comparable.

A comparison of the present data for CsCl and NaCl with those of the previously made hot-cell measurements[7] shows a significant improvement in accuracy in the values for the three constants making up B_v. The greatest improvement of the present study over the previous results arises in the measurement of the centrifugal distortion constants D_e and β_e and in the evaluation of other constants which are influenced by these constants. The earlier microwave measurements,

which were performed at lower frequencies, did not yield these constants.

The slight effects of Y_{03} or H_e on the observed frequencies were obtained from values of the other structural constants with the equation

$$Y_{03}=H_e=2D_e(12B_e^2-\alpha_e\omega_e)/3\omega_e^2). \quad (22)$$

Only one pass through the computor was required for reduction of the measured frequencies to structural constants when this calculated value was used. The values of H_e as calculated from previous constants and as calculated from the constants derived from the first passage through the computor agreed within the limits of the effect of the H_e's on the measured frequencies. Values for H_e, listed in Table III, show about two more significant figures than would have been obtained if the value for H_e had been extraced directly from the measured frequencies.

The measured constants under consideration have been found to be consistent under the mass ratio transformation within the experimental errors. The values for Y_{00} and Y_{04} (Table IV) have a number of significant figures and thus provide some check for the Dunham theory. Derived values for Y_{00} and Y_{04} are consistent for different isotopic species of the same molecule, as are all the derived constants presented in the following sections.

Equation (16) was used for derivation of B_e from Y_{01}. The equilibrium moment of inertia and equilibrium nuclear distance, I_e and r_e, were derived from B_e by use of Eqs. (17) and (19), respectively. These values are listed with two-figure errors to allow for adequate comparison between isotopes. If, at a later date, a more accurate value of Planck's constant h should become available, these values may be calculated from the data with greater absolute accuracy. Values for I_e and r_e both agree within their experimental errors with previous measurements because the five-figure accuracy of h masks the differences between these and the hot-cell measurements. All conclusions reached by Honig *et al.*[7] regarding I_e and r_e remain unaffected. Values for these constants are listed in Table V.

VIBRATIONAL CONSTANTS

The vibrational constants ω_e and $\omega_e x_e$ were derived from the experimentally observed Y's by use of the Dunham theory, Eqs. (6)–(20). Values thus obtained are compared in Table VI with the values obtained from infrared measurements by Rice and Klemperer.[18] The present values of ω_e agree within experimental error with those from their infrared data, but are an order of magnitude more accurate if one can trust the Dunham theory to hold within the limits of our experimental error. It is worthy of note that the ω_e values of Rice and Klemperer are in much better agreement with our ω_e values, and also with those of Rusk and Gordy on the alkali bromides and iodides than are any other previous values from infrared or optical spectroscopy. Through an oversight their excellent infrared values were not listed for comparison in the earlier paper.[2]

[a] From present data calculated with Dunham's theory.
[b] Infrared results of Rice and Klemperer (Ref. 18).

There is an interesting regularity evident in the comparison of the theoretical values of $\omega_e x_e$ from the Dunham equations, from a formula derived by Pekeris,[19] and the experimental values of Rice and Klemperer.[18] Pekeris' formula, shown below, gives better agreement with the $\omega_e x_e$ values of Rice and Klemperer than does the Dunham expression for the lighter molecules, particularly NaCl (see Table VII). The agreement of infrared data with the Dunham or Pekeris formula shows a regular variation with increasing molecular mass.

[a] Calculated with Dunham's Theory.
[b] Infrared measurements, Rice and Klemperer (Ref. 18).
[c] Calculated with Pekeris's theory (Morse potential).
[d] Rusk and Gordy (Ref. 2).

[18] S. A. Rice and W. Klemperer, J. Chem. Phys. 27, 573 (1957).
[19] C. L. Pekeris, Phys. Rev. 45, 98 (1934).

The Pekeris formula for $\omega_e x_e$ follows from one for α_e, which was derived from a perturbation treatment with the Morse potential[14] as a basis.

$$\alpha_e = (2\omega_e x_e B_e/\omega_e)[3(B_e/\omega_e x_e)^{1/2} - 3(B_e/\omega_e x_e)]. \quad (23)$$

This equation may be solved for $\omega_e x_e$ to give

$$\omega_e x_e = B_e[(\alpha_e \omega_e/6B_e^2)+1]^2, \quad (24)$$

which in terms of Dunham's constant a_1 is

$$\omega_e x_e = B_e a_1^2. \quad (25)$$

Formula (25) may also be obtained from Dunham's relations if Y_{00} is equated to zero in Eq. (12) and the expression thus obtained for a_2 is substituted into Dunham's Eq. (11) for Y_{20}. By Eq. (11), Y_{20} equals $-\omega_e x_e$. The constant Y_{00} is invariant between isotopic species and is independent of the nuclear mass of a given molecule. Therefore, Y_{00} must be dependent on the nature of the potential function. It cannot arbitrarily be set to zero because its value is determined by the potential coefficients a_1 and a_2, whose values depend on the measured rotational constants. Table IV shows that the value for Y_{00} obtained from the rotational constants is definitely not zero.

The only spectral quantity which shows any possibly significant discrepancy within the Dunham theory is the anharmonicity constant, $\omega_e x_e$. This possible discrepancy should be examined further. Although Rice and Klemperer did not give estimates of the limits of error for their $\omega_e x_e$ values, the good agreement between their ω_e values and those of the present study gives credence to their $\omega_e x_e$ values. The Dunham theory is based upon an expansion of the potential function in a power series around the equilibrium position. The Morse potential function upon which the Pekeris formula is based should give a better representation than does the Dunham potential for regions not so near the equilibrium position. This might explain the better agreement of the Pekeris formula with the $\omega_e x_e$ values from the infrared measurement of the lighter molecules with their higher vibrational energies. Varshni and Sukla[20] compare these and other observed constants of the alkali halides with values calculated from a number of different potential functions. It is of interest to compare their different values for $\omega_e x_e$ (see their Table IV) with those obtained here.

MASS RATIOS

The mass ratios between Cl^{35} and Cl^{37}, also those between Rb^{85} and Rb^{87}, were calculated for all the molecules measured. All mass ratios are shown in Table VIII, along with some previously obtained values for

for each individual molecule. They were obtained with Eqs. (6)–(20). The potential coefficients between isotopic species are equal (within the stated errors) as should be expected.

Table X, which includes results for the bromides and iodides by Rusk and Gordy,[2] compares values of a_0, a_1, a_2, and a_3 for three different halides of the same alkali metals. The coefficients a_1 are shown to be approximately the same between the iodide, the bromide, and the chloride for a given alkali metal, except for cesium, where the relationship is one of slightly increasing absolute value of a_1 with decreasing mass. The coefficients a_0 also show a regularity in that a_0 increases smoothly with decreasing halide mass for the same alkali metal. These regularities were noted in the results on the iodides and bromides previously reported from this laboratory.[2] This chloride work extends and confirms them. They had not been shown before the development of our millimeter-wave, molecular-beam spectrometer, apparently because values of D_e and β_e were not available to sufficient accuracy for precise calculation of the potential coefficients. For comparison, we have given in parentheses the potential coefficients earlier obtained by Honig *et al.*[7] It will be noted that in many instances there are rather wide discrepancies between our values and theirs.

[a] Data for bromides and iodides come from Rusk and Gordy (Ref. 2), those for chlorides from the present study. Values given in parentheses are those of Honig *et al.* (Ref. 7).

FUTURE WORK

Modifications of the oven are being made which will permit measurements to be made on substances which vaporize at higher temperatures than do the alkali chlorides. Millimeter-wave rotational transitions of NaF in different vibrational states have already been detected,[21] and it is hoped that a series similar to these on bromides, iodides, and chlorides can soon be reported from this laboratory on the alkali fluorides.

Precision Evaluation of the High-Frequency Limit of the Continuous X-Ray Spectrum Using a Gas Target X-Ray Tube*†

JON J. SPIJKERMAN‡ AND J. A. BEARDEN
Department of Physics, The Johns Hopkins University, Baltimore, Maryland
(Received 30 December 1963)

The major uncertainty in previous measurements of the high-frequency limit of the continuous x-ray spectrum was due to the fine structure associated with the observed cutoff. The development of a high-power mercury vapor target x-ray tube permitted observations to be made under idealized thin-target conditions. The x-ray intensity near the high-frequency limit was comparable to that of a solid target x-ray tube. The x-ray intensity was measured as a function of the voltage applied across the tube, with a double-crystal monochromator adjusted for the 1.537400 kxu wavelength of the Cu $K\alpha_1$ line. The absence of fine structure in the observed isochromat, in contrast to most solid targets, greatly increased the accuracy in the determination of the voltage cutoff. Accurate measurements of this voltage yielded a voltage-wavelength conversion factor $V\lambda_s = (12372.26 \pm 23$ ppm) xu-volts. Using h/e from non-x-ray data, the x-ray wavelength conversion factor from x units to cm (or angstroms) can be calculated, or conversely h/e evaluated. The effects of a revision in the Cu $K\alpha_1$ wavelength, which is now in publication by one of the authors, are also discussed.

INTRODUCTION

ELEMENTARY quantum theory considerations give the short wavelength limit of the continuous x-ray spectrum in terms of the voltage applied to the x-ray tube. This relation is $Ve = h\nu$, which may be rewritten as

$$h/e = V\lambda_s(\Lambda/c^2), \tag{1}$$

where h/e (the ratio of Planck's constant to the charge on the electron) is expressed in erg·sec/esu, V in volts, λ_s in kxu, and c, the velocity of light, in cm/sec. $\Lambda = \lambda_g/\lambda_s$, the x-ray wavelength conversion factor, represents the ratio between wavelength on the Siegbahn scale and wavelength on the absolute scale, i.e., Å/kxu. (1 kxu $= 10^3$ xu.)

This relationship has traditionally been used as a means of measuring h/e, but of course the x-ray measurement only evaluates $V\lambda_s$. The three[1–3] most precise evaluations of $V\lambda_s$ and the calculated values of h/e have yielded values which were considerably lower than those obtained through non-x-ray measurements.[4] The discrepancy was so great that DuMond and Cohen[5] gave such values a low weight in their evaluation of atomic constants while Bearden and Thomsen[4] excluded these measurements entirely. This discrepancy was largely attributed to the fine structure observed at the high-frequency limit of the continuous spectrum. Detailed measurements of the structure as a function of atomic number and voltage applied to the x-ray tube have been made by Johnson[6] and Per Johansson.[7] Its origin has been interpreted by Ulmer[8] as due to solid-state band structure. The initial state of the electron is determined by the cathode of the x-ray tube while the final state is characterized by the target. The distribution of those unoccupied energy levels to which a significant number of transitions are allowed then determines the shape of the continuous spectrum near cutoff. In principle this result holds only for a "thin target"; however since characteristic energy losses[9] occur in discrete steps of the order of 10 eV, it will also hold for a thick target within a few electron volts of the cutoff point.

In order to eliminate the fine structure, due to the solid state, a gas target x-ray tube[10] has been developed in which an electron beam of 20–50 mA and 8–20 kV is focused to a mercury jet as target. The intensity observed near the high-frequency limit is comparable to that of a solid target. This effectively thin target satisfies the assumptions of the Sommerfeld[11] theory and hence greatly simplifies the interpretation of the measurements which can then be used to obtain a refined value of h/e. On the other hand, if h/e is known with sufficiently high accuracy from non-x-ray sources, it gives a means of determining Λ, as is evident from Eq. (1). At the present moment, the relative uncertainty in the value of Λ appears somewhat greater than

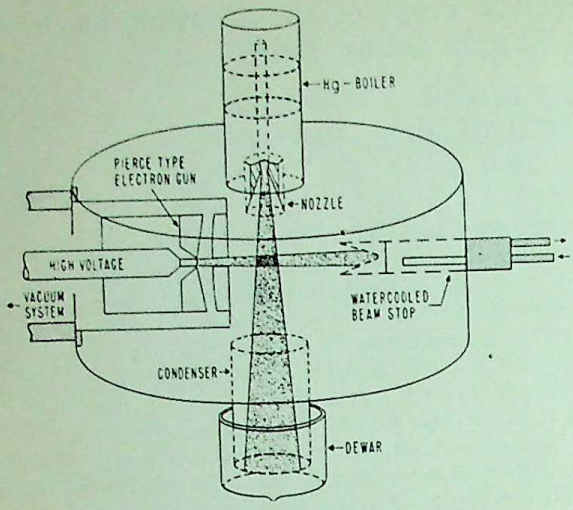

FIG. 1. Three-dimensional view of the gas target x-ray tube.

that of h/e, although both are of the same order of magnitude.

In interpreting the results, certain small corrections to the measured potential are essential, including those due to space charge and to work functions of the cathode and anode.[12] These are obtained, in part by a measurement of the ionization potential of the gas.

GAS TARGET X-RAY TUBE

Two gas target x-ray tubes have been used in the present work. The basic principles of both tubes are shown schematically in Fig. 1. The x rays were observed along an axis which was perpendicular to both the electron beam and the mercury jet.

The required area density of the jet can be estimated as follows: From solid target measurements[13,14] and electron energy losses in thin foils[9] it can be shown that the radiation near the high-frequency limit is produced by a solid target thickness of the order of 500 Å. Thus, to obtain sufficient x-ray intensity for precision measurements, the total atomic cross section for the gas target should be equivalent to a 500 Å thickness of a solid. This was achieved by using a vapor jet formed by a nozzle, as shown in Fig. 1. The diameter of the mercury beam as indicated by the focal spot was approximately 5 mm. The vapor was formed by an electrically heated Hg boiler, and the jetstream directed into a dry-ice cold trap. The freezing out of the Hg vapor greatly reduced the pumping speed required to maintain a pressure of 10^{-4} mm of Hg in the target chamber. A 500 liter/sec mercury vapor diffusion pump and liquid nitrogen traps were used to evacuate the electron gun and high voltage section of the x-ray tube.

The electron beam was formed by a two-element Pierce electron gun,[15] with a unipotential dispenser cathode.[16] This gun operated very satisfactorily, and at 8 kV produced a maximum beam current of 50 mA with a beam diameter of about 3 mm. The accelerating anode of the Pierce gun, the electron collector (beam stop), the nozzle, and the condenser were all electrically connected and maintained at ground potential, except for possible small effects such as contact and thermal emf's. The presence of Hg atoms in the tube largely neutralized the space charge[17] and collimated the electron beam through gas focusing. However, the ion bombardment of the cathode reduced its life to approximately 40 h.

In order to obtain effective work function corrections, as described in the section on corrections and probable errors, the ionization potential of Hg was measured by the usual method. This required a shielding grid at the potential of the target chamber and an ion collecting plate at a small negative potential. (These auxiliary electrodes are not shown in Fig. 1.) In the first tube a small grid and plate were inserted through the port where the x-ray beam was normally observed. In the second tube, both the stainless steel grid and plate were cylindrical and concentric with the mercury jet, with openings to permit passage of the electron and x-ray beams; they remained in place throughout the x-ray measurements, permitting an ionization curve to be run after each isochromat.

The first tube[18] was essentially two intersecting stainless steel cylinders each 2 in. in internal diameter and 4.5 in. long. The mercury jet was directly vertically upwards and an arrangement provided for condensing the mercury and returning it to the boiler. The second tube was designed on a larger scale, the actual geometry being very similar to the schematic shown in Fig. 1. The enclosing steel cylinder was 11 in. i.d. and 3.5 in. in height, with end plates of 0.5 in. thickness. The mercury jet was directly vertically downwards; no return was provided, since less than 300 cc of mercury was required for a 12-h run.

POWER SUPPLY AND MONOCHROMATOR

Power supply. The high-voltage regulated power supply and the high-voltage measurement circuit were basically the same as reported by Bearden and Schwarz,[1] with minor modifications. The regulating amplifier was replaced by a commercial high-gain operational amplifier, and a phase-shift-free voltage divider[19] was designed for the feedback loop. This circuit reduced the ripple voltage to 0.05 V peak to peak.

The high voltage V_m (see Table I) was measured with

a precision voltage divider and a potentiometer. The precision voltage divider, consisting of an 8526-Ω protective resistor in series with two 1-MΩ standard resistors (each with 10 subdivisions) and two standard resistors of 100 Ω, was so arranged that the smaller voltage was almost exactly equal to that of a standard cell for the average value of high voltage used in the measurements. The precision potentiometer then was used only to measure the small incremental difference between the voltage drop in the two 100-Ω standards of the divider and that of the standard cell. Hence the high voltage V_m was determined from the difference between the emf of the NBS 968 saturated standard cell and the potentiometer reading ΔE, multiplied by the voltage divider ratio of 8047.688. The standard resistors and standard cells used have been calibrated by the National Bureau of Standards a number of times, including one check during the present experiment.

Monochromator. A double-crystal spectrometer,[20] with quartz crystals cut parallel to the $10\bar{1}1$ plane, was used for a monochromator with a resolution of approximately 13 000 as determined from the parallel $(1, -1)$ position rocking curve. The monochromator was adjusted for the wavelength of the Cu $K\alpha_1$ line, which is one of the best known standard x-ray wavelengths. The monochromator was aligned by replacing the vapor target with a Cu target, and accurately calibrated against the $K\alpha_1$ line, assuming a peak wavelength of 1.537400 kxu.[21] In the different experimental runs the exact wavelength setting was determined with respect to this peak angle position. The x rays were detected by a scintillation counter with a 25-mil-thick NaI(Tl) crystal placed on a selected photomultiplier tube and shielded by a low radioactive iron housing. For a pulse-height discriminator setting which gave 80% detection efficiency the background was 0.3 counts/min.

ISOCHROMATS

In principle the high-frequency limit of the continuous spectrum can be found most simply by holding a fixed voltage on the x-ray tube and determining the shortest wavelength emitted. In practice it is usually more convenient to adjust the monochromator for a fixed wavelength and determine the variation of intensity as the voltage is changed in small steps. The resulting curve is called an isochromat.

Four averaged isochromats were used in the four runs shown in Table I. These were obtained as follows: Each averaged isochromat is the composite of ten individual isochromats. Seventeen voltage points in the vicinity of cutoff were selected and the x-ray intensity recorded for a period of 200 sec at each point. In order to minimize instrumental drift, these measurements were first recorded for increasing voltage and then repeated for decreasing voltage for each individual isochromat. After initial adjustment of the apparatus was completed and definitive recording was begun, no individual isochromat was rejected for any reason. One of the averaged isochromats is indicated by the data points in Fig. 2, where the normalized intensity is plotted against voltage change. Measurements up to 500 V above the short wavelength limit indicated no further appreciable increase in intensity.

Since the profile near the high-frequency limit is of primary interest, both for an h/e determination (or $V\lambda_s$) and from a theoretical standpoint, the observed

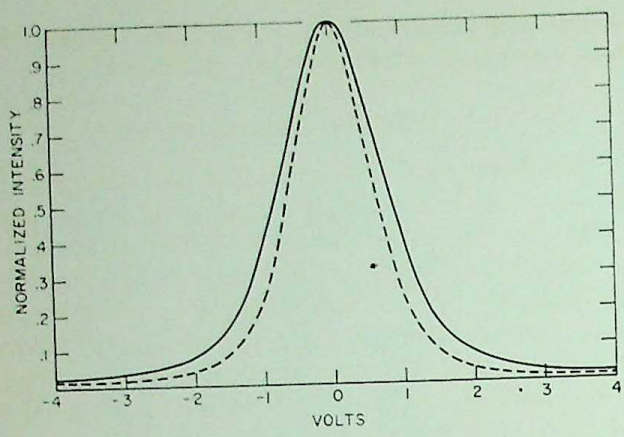

FIG. 2. Experimental window (solid line) and theoretical window (dashed line) of the double-crystal monochromator.

isochromat was corrected for instrumental smearing, which is primarily due to the width of the monochromator window. This window, shown in Fig. 3, was obtained from the parallel position (1,−1) rocking curve using a copper target. The double crystal diffraction pattern was also calculated from the Darwin-Prins-Ewald theory of single crystal diffraction.[22] The greater width of the observed pattern must be attributed to slight imperfections in the quartz crystals. A study of the crystals[23] showed that they were not perfect specimens. Since a 3 cm width of the crystal was used for both copper and vapor targets (due to the extended x-ray source), the crystal irregularities broadened the diffraction pattern.

The measured window was used to correct the observed isochromat, but the extended wings made an unfolding procedure inaccurate. This difficulty was avoided by using an IBM-7094 computer to fold assumed isochromat profiles with the observed window and finding the best fit for the observed data. The assumed profiles were based on the Sommerfeld theory,[24] which gives the x-ray intensity as a constant independent of the frequency for $h\nu<eV$, and zero for $h\nu>eV$. However, near cutoff the shape of the profile is determined by the distribution of final states available to the electron. If one assumes no electric or magnetic field at the target, the density of final states is proportional to $(\Delta E)^{1/2}$, where $\Delta E=e(V-V_0)$ or the energy difference between the incoming electron and the emitted photon.[25]

Consequently the x-ray intensity was represented by the empirical relation

$$I=I_0\{1-\exp[-\alpha(V-V_0)^{1/2}]\}, \qquad (2)$$

where α is an adjustable parameter. Equation (2) approximates the Sommerfeld profile, except near the high-frequency limit, and becomes proportional to the density of the final states as this limit is approached. The observed x-ray intensity should be given by folding Eq. (2) with the observed window of Fig. 3.

The parameters V_0 and α were varied stepwise; for each pair of values an isochromat was computed, and compared with the observed curve. The best fits were obtained with values of α between 1 and 2 V^{-1}; outside this range the predicted isochromat varied significantly from the observed one. The isochromats for these two values of α are shown in Fig. 2. For the best fit the value of V_0 differed only about 5 ppm from the voltage at the half-intensity point; hence, the latter was used as a sufficiently accurate criterion for the high-frequency cutoff.

CORRECTIONS AND PROBABLE ERRORS

Work Function Correction

The voltage measured, V_m, represents the potential across the x-ray tube and not the electron energy, since contact potentials and the initial thermal electron energy must be taken into account. In the solid target h/e experiments, the applied potential must be corrected for the work function of the cathode only; the work function of the anode is not involved, since the electron comes to rest near the Fermi level of the anode. For the gas target tube, however, both initial and final states are those of a free electron, and the difference between the work function of the cathode φ_c and the anode φ_a plus the thermal energy kT must be added to the measured potential.

The retardation of the electrons due to the space charge *at the cathode* has the effect of increasing the cathode work function. This space charge potential V_s

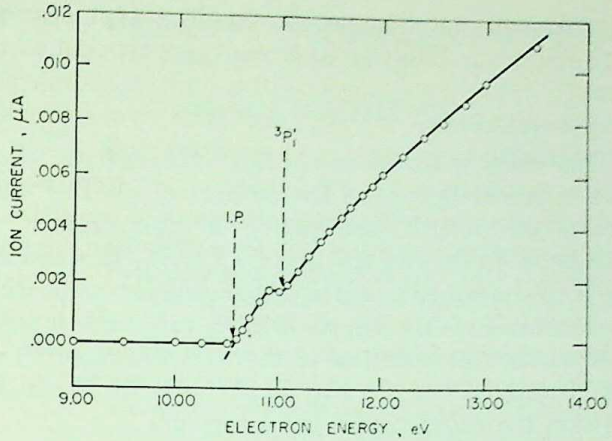

FIG. 4. Experimentally determined probability of ionization by electron impact in Hg gas. Cathode temperature 1493°K.

can be calculated[26] from the cathode work function φ_c, the critical cathode temperature θ (where the space charge minimum disappears), and operating temperature T, by

$$V_s=\varphi_c\left(\frac{T-\theta}{\theta}\right)-\frac{kT}{e}\ln\frac{I}{I_\theta}. \quad (3)$$

In this expression I_θ represents the cathode current at the critical temperature θ, and I that at operating temperature T, while k and e are the Boltzmann constant and the electronic charge. With the above-mentioned corrections to the measured voltage V_m, the effective difference V becomes

$$V=V_m+V_{kT}+(\varphi_c-\varphi_a)+V_s. \quad (4)$$

To determine these correction terms experimentally, a measurement was made of the ionization potential[27] of Hg (for which a value of 10.434 V is known from spectroscopic data). The observed probability of ionization by electron impact for Hg vapor is indicated in Fig. 4. The structure in the curve is due to autoionization [28] corresponding to the $^3P_1{}^1$ state of mercury 0.6 eV above the ground state, which competes with the ionization process.

For the ionization potential of mercury at the same cathode temperature, the relation corresponding to Eq. (4) is

$$V_i=V_{mi}+V_{kT}+(\varphi_c-\varphi_a)+V_{si}, \quad (5)$$

where the subscript i denotes quantities involved in the ionization potential measurement. Subtracting Eq. (5) from Eq. (4) and making use of Eq. (3) now yields

$$V=V_m+V_i-V_{mi}-\frac{kT}{e}\ln\frac{I}{I_i}, \quad (6)$$

the last term being simply V_s-V_{si}. Numerical values of these correction terms are shown in Table I.

Potential Depression

Since there is no external electric field acting on the electron beam in the target chamber, the space charge effects could produce a potential variation across the electron beam, which might become significant at moderate current densities.[29] The space charge effect would lower the electron energy. It should also produce an energy spread of several electron volts in the cutoff of the isochromat, unless it is largely neutralized by the presence of positive ions, which are trapped by the electron beam. Linder and Hernqvist[30] have studied the degree of neutralization of space charge by positive ions, and derived an expression for the potential depression as a function of the gas pressure.

For an operating pressure of 10^{-5} mm Hg in the described apparatus, the calculated voltage depression V_D is 0.07 V (Table I). This could be in error by 0.07 V, since complete neutralization would take place at 2×10^{-4} mm Hg and the pressure measurement could be in error by an order of magnitude.

Errors

The probable errors, in parts per million (ppm) of the final result are estimated as follows:

1. Determination of the voltage at the isochromat cutoff:	
Potentiometer measurements	3.5 ppm
Precision voltage divider	2.0
Isochromat cutoff	12
Work function correction	13
Voltage depression	9
Total (rms)	21 ppm
2. Spectrometer calibration	10 ppm

Total probable error in the voltage-wavelength conversion factor is thus 23 ppm; the error in the conversion factor from NBS to absolute volts (5 ppm) does not significantly increase this figure.

The four separate runs were assigned weights based on the statistics of the isochromat recording.

RESULTS

A summary of the experimental results is given in Table I. The total recording time for each run was slightly less than 19 h. Runs 1 and 2 were made with the tube briefly described in the gas target x-ray tube section and reported in detail in the thesis of one of the authors (J. J. S.). Runs 3 and 4 were made with the tube design shown in Fig. 1. The excellent agreement of the final values lends support to the methods and experimental measurements involved in applying the necessary corrections.

The voltage of standard cell E (actually three were used and frequently intercompared) has been corrected for the difference between the National Bureau of Standards volt and the absolute volt, using the conversion factor given by Driscoll and Cutkosky[31]

$$1 \text{ NBS volt} = 1.000\,010 \text{ absolute volts} \pm 5 \text{ ppm}.$$

ΔE is the incremental voltage measured by the K3 potentiometer.

As shown in Table I the weighted average of the above measurements gives

$$V\lambda_s = (12\,373.26 \pm 23 \text{ ppm}) \text{ xu-volts}.$$

Combining this with the commonly accepted value of $\Lambda = 1.002\,02 \pm 20$ ppm and $c = 299\,792.5$ km/sec,[32] one obtains

$$h/e = (1.379\,49 \pm 30 \text{ ppm}) \times 10^{-17} \text{ erg} \cdot \text{sec/esu}.$$

The non-x-ray value[32] is

$$h/e = (1.379\,47 \pm 7 \text{ ppm}) \times 10^{-17} \text{ erg} \cdot \text{sec/esu}.$$

The probable errors overlap, and for the first time the x-ray and non-x-ray values of h/e are in good agreement. However, the probable error of the x-ray value is more than four times that of the non-x-ray one. Approximately half of this is due to the uncertainty in the value of Λ.

DuMond and Cohen[33] have pointed out that the optical calibration lines used by Tyrén[34] in his concave grating measurement of Λ require correction for the Lamb shift. This might increase his reported value of $\Lambda = 1.001\,99$ by the order of 50 ppm (due to loss of data and plates it is impossible to determine the exact correction). DuMond and Kirkpatrick in a recent report to the National Science Foundation on a new concave grating experiment give a provisional value

$$\Lambda = 1.001\,80 \pm 10 \text{ ppm}.$$

This is about 200 ppm lower than Tyrén's value or the plane grating values. Thus the true value of Λ may be considerably outside the $1.002\,03 \pm 20$ ppm range calculated by Birge,[35] based principally on measurements with plane gratings.

From these considerations the measured value of $V\lambda_s$ could best be used to evaluate Λ. With $h/e = (1.37947 \pm 7 \text{ ppm}) \times 10^{-17}$ erg·sec/esu[32] the value is

$$\Lambda = 1.002\,005 \pm 24 \text{ ppm}.$$

This value is based on Cu $K\alpha_1 = 1537.400$ xu. However, a report by one of the authors (J. A. B.)[36] on a serious wavelength discrepancy of approximately 20 ppm between the Mo $K\alpha_1$ and the Cu $K\alpha_1$ xu standards has been confirmed and is in preparation for publication. On the basis of Mo $K\alpha_1$ as 707.831 xu (which is taken as a provisional definition of the xu in this report[37]) the wavelength of the Cu $K\alpha_1$ is 1537.370 xu. With this revision the experimental value becomes

$$V\lambda_s = (12\,373.02 \pm 23 \text{ ppm}) \text{ xu} \cdot \text{V}$$

and

$$\Lambda = 1.002\,024 \pm 24 \text{ ppm}.$$

(This revision will not significantly alter the value of h/e calculated above, since the change in Cu $K\alpha_1$ wavelength also implies a compensating change in the ruled grating values of Λ.)

CONCLUSION

The absence of structure and the sharpness of the high-frequency limit of the continuous x-ray spectrum, together with a measurement of the work function correction made possible a precision determination of $V\lambda_s$. The lack of structure in the gas target isochromat tends to support Ulmer's theory as to the origin of the structure. The profile of the isochromat gave the shape of the continuous spectrum produced by single electron bombardment. The measured intensity was constant from a few eV of cutoff to 500 eV above in accordance with the Sommerfeld theory.

With the use of the non-x-ray value of h/e, a precision determination of Λ has been obtained. The accuracy of this value appears comparable to those obtained by either ruled-grating or crystal measurements.

Inelastic Scattering of Electrons by the Hydrogen Molecule Ion*

JAMES M. PEEK
Sandia Laboratory, Albuquerque, New Mexico
(Received 23 December 1963)

The inelastic scattering of electrons by H_2^+ is investigated by means of the first Born approximation. Using the exact electronic wave functions, the integral that must be evaluated to find the differential cross section for fixed internuclear separation is studied for an electronic excitation from the ground state to any discrete excited state. Values related to this integral are tabulated for the processes $1s\sigma_g$–$2p\sigma_u$, $1s\sigma_g$–$2p\pi_u$, $1s\sigma_g$–$2s\sigma_g$ at the equilibrium internuclear distance, while the first case is studied at two additional internuclear separations. The corresponding total cross sections are calculated for incident energies up to 400 eV. Assuming that rotational and vibrational levels of the final electronic state cannot be resolved, it is known that an observed cross section necessarily depends on the initial vibrational state of the molecular ion. The effect of two different initial vibrational states ($\nu=0,3$) is investigated for the $1s\sigma_g$–$2p\sigma_u$ case and it is observed that the vibrational state has a marked influence on the total cross section.

INTRODUCTION

THE problem of inelastic electron scattering by molecules has a complication in addition to those found when considering scattering by atomic systems in that the internal degrees of freedom of the molecule must be taken into consideration. However, in the range of incident energies where the first Born approximation can be expected to be valid, experimentally determined cross sections which resolve rotational effects on electronic transitions have yet to be published, and it appears that the resolution of vibrational structure is just now becoming an experimental possibility. This being the case, it seems highly plausible to treat the internal degrees of freedom so that specific vibrational and rotational excitations are ignored while considering a given electronic process. A detailed analysis of the first Born approximation to scattering by molecules, where the above treatment of the internal modes was employed, has been given by Lassettre[1] and by Craggs and Massey.[2] Following their treatment, the differential cross section, where the excitation is $n\rightarrow n'$ for the electronic system, $L,M\rightarrow L',M'$ for rotation and $\nu\rightarrow\nu'$ for vibration, can be written

$$I(nLM\nu,n'L'M'\nu';\theta)$$
$$=(4k_{n'}/k_nK^4)\left|\int_0^\infty\int_0^{2\pi}\int_0^{\pi}\epsilon(K,\delta,\xi,R)\cdot\Theta_{LM}(\delta,\xi)\Theta_{L'M'}{}^*(\delta,\xi)\mathrm{X}_\nu(R)\mathrm{X}_{\nu'}{}^*(R)R^2\times\sin\delta d\delta d\xi dR\right|^2. \quad (1)$$

Θ, X are rotation and vibration functions, respectively, where it has been assumed that these functions do not mutually interact in addition to the usual assumption that the nuclear and electronic coordinates are separable. This expression and all remaining equations are given in atomic units unless stated otherwise. The quantity ϵ is defined for a molecule with j electrons as (neglecting spin variables)

$$\epsilon(K,\delta,\xi,R)=\int\Psi_{n'}{}^*(\mathbf{r}_1\cdots\mathbf{r}_j;R)\left[\sum_{i=1}^{j}\exp(i\mathbf{K}\cdot\mathbf{r}_i)\right]\times\Psi_n(\mathbf{r}_1\cdots\mathbf{r}_j;R)d\mathbf{r}_1\cdots d\mathbf{r}_j, \quad (2)$$

where the states n,n' cannot be the same. The quantities K, δ, ξ, R refer to the parameters that must be fixed during the integration over the electronic coordinates. The symbol K, the magnitude of $\mathbf{K}$, defines the momentum change of an incident electron scattered through an angle θ; $K^2=k_n{}^2+k_{n'}{}^2-2k_nk_{n'}\cos\theta$, where k_n, $k_{n'}$ are the magnitudes of the momentum for the incident electron before and after scattering. The angles δ, ξ fix the orientation of the molecule in space and R is the internuclear distance. Lassettre[1] has shown that the differential cross section becomes

$$I(n\nu,n'\nu';\theta)=(4k_{n'}/k_nK^4)\left\{(1/4\pi)\times\int_0^{2\pi}\int_0^{\pi}\left|\int_0^\infty\epsilon(K,\delta,\xi,R)\mathrm{X}_\nu(R)\mathrm{X}_{\nu'}{}^*(R)R^2dR\right|^2\times\sin\delta d\delta d\xi\right\} \quad (3)$$

when one sums over all final rotational states and averages over the degenerate levels of the initial state. Equation (3) will be true if the rotation of the molecule can be described by a symmetrical top and if the dependence of $k_{n'}$, K on $L'M'$ is ignored.[1] It has been

assumed that the final vibrational levels cannot be resolved, so a sum over all ν' can be made, which gives

$$I(n\nu,n';\theta)=(4k_{n'}/k_nK^4)\Big\{(1/4\pi)\times\int_0^\infty\int_0^{2\pi}\int_0^{\pi}|\epsilon(K,\delta,\xi)|^2|X_\nu(R)|^2R^2\sin\delta\times d\delta d\xi dR\Big\} \quad (4)$$

if the dependence of $k_{n'}$, K on ν' is neglected. This is then the first Born approximation for a given electronic excitation of a molecule when the final rotational and vibrational states of the system are unresolved.

The simplest molecular system available for study is the hydrogen molecule ion. Previous calculations on electron scattering by this system have been reported by Ivash[3] and Kerner.[4] Ivash treats the electronic excitation $1s\sigma_g$–$2p\sigma_u$ (in the notation of Bates, Ledsham and Stewart[5]), where he approximates to the ground vibrational state by fixing $R=R_e$, the equilibrium internuclear distance, and then evaluates Eq. (4) by ignoring the integration over R. In evaluating Eq. (2), he also treats the possibility of electron exchange. Kerner does not use Eq. (4), but evaluates Eq. (1) by considering an excitation to a specific rotational and vibrational state while treating the $1s\sigma_g$–$2p\sigma_u$ electronic transition. In each of these studies, the electronic wave functions that appear in Eq. (2) were replaced by linear combinations of $1s$ atomic orbitals. Since the exact wave functions for H_2^+ (assuming fixed nuclei) are available[5] and the use of exact wave functions for the scatterer is assumed in the derivation of the first Born approximation, it would seem that electron scattering by H_2^+ should be reexamined using these wave functions. This will make it possible to give a quantitative estimate of the error introduced into the first Born approximation when approximate electronic wave functions are used to evaluate Eq. (2), at least for this relatively simple case. In addition, there are a number of electronic processes which can be expected to contribute to the inelastic scattering by H_2^+ and it would be interesting to obtain quantitative information about some of these electronic transitions.

The integral defined in Eq. (2) is studied for transitions from the ground state to any discrete excited electronic state. It is found that this integral can be evaluated analytically with respect to all coordinates except one. The behavior of this integral as a function of K and the orientation parameters is explored and a quantitative example is given for one transition. A table of this integral, after the appropriate integration over nuclear orientation has been performed, is given for the transitions $1s\sigma_g$–$2p\sigma_u$, $1s\sigma_g$–$2p\pi_u$, $1s\sigma_g$–$2s\sigma_g$. All transitions are studied at the equilibrium internuclear distance while the $1s\sigma_g$–$2p\sigma_u$ case is evaluated at two additional internuclear separations. The total cross section for incident energies up to 400 eV and fixed R is then calculated for these various cases. The effect of two different vibrational states for the ground state, $\nu=0$, 3, is also studied for the $1s\sigma_g$–$2p\sigma_u$ transition and the corresponding total cross sections are given.

GENERAL CONSIDERATIONS

The total cross section corresponding to Eq. (4) is

$$Q_\nu=\int I(n\nu,n';\theta)d\Omega=(8\pi/k_n^2)(1/4\pi)\times\int_{kn-kn'}^{kn+kn'}\int_0^\infty\int_0^{2\pi}\int_0^{\pi}\left\{\frac{|\epsilon(K,\delta,\xi,R)|^2}{K^3}\right\}|X_\nu(R)|^2\times R^2\sin\delta d\delta d\delta d\xi dRdK, \quad (5)$$

where $d\Omega$ is the solid-angle volume element. Carrying out the integration over the orientation angles,[1]

$$|\epsilon(K,R)|^2=(1/4\pi)\int_0^{2\pi}\int_0^{\pi}|\epsilon(K,\delta,\xi,R)|^2\sin\delta d\delta d\xi \quad (6)$$

is found. Defining

$$Q(R)=(8\pi/k_n^2)\int_{kn-kn'}^{kn+kn'}[|\epsilon(K,R)|^2/K^3]dK \quad (7)$$

and interchanging the order of integration, the total cross section becomes

$$Q_\nu=\int_0^\infty Q(R)|X_\nu(R)|^2R^2dR. \quad (8)$$

In order to obtain $Q(R)$ the integrations defined by Eqs. (2), (6), (7) must be carried out for a fixed R. Then $Q(R)$ must be found as a function of R to effect the evaluation of Eq. (8).

For the hydrogen molecule ion, Eq. (2) becomes

$$\epsilon(K,\delta,R)=\int_1^\infty\int_0^{2\pi}\int_{-1}^{1}\exp\{(iKR/2)[\lambda\mu\cos\delta+[(\lambda^2-1)(1-\mu^2)]^{1/2}\sin\phi\sin\delta]\}\times\Psi_n\Psi_{n'}^*(R/2)^3(\lambda^2-\mu^2)d\mu d\phi d\lambda, \quad (9)$$

where the coordinate system is shown in Fig. 1. It should be noted that for any linear scattering system ξ can be suppressed. The wave functions to be used in evaluating Eq. (9) are given by Bates, Ledsham, and

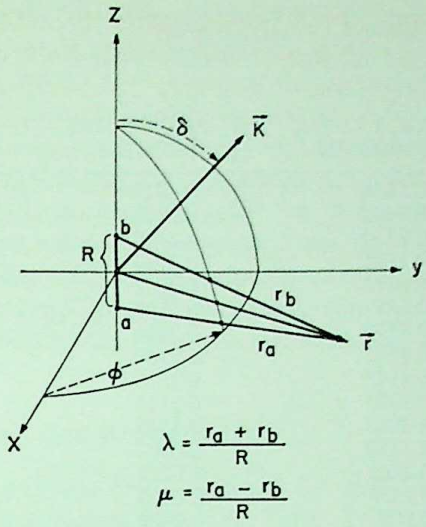

FIG. 1. The coordinate system for H_2^+ and its orientation with respect to K.

Stewart[5] and are of the form

$$\Psi_n = \left[(\lambda+1)^{\sigma}(\lambda^2-1)^{m/2} e^{-p\lambda} \sum_i q_i \left(\frac{\lambda-1}{\lambda+1}\right)^i \right] \times \left[\sum_t{}' f_t P_{t+m}{}^m(\mu)\right] e^{\pm im\phi}. \quad (10)$$

The primed sum means that only even or odd values of t are to be used. The quantities σ, p, m are eigenparameters for the nth state and $P_{t+m}{}^m$ is an associated Legendre polynomial of the first kind. The product $\Psi_n \Psi_{n'}{}^*$ appearing in Eq. (9) can be written in the form

$$\mu^2 \Psi_n \Psi_{n'}{}^* = \mu^2 f(\lambda) \exp(im\phi) \sum_t{}' a_t P_{t+m}{}^m(\mu)$$

$$= f(\lambda) \exp(im\phi) \sum_t{}' b_t P_{t+m}{}^m(\mu), \quad (11)$$

since the product of any two Legendre polynomials can be written as a sum of Legendre polynomials. [See Ref. 6 for a general formula applicable to the case $m=0$.] The ground state involves only terms of the type P_{2k}; hence, the sum in Eq. (11) will have values of m and $t+m$ identical to those representing the excited state.

In this notation Eq. (9) becomes

$$\epsilon(K,\delta,R) = 4\pi(R/2)^3 \left\{ \sum_n{}' i^n a_n \times \int_1^{\infty} \lambda^2 f(\lambda) j_{n+m}(y) P_{n+m}{}^m(\cos\psi) d\lambda - \sum_n{}' i^n b_n \int_1^{\infty} f(\lambda) j_{n+m}(y) P_{n+m}{}^m(\cos\psi) d\lambda \right\}, \quad (12)$$

where

$$y = (KR/2)(\lambda^2 - \sin^2\delta)^{1/2}, \quad (13)$$

$$\cos\psi = \lambda \cos\delta / (\lambda^2 - \sin^2\delta)^{1/2}, \quad (14)$$

and j is a spherical Bessel function. The details of this derivation are sketched in the Appendix.

NUCLEAR ORIENTATION

The qualitative behavior of $\epsilon(K,\delta,R)$ as a function of δ for various final states can easily be determined from Eq. (9) or Eqs. (12)–(14). Expanding the exponential of Eq. (9) in a power series of the exponent and then noticing the symmetry of the integral with respect to μ or ϕ, a large number of terms will be found to vanish. In addition, each nonvanishing term in this series will have a very restricted dependence on δ. Listing the results for the cases studied here, it is found all nonvanishing terms involve $\cos(2k+1)\delta$ for final $np\sigma_u$ states, $\sin(2k+1)\delta$ for final $np\pi_u$ states, and $\cos 2k\delta$ for final $ns\sigma_g$ states, where n, k are positive integers. These same conclusions can be reached by using Eqs. (12)–(14). It is also known that $\epsilon(K,\delta,R)$ must be either symmetric or antisymmetric about $\delta=0$, $\pi/2$, π, since $|\epsilon(K,\delta,R)|^2$ must be symmetric about these points. This follows immediately from the symmetry of H_2^+ and implies that we need $\epsilon(K,\delta,R)$ only over the range $0 \leq \delta \leq \pi/2$.

From the above analysis or directly from Eqs. (12)–(14), it can be shown that for certain transitions $\epsilon(K,\delta,R)$ will vanish identically for a specific orientation. It is apparent that $\epsilon(K,\delta,R)$ is zero when $\delta=\pi/2$ for $np\sigma_u$ final states and when $\delta=0$ for $np\pi_u$ final states. $\epsilon(K,\delta,R)$ is never identically zero for final states of the type $ns\sigma_g$. This type of orientation selection rule has been noticed by other authors and the results here are consistent with the conclusions of Dunn[7] for the homonuclear diatomic molecule.

The quantitative behavior of $\epsilon(K,\delta,R)$ as a function of K and δ is shown in Fig. 2 for the case $1s\sigma_g$–$2p\sigma_u$, $R=2.0$. In the limit of small K, $\epsilon(K,\delta,R)$ approaches

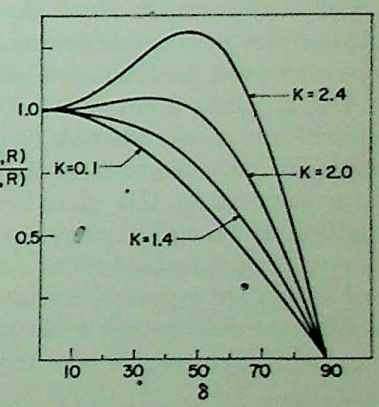

FIG. 2. The behavior of $\epsilon(K,\delta,R)$ shown as a function of δ for the $1s\sigma_g$–$2p\sigma_u$ ($R=2.0$) case and several values of K.

cosine behavior; hence, the differential cross section will have a cosine-squared dependence on δ. As K increases, the behavior changes from a cosine curve to one quite eccentric, although still possessing cosine symmetry. Note that the maximum in $\epsilon(K,\delta,R)$ moves away from $\delta=0$ and approaches $\delta=\pi/2$. From the form of Eq. (9), when the exponential is expanded in a power series, it is possible to say something about the behavior of this eccentricity as the internuclear separation is altered. As $R\rightarrow 0$, $\epsilon(K,\delta,R)$ becomes much less dependent on K while, as R is allowed to become large, its behavior becomes much more dependent on K and quite complex in general. This behavior is observed in the case where several internuclear separations are studied. These general arguments apply to other transitions but both the symmetry and quantitative behavior can be expected to be different.

These observations about the dependence of $\epsilon(K,\delta,R)$ are useful when the integration of Eq. (6) is performed. $\epsilon(K,\delta,R)$ need be evaluated only over the range $0\leq\delta\leq\pi/2$, as pointed out above. Since this must be done numerically, a considerable saving in labor ensues. In addition, since the form of the trigonometric behavior is well specified, this gives a strong hint as to the method of numerical integration that should be used. If one evaluates $\epsilon(K,\delta,R)$ at a series of equally spaced values of δ for a given K and then fits these points with a trigonometric interpolation formula,[8] a simple series results which contains only terms like $\cos(2n+1)\delta$ for the $1s\sigma_g$–$2p\sigma_u$ case. Similar behavior results for the other cases. It is a simple matter to then square this series and carry out the indicated integration. In practice, $\epsilon(K,\delta,R)$ was evaluated for increments of 10 deg in δ; hence, the series consists of nine terms. This procedure is exact if the expansion of the exponential in Eq. (9) can be truncated to the first nine nonvanishing terms. Obviously, as K and R increase, this expansion becomes less valid. However, for the cases studied, a sufficient range of K could be covered so that all significant contributions to the total cross section were obtained. The resulting values of $|\epsilon(K,R)|^2/K^2$ for the various cases are given in Table I. An accurate error analysis seems out of the question but it is estimated that any error should be confined to the last figure quoted.

One check of the values given in Table I can be made through the relationship

$$\lim_{K\rightarrow 0} f(K,R)\rightarrow f(R), \tag{15}$$

where

$$f(K,R)=2\Delta E\frac{|\epsilon(K,R)|^2}{K^2}. \tag{16}$$

$f(R)$ is the optical oscillator strength and $f(K,R)$ is the generalized optical oscillator strength as defined by Bethe.[9] Values of $f(R)$ for the $1s\sigma_g$–$2p\sigma_u$ case are

available[10] and are 0.309 ($R=1.4$), 0.319 ($R=2.0$), 0.281 (R=3.2) which are to be compared with 0.3087, 0.3198, 0.2772, the values of $f(R)$ obtained from Eq. (15). The optical oscillator strength for the $1s\sigma_g$–$2p\pi_u$ transition[11] is 0.460 which is to be compared to 0.4601. Obviously, $f(R)$ vanishes for the forbidden $1s\sigma_g$–$2s\sigma_g$ transition, as does the limit of Eq. (15) for this case. [Nonvanishing limits were found directly from Eq. (9) rather than using Eq. (12).] Agreement is quite good for all cases except $1s\sigma_g$–$2p\sigma_u$ ($R=3.2$) and the value obtained here is within the limits of accuracy (3%) claimed by Bates.[10]

TOTAL CROSS SECTIONS

The total cross sections $Q(R)$, defined by Eq. (7), were found from the values listed in Table I in the following way: For small values of K ($K\leq 0.4$) Table I was interpolated graphically to intervals in K of 0.01. Then the integrand of Eq. (7) was evaluated for available values of $|\epsilon(K,R)|^2/K^2$ and the integration was carried out using Simpson's rule. In general, Table I does not contain values of $|\epsilon(K,R)|^2/K^2$ for K large enough to include the upper limit of the integral in Eq. (7). However, the contributions to the total cross section from this range are quite small and in practice this remainder was estimated by fitting the integrand with a function depending on K^{-5}.

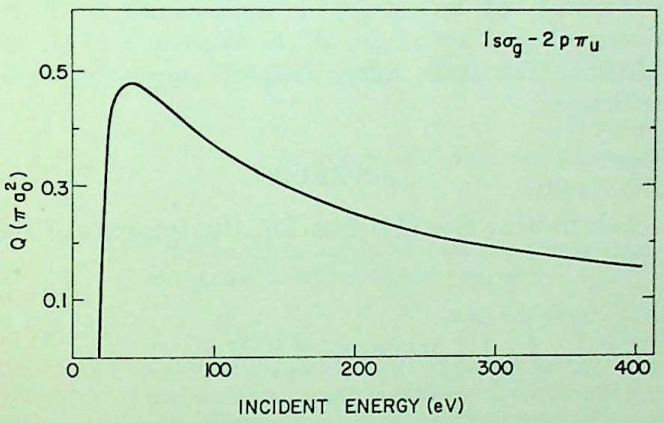

FIG. 3. The total cross section $Q(R)$ for the $1s\sigma_g$–$2p\pi_u$ ($R=2.0$) case.

The cross section $Q(2.0)$ for the $1s\sigma_g$–$2p\pi_u$ case is shown in Fig. 3. (The equilibrium internuclear distance of H_2^+ is $R_e=2.0\ a_0$.) It is apparent that this transition contributes quite heavily to scattering by H_2^+ and must be taken into account when considering processes where this final state is possible. The $1s\sigma_g$–$2s\sigma_g$, $R=2.0$ case is shown in Fig. 4. This corresponds to an optically forbidden transition and the total cross section is relatively small, as expected. The $1s\sigma_g$–$2p\sigma_u$ case is shown in Fig. 5 for three internuclear separations. The curve for $R=2.0$ corresponds to the equilibrium internuclear separation and is, therefore, an approximation to the Born cross section when the effects of the integration in Eq. (8) are ignored. This is, of course, most accurate when H_2^+ is in the $v=0$ vibrational state. The other two curves are for internuclear separations that correspond roughly to the turning points of the vibrational state $v=3$. It is apparent that the cross section for this case is strongly dependent on internuclear distance for intermediate incident energies. In the limit of infinite incident energies, these cross sections approach constant ratios of each other; specifically, $Q(3.2)/Q(2.0)=2.1$ and $Q(2.0)/Q(1.4)=1.6$. The effect of this strong dependence of $Q(R)$ on R is investigated below where Eq. (8) is evaluated for two different vibrational states.

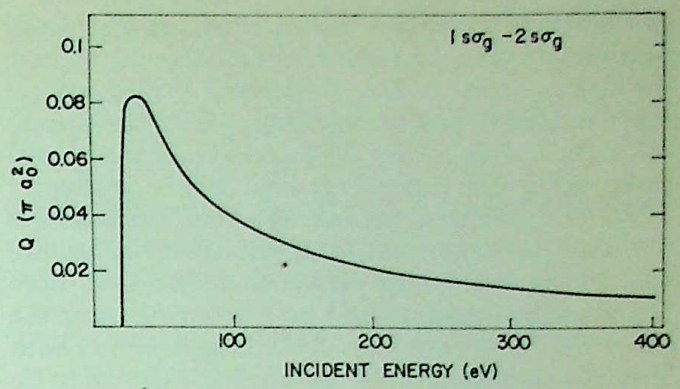

FIG. 4. The total cross section $Q(R)$ for the $1s\sigma_g$–$2s\sigma_g$ ($R=2.0$) case.

The curve for $1s\sigma_g$–$2p\sigma_u$ ($R=2.0$) can be compared with the results, ignoring exchange, given by Ivash[3]

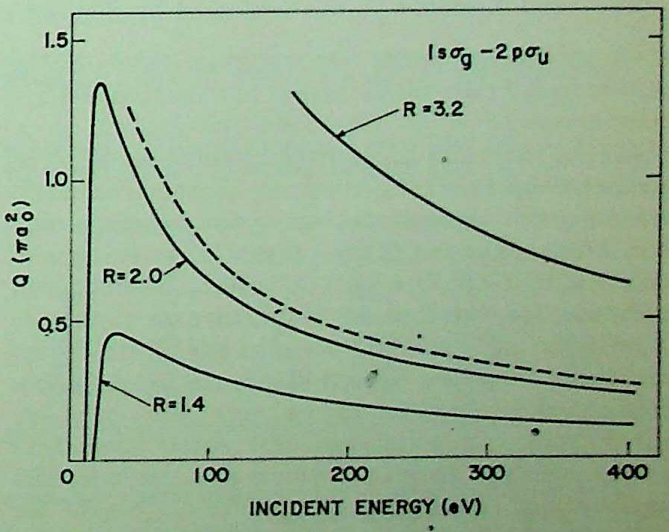

FIG. 5. The total cross section $Q(R)$ for the $1s\sigma_g$–$2p\sigma_u$ ($R=1.4$, 2.0, 3.2) case. The dashed line is from a calculation by Ivash (Refs. 3, 12).

which are shown as the dashed curve[12] in Fig. 5. To obtain this curve, he used wave functions of the form $\Psi=u_a+u_b$, where u is a $1s$ screened hydrogen wave function. His results are uniformly above the present calculation of $Q(2.0)$ by 20% or more in this energy range and in the high-energy limit will be greater by 17%. The difference between the two calculations is not large but the present treatment has the advantage that all aspects of the derivation of the first Born approximation remain valid as a result of using the exact H_2^+ wave functions. A direct comparison with Kerner's calculation does not seem justified since he treats a specific rotational and vibrational excitation in conjunction with the $1s\sigma_g$–$2p\sigma_u$ electronic transition. However, it is interesting to note that his cross section is roughly an order of magnitude less than $Q(2.0)$.

To study the effect of vibration on the total cross section, it is necessary to evaluate Eq. (8). If a diatomic molecule is in its lowest vibrational state ($\nu=0$) and it is assumed that $Q(R)$ varies slowly with R, it is a good approximation[2] to replace Q_0 with $Q(R_e)$, since $|X_0(R)|^2$ will be strongly peaked at the equilibrium internuclear distance R_e. For the transition under consideration, $Q(R)$ is seen to be rather strongly dependent on R, so it appears that Q_0 must be evaluated without using the above approximation. In addition, it is known that H_2^+ is often observed in excited vibrational states which have a rather long lifetime. Hence, Q_ν will be evaluated using Eq. (8) for the vibrational state $\nu=3$. This state is chosen because it is a highly probable vibrational state for H_2^+ if this ion results from the ionization of H_2 in its ground electronic and vibrational state.

The integral defined by Eq. (8) was estimated in the following way: $Q(R)$ for a given incident energy was fit by a polynomial in R. Since $Q(R)$ is known for only three points this polynomial was necessarily a quadratic. Then, using the vibrational functions given by Cohen, Hiskes, and Riddell,[13] Q_ν was evaluated by Simpson's rule.

The results for Q_0, Q_3 are shown in Table II along with $Q(1.4)$, $Q(2.0)$, $Q(3.2)$. It is interesting to note that Q_0 is about 10% higher than $Q(2.0)$ and that Q_3 is almost 70% higher at 400 eV with the deviation increasing as the incident energy decreases. Hence, to predict the inelastic electron scattering into the $2p\sigma_u$ state, it is necessary to know precisely what vibrational levels are populated, and to what degree. It does not follow that scattering into other final electronic states will show such marked dependence on ν, but points out the necessity for caution before neglecting the initial vibrational state. Relationships equivalent to Eq. (8) can easily be derived for the differential cross section and the generalized oscillator strength. The effects of ν on the differential and total cross sections can be expected to be quite similar. However, using the information in Table I, it can be seen that $f(K,R)$ has a maximum near R_e for the $1s\sigma_g$–$2p\sigma_u$ case; hence, the generalized oscillator strength will be much less dependent on ν.

TABLE II. The total cross sections $Q(R)$ and Q_ν (in units of πa_0^2) for the $1s\sigma_g$–$2p\sigma_u$ transition tabulated as a function of the incident energy.

APPENDIX

Substituting Eq. (11) into Eq. (9), integrals of the type

$$I_k^m=\int_1^\infty\int_{-1}^1\int_0^{2\pi} f(\lambda)\exp\{(iKR/2)\times[\lambda\mu\cos\delta+(\lambda^2-1)^{1/2}(1-\mu)^{1/2}\sin\phi\sin\delta]-im\phi\}P_{k+m}^m(\mu)d\phi d\mu d\lambda \quad \text{(A1)}$$

are obtained. Utilizing the integral[14]

$$\int_\alpha^{2\pi+\alpha} e^{i(n\phi-Z\sin\phi)}d\phi=2\pi J_n(Z), \quad \text{(A2)}$$

where J_n is a Bessel function of the first kind,

$$I_k^m=2\pi\int_1^\infty\int_{-1}^1 f(\lambda)\exp\{i(KR/2)\lambda\mu\cos\delta)\}\times J_m[\tfrac{1}{2}KR(\lambda^2-1)^{1/2}(1-\mu^2)^{1/2}\sin\delta]\times P_{k+m}^m(\mu)d\mu d\lambda \quad \text{(A3)}$$

is found. Gegenbauer's finite integral[15] can be rewritten

[14] G. N. Watson, *A Treatise on the Theory of Bessel Functions* (Cambridge University Press, Cambridge, 1958), p. 20.

[15] Ref. 14, p. 378.

in the form

$$\int_{-1}^{1} \exp(iy\mu\cos\psi) J_m[y(1-\mu^2)^{1/2}\sin\psi] P_{k+m}{}^m(\mu) d\mu = 2i^k P_{k+m}{}^m(\cos\psi)\, j_{k+m}(y), \quad \text{(A4)}$$

where $j_n(x)$ is a spherical Bessel function defined by

$$j_n(x) = (\pi/2x)^{1/2} J_{n+1/2}(x). \quad \text{(A5)}$$

Let

$$y = (KR/2)(\lambda^2 - \sin^2\delta)^{1/2} \quad \text{(A6)}$$

$$\cos\psi = \lambda\cos\delta/(\lambda^2-\sin^2\delta)^{1/2}; \quad \text{(A7)}$$

then

$$\sin\psi = (\lambda^2-1)^{1/2}\sin\delta/[\lambda^2-\sin^2\delta]^{1/2}. \quad \text{(A8)}$$

Substituting Eqs. (A6)–(A8) into Eq. (A4), we find an integral of the same form that appears in Eq. (A3), and it follows that

$$I_k{}^m = 4\pi i^k \int_1^\infty f(\lambda) j_{k+m}(y) P_{k+m}{}^m(\cos\psi) d\lambda. \quad \text{(A9)}$$

Using these results, Eqs. (12)–(14) are easily verified.

Assuming that Eq. (A9) cannot be evaluated analytically, the following numerical scheme was used for this purpose. A program for a digital computer, the Control Data Corporation's 1604, was written which carried out the integration of Eq. (A9) for a given choice of K, δ, R by means of Weddle's quadrature formula. With these values it is then possible to evaluate Eq. (12). The sum in Eq. (12) was usually truncated to three terms, although four terms were used in some cases. The same program was used to evaluate $\epsilon(K,\delta,R)$ and carry out the integration of Eq. (6).

$\Delta S = \pm 1$ Magnetic Multipole Radiative Transitions*

MASATAKA MIZUSHIMA
Department of Physics and Astrophysics, University of Colorado, Boulder, Colorado

(Received 20 December 1963)

The magnetic multipole transition probability is calculated in terms of the matrix elements of the magnetic multipole. The magnetic jm moment $Q_{jm}{}^{(mg)}$ is defined as

$$(e/\mu)[4\pi/(2j+1)]^{1/2} \sum_i (\nabla r_i{}^j Y_{jm})[(j+1)^{-1}\mathbf{l}_i + \mathbf{s}_i],$$

where e and μ are electron charge and electron mass, r_i, $\mathbf{l}_i$, and $\mathbf{s}_i$ are the coordinate, orbital angular momentum, and spin-angular momentum of the ith electron and Y_{jm} is the spherical harmonic. Magnetic quadrupole and octupole moments are explicitly given. It is shown that for the ${}^3\Sigma_u{}^+ \leftrightarrow {}^1\Sigma_g{}^+$ transition of the hydrogen molecule, the magnetic quadrupole transition is more important than the conventional spin-orbit electric dipole transition. The magnetic octupole transition has the same order of magnitude as the spin-orbit magnetic dipole transition.

INTRODUCTION

THE transition between states with different multiplicity is a very weak one. The corresponding emission line of some ions were first found in the spectra of some nebulas[1] and the theory has been given by Condon and other people.[2] This type of transition has been investigated for many ions since then, a brief review can be found in Garstang's article.[3] In all these theories the mixing of different multiplicity states through the spin-orbit interaction was assumed to be important. The ${}^1D_2$ state of O III, for example, has 0.0074 of ${}^3P_2$ wave function mixed through the spin-orbit interaction, and the transition to a triplet state can occur through this small part of the wave function. Most of the phosphorescences of molecules are interpreted as due to the singlet-triplet transition.[4] McClure first suggested the transition through the spin-orbit interaction for these molecules.[5] The present author and Koide formed a theory starting with the Dirac equation of electron and calculated the singlet-triplet transition probability of the benzene molecule.[6] The result with some approximation gave about 1 sec for the lifetime of the lowest ${}^3B_{2u}$ state of this molecule. Hameka and Oosterhoff[7] refined the calculation and showed the lifetime of the same state to be 190 sec. Calculations for

other molecules have also been done following the same idea, and they are briefly reviewed by Garstang.[3]

In this paper a completely different mechanism, namely, the magnetic multipole transition is proposed. If the probability of the electric dipole transition is $P_1^{(el)}$, the conventional theory of $\Delta S=\pm 1$ transitions gives the probability of about $(\hbar\omega/\mu c^2)^2 P_1^{(el)}$ for the case of spin-orbit electric dipole transition, since the spin-orbit coupling is a first-order relativistic correction to the Coulomb energy which is about $\hbar\omega$. $\hbar\omega$ is the photon energy which appears or disappears in our transition and μc^2 is the rest-mass energy of the electron. It will be shown that the magnetic quadrupole transition has the probability of the same order of magnitude, namely, $(\hbar\omega/\mu c^2)P_1^{(el)}$. In the same way one can show that the spin-orbit magnetic dipole transition has the same order of magnitude as the magnetic octupole transition.

MAGNETIC MULTIPOLE TRANSITION PROBABILITY

The theory of the spherical photon is given in Akhiezer and Berestetsky's book.[8] They showed that the electric field for a photon which is the eigenstate of the total angular momentum with eigenvalues j and m, and the eigenstate of the energy with eigenvalue $\hbar\omega$ and at the same time the eigenstate of the parity operator with eigenvalue $(-1)^{j+1}$, is

$$\mathbf{E}_{\omega jm}=\boldsymbol{\mathcal{E}}_{\omega jm}+\boldsymbol{\mathcal{E}}_{\omega jm}^*, \tag{1}$$

$$\boldsymbol{\mathcal{E}}_{\omega jm}=(\hbar\omega^3/16\pi^3\epsilon_0 c^2)^{1/2}e^{-i\omega t}g_j(\omega r/c)\mathbf{Y}_{jjm}(\mathbf{r}/r), \tag{2}$$

where ϵ_0 is the permittivity of the vacuum and

$$g_j(\omega r/c)=(2\pi)^{3/2}i^j J_{j+1/2}(\omega r/c)/(\omega r/c)^{1/2}, \tag{3}$$

with the Bessel function $J_{j+1/2}$, and $\mathbf{Y}_{jjm}(\mathbf{r}/r)$ is the spherical vector given by the spherical harmonics $Y_{jm}(\mathbf{r}/r)$ as

$$\mathbf{Y}_{jjm}(\mathbf{r}/r)=\begin{Bmatrix}[(j+m)(j-m+1)]^{1/2}Y_{jm-1}+[(j-m)(j+m+1)]^{1/2}Y_{jm+1}\\ i[(j+m)(j-m+1)]^{1/2}Y_{jm-1}-i[(j-m)(j+m+1)]^{1/2}Y_{jm+1}\\ 2mY_{jm}\end{Bmatrix}[4j(j+1)]^{-1/2}. \tag{4}$$

There exists another state with the same ω, j, and m eigenvalues, but with the parity of $(-1)^j$. Such state is called an electric state while our state is called a magnetic state. In this paper we are interested in the magnetic states only.

If we take the Coulomb gauge we see from (2) that the vector potential $\mathbf{A}_{\omega jm}$ is

$$\mathbf{A}_{\omega jm}=\mathcal{A}_{\omega jm}+\mathcal{A}_{\omega jm}^*, \tag{5}$$

$$\mathcal{A}_{\omega jm}=i(\hbar\omega/16\pi^3\epsilon_0 c^2)^{1/2}e^{-i\omega t}g_j(\omega r/c)\mathbf{Y}_{jjm}(\mathbf{r}/r). \tag{6}$$

Note that the normalization is such that

$$\epsilon_0\int \boldsymbol{\mathcal{E}}_{\omega jm}\cdot\boldsymbol{\mathcal{E}}_{\omega' j'm'}^* d\mathbf{r}=\tfrac{1}{2}\hbar\omega c\delta(\omega-\omega')\delta_{jj'}\delta_{mm'},$$

$$\int \boldsymbol{\mathcal{E}}_{\omega jm}^*\cdot\boldsymbol{\mathcal{E}}_{\omega' j'm'}^* d\mathbf{r}=0=\int \boldsymbol{\mathcal{E}}_{\omega jm}\cdot\boldsymbol{\mathcal{E}}_{\omega' j'm'} d\mathbf{r}. \tag{7}$$

Thus, if we expand a given field as

$$\mathbf{E}=\sum_{jm}\int F(\omega jm)\boldsymbol{\mathcal{E}}_{\omega jm}d\omega/c^{1/2}+\sum_{jm}\int F^*(\omega jm)\boldsymbol{\mathcal{E}}_{\omega jm}^* d\omega/c^{1/2}, \tag{8}$$

we see the field energy U is

$$U=\epsilon_0\int E^2 d\mathbf{r}=2\epsilon_0\sum_{jm}\sum_{j'm'}\int F(\omega jm)\times F^*(\omega' j'm')\boldsymbol{\mathcal{E}}_{\omega jm}\cdot\boldsymbol{\mathcal{E}}_{\omega' j'm'}^* d\omega d\omega' d\mathbf{r}/c$$
$$=\sum_{jm}\int \hbar\omega F(\omega jm)F^*(\omega jm)d\omega, \tag{9}$$

which indicates that $F(\omega jm)$ and $F^*(\omega jm)$ are annihilation and creation operators for the (ωjm), photon respectively,

$$(\nu_{\omega jm}|F^*(\omega jm)|\nu_{\omega jm}-1)=(\nu_{\omega jm}/d\omega)^{1/2}=(\nu_{\omega jm}-1|F(\omega jm)|\nu_{\omega jm}), \tag{10}$$

where $\nu_{\omega jm}$ is the number of the (ωjm) photon.

The probability of transition $n_1\nu_1\leftrightarrow n_2\nu_2$ is[9]

$$P(n_1\nu_1\leftrightarrow n_2\nu_2)=(\pi/\hbar^2)|(n_1\nu_1|H_i|n_2\nu_2)|^2\delta(\omega_{\nu_1\nu_2}-\omega_{n_1 n_2}), \tag{11}$$

where n_1 and n_2 are molecular states, ν_1 and ν_2 are photon numbers,

$$\omega_{ab}=(E_a-E_b)/\hbar \tag{12}$$

and

$$H_i=(e/\mu)\sum_i[\mathbf{p}_i\cdot\mathbf{A}_i-\mathbf{s}_i\cdot(\nabla\times\mathbf{A}_i)], \tag{13}$$

where $\mathbf{p}_i$ and $\mathbf{s}_i$ are the momentum and spin of ith electron, respectively. $\mathbf{A}_i$ is the vector potential at the position of ith electron. e and μ are the electron charge and mass, respectively. In H_i the contributions of nuclei are neglected.

In the same way as in (8) we set

$$\mathbf{A}_i=\sum_{jm}\int F(\omega jm)\mathcal{A}_{\omega jm}(\mathbf{r}_i)d\omega/c^{1/2}+\sum_{jm}\int F^*(\omega jm)\mathcal{A}_{\omega jm}^*(\mathbf{r}_i)d\omega/c^{1/2} \tag{14}$$

in (13). If

$$\nu_1 = \nu - 1, \quad \nu_2 = \nu \tag{15}$$

in (11), we have

$$P(n_1\nu - 1 \leftrightarrow n_2\nu) = (\pi/\hbar^2)(\nu_{\omega_0 jm}{}^{(\mathrm{mg})}/c)\,|\,(n_1|\,(e/\mu)\sum_i [-\mathbf{p}_i\cdot\mathcal{A}_{\omega_0 jm} + \mathbf{s}_i\cdot(\nabla\times\mathcal{A}_{\omega_0 jm})]\,|\,n_2)^2, \tag{16}$$

where

$$\omega_0 = \omega_{n_1 n_2} \tag{17}$$

and $\nu_{\omega_0 jm}{}^{(\mathrm{mg})}$ is the number of the (magnetic jm) photons with frequency $\omega_0 \sim \omega_0 + d\omega$.

From (6) we see

$$\mathbf{p}_i\cdot\mathcal{A}_{\omega_0 jm} = (\hbar\omega/16\pi^3 c^2\epsilon_0)^{1/2} e^{-i\omega_0 t} g_j(\omega_0 r_i/c) \times r_i^{-2}(\mathbf{r}_i\times\mathbf{Y}_{jjm})\cdot\mathbf{l}_i, \tag{18}$$

where $\mathbf{l}_i$ is the orbital angular momentum of ith particle.

Using formulas

$$g_j r_i^{-2}(\mathbf{r}_i\times\mathbf{Y}_{jjm}) = -\nabla g_j Y_{jm}/[j(j+1)]^{1/2} \tag{19}$$

and

$$\nabla\times g_j\mathbf{Y}_{jjm} = \nabla g_j Y_{jm}[(j+1)/j]^{1/2}, \tag{20}$$

which can be shown from (4) we have

$$-\mathbf{p}_i\cdot\mathcal{A}_{\omega_0 jm} + \mathbf{s}_i\cdot(\nabla\times\mathcal{A}_{\omega_0 jm}) = (\hbar\omega_0/16\pi^3 c^2\epsilon_0)^{1/2} e^{-i\omega_0 t}\nabla g_n Y_{jm} \cdot[\{j(j+1)\}^{-1/2}\mathbf{l}_i + \{(j+1)/j\}^{1/2}\mathbf{s}_i]. \tag{21}$$

One can define the (magnetic jm) moment as

$$Q_{jm}{}^{(\mathrm{mg})} = (e/\mu)[(2j+1)/4\pi]^{1/2}(2j-1)!\,(i\omega_0/c)^{-j} \times\sum_i (\nabla g_j Y_{jm})_i\cdot[(j+1)^{-1}\mathbf{l}_i + \mathbf{s}_i]$$

$$\cong (e/\mu)[4\pi/(2j+1)]^{1/2} \times\sum_i (\nabla r_i{}^j Y_{jm})\cdot[(j+1)^{-1}\mathbf{l}_i + \mathbf{s}_i], \tag{22}$$

where the last expression is obtained when

$$\omega_0 r_i/c \ll 1, \tag{23}$$

so that

$$g_j(\omega_0 r/c) \cong 4\pi(i\omega_0 r/c)^j/(2j+1)!. \tag{24}$$

Note that

$$Q_{10}{}^{(\mathrm{mg})} = (e/\mu)\sum_i (l_{iz} + 2s_{iz}), \tag{25}$$

which is the familiar magnetic dipole moment.

From (21) and (22) we see

$$\sum_i [-\mathbf{p}_i\cdot\mathcal{A}_{\omega_0 jm} + \mathbf{s}_i\cdot(\nabla\times\mathcal{A}_{\omega_0 jm})](e/\mu) = [(j+1)/j(2j+1)]^{1/2}[(2j-1)!]^{-1} \times e^{-i\omega_0 t}(i\omega_0/c)^j Q_{jm}{}^{(\mathrm{mg})}/2\pi c. \tag{26}$$

Thus, from (16) the probability of the (magnetic jm) moment transition is

$$P_{jm}{}^{(\mathrm{mg})}(n_1 \rightarrow n_2) = (j+1)[j(2j+1)\{(2j-1)\}^2]^{-1}\nu_{\omega_0 jm}{}^{(\mathrm{mg})}\omega_0{}^{2j+1} \times(4\pi c^{2j+3}\hbar\epsilon_0)^{-1}\,|\,(n_1|Q_{jm}{}^{(\mathrm{mg})}|\,n_2)\,|^2. \tag{27}$$

ELECTRIC MULTIPOLE TRANSITION

The electric multipole transition can be discussed in the similar way. Since it is not the main purpose of the present paper, we will just show the result.

The only difference is to start with a photon wave function which is the eigenfunction of the total angular momentum and energy with eigenvalues j, m, and $\hbar\omega$, while the parity is $(-1)^j$, instead of $(-1)^{j+1}$.

The (electric jm) moment is defined as

$$Q_{jm}{}^{(\mathrm{el})} = \sum_i e_i[4\pi/(2j+1)]^{1/2} r_i{}^j Y_{jm}, \tag{28}$$

where we should include both electrons and nuclei in the summation, and e_i is the charge of ith particle. This definition gives

$$Q_{10}{}^{(\mathrm{el})} = \sum_i e_i z_i, \tag{29}$$

which is the familiar electric dipole moment.

The transition probability is

$$P_{jm}{}^{(\mathrm{el})}(n_1 \leftrightarrow n_2) = j(j+1)[(2j+1)\{(2j-1)!\}^2]^{-1}\nu_{\omega_0 jm}{}^{(\mathrm{el})}\omega_0{}^{2j+1} \times(4\pi c^{2j+1}\hbar\epsilon_0)^{-1}\,|\,(n_1|Q_{jm}{}^{(\mathrm{el})}|\,n_2)\,|^2. \tag{30}$$

Since the matrix element of $Q_{jm}{}^{(\mathrm{mg})}$ is about $(e/\mu)r_0{}^{j-1}\hbar$ as seen from (22), while that of $Q_{jm}{}^{(\mathrm{el})}$ is about $er_0{}^j$ as seen from (28), taking r_0 for the atomic dimension, we obtain the order of magnitude of $P_{jm}{}^{(\mathrm{mg})}$ by means of $P_1{}^{(\mathrm{el})}$ as

$$P_{jm}{}^{(\mathrm{mg})} = (\omega_0{}^{j-1}r_0{}^{j-2}\hbar/c^j\mu)^2(\nu_{\omega_0 jm}{}^{(\mathrm{mg})}/\nu_{\omega_0 1}{}^{(\mathrm{el})})P_1{}^{(\mathrm{el})}. \tag{31}$$

SPIN-ORBIT ELECTRIC OR MAGNETIC DIPOLE TRANSITION

The conventional theory of $\Delta S = \pm 1$ transition is to take into account the effect of the spin-orbit interaction

$$H_{\mathrm{so}} = -i(e\hbar/2\mu^2 c^2)\sum_i \mathbf{s}_i\cdot(\mathbf{E}\times\nabla)_i. \tag{32}$$

Since this interaction is similar to $Q_{2m_s}{}^{(\mathrm{mg})}$, which is given by (33), it can connect a singlet to a triplet. Thus,

$$|a00) + \sum_{c,M_s}(c1M_S|H_{\mathrm{so}}|a00)(E_a - E_c)^{-1}|c1M_S)$$
$$|b1M_S) + \sum_d (d00|H_{\mathrm{so}}|b1M_S)(E_b - E_d)^{-1}|d00) \tag{33}$$

are the improved wave functions of the initial and the final states. The electric dipole transition for $a \leftrightarrow b$ is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

thus from (30)

$$P_{1mso}^{(el)}=(\nu_{\omega 01m}^{(el)}\omega_0^2/6\pi c^3\hbar^2 c_0)\times\Big|\sum_{c,M_s}(a00|H_{so}|c1M_S)(E_a-E_c)^{-1}\times(c|Q_{1m}^{(el)}|b)+\sum_{d,M_s}(d00|H_{so}|b1M_S)\times(E_b-E_d)^{-1}(a|Q_{1m}^{(el)}|d)\Big|^2. \quad (34)$$

Since the order of magnitude of the electric field E is (electric energy)$/r_0$ or $\mu\omega_0^2 r_0$, we see the order of magnitude of the matrix element of H_{so} is $\hbar\omega_0/\mu c^2$ as expected from the fact that the spin-orbit interaction appears as a relativistic correction. Thus, the transition probability due to this mechanism is

$$P_{1\,so}^{(el)}\cong(\hbar\omega_0/\mu c^2)^2 P_1^{(el)}. \quad (35)$$

From (31) we see that the spontaneous emission probability through the magnetic quadrupole transition, which is $P_2^{(mg)}$ with $\nu=1$, gives exactly the same expression as (35).

In some cases the electric dipole transition is still forbidden and only the magnetic dipole transition can appear with the spin-orbit coupling. The transition probability for such case has the order of magnitude given by

$$P_{1\,so}^{(mg)}\cong(\hbar\omega_0/\mu c^2)^2 P_1^{(mg)}. \quad (36)$$

From (31) we see

$$P_3^{(mg)}=(\omega_0^2 r_0^2/c^2)^2 P_1^{(mg)}=(\omega_0\mu\omega_0 r_0^2/\mu c^2)^2 P_1^{(mg)}\cong(\hbar\omega_0/\mu c^2)^2 P_1^{(mg)}, \quad (37)$$

which shows that the magnetic octupole transition is as important as the spin-orbit magnetic dipole transition.

Somehow the magnetic multipole transition has never been discussed, but it should be as important as the spin-orbit electric or magnetic dipole transition for $\Delta S=\pm 1$ transitions.

MAGNETIC QUADRUPOLE MOMENT

From (22) with $j=2$ we obtain the five components of the magnetic quadrupole moment. They are

$$Q_{2m}^{(mg)}=Q_{2ml}^{(mg)}+Q_{2ms}^{(mg)}, \quad (38)$$

$$Q_{2ms}^{(mg)}=(e/\mu)\sum_i[q_{iz}^{2m}s_{iz}+\tfrac{1}{2}q_{i+}^{2m}(s_{ix}+is_{iy})+\tfrac{1}{2}q_{i-}^{2m}(s_{ix}-is_{iy})]; \quad (39)$$

while $Q_{2ml}^{(mg)}$ is obtained by replacing s by l/3 in (33). Coefficients q's are tabulated in Table I.

Let us assume a two-electron system. Such system can be either a triplet or a singlet, if we neglect the spin-orbit interaction. The wave function of each state is a product of the orbital part and the spin part which can be designated as $|\xi SM_S)$. It is easy to see that

$$(a00|q_{1z}^{2m}s_{1z}+q_{2z}^{2m}s_{2z}|b10)=(\hbar/2)(a|q_{1z}^{2m}-q_{2z}^{2m}|b),$$
$$(a00|q_{1+}^{2m}s_{1+}+q_{2+}^{2m}s_{2+}|b1-1)=(\hbar/2)(a|q_{1+}^{2m}-q_{2+}^{2m}|b), \quad (40)$$
$$(a00|q_{1-}^{2m}s_{1-}+q_{2-}^{2m}s_{2-}|b11)=(\hbar/2)(a|q_{1-}^{2m}-q_{2-}^{2m}|b),$$

are the only finite matrix elements. We see that these matrix elements are not generally zero because the orbital part of the wave function $|a)$ and $|b)$ are symmetric and antisymmetric, respectively, under the exchange of two electrons. Since, as shown by Mizushima and Koide,[6] the corresponding matrix elements of all the electric multipole moments and the magnetic dipole moment are zero, the magnetic quadrupole moment is the lowest moment which has finite matrix elements between states with different total spin.

If we assume that

$$|a)=N[u(1)v(2)+v(1)u(2)],$$
$$|b)=N'[u'(1)v'(2)-v'(1)u'(2)], \quad (41)$$

where

$$N^{-2}=2\left[1+\left\{\int u(1)v(1)d\mathbf{r}_1\right\}^2\right],$$
$$N'^{-2}=2\left[1-\left\{\int u'(1)v'(1)d\mathbf{r}_1\right\}^2\right], \quad (42)$$

we obtain

$$(a|q_1-q_2|b)=2NN'[(v|v')(u|q|u')-(u|u')(v|q|v')+(u|v')(v|q|u')-(v|u')(u|q|v')]. \quad (43)$$

MAGNETIC OCTUPOLE MOMENT

The magnetic octupole moment $Q_{3m}^{(mg)}$ can also be divided into two parts:

$$Q_{3m}^{(mg)}=Q_{3ml}^{(mg)}+Q_{3ms}^{(mg)}, \quad (44)$$

$$Q_{3ms}^{(mg)}=(e/\mu)\sum_i[q_{iz}^{3m}s_{iz}+\tfrac{1}{2}q_{i+}^{3m}(s_{ix}+is_{iy})+\tfrac{1}{2}q_{i-}^{3m}(s_{ix}-is_{iy})], \quad (45)$$

while $Q_{3ml}^{(mg)}$ is obtained by replacing s by l/4 in (45).

Coefficients q's are tabulated in Table II.

For the matrix elements we see that formulas (40) and (43) holds for q^{3m}.

TABLE I. Coefficients q^{2m}.

m	q_z^{2m}	q_+^{2m}	q_-^{2m}

HYDROGEN MOLECULE

The lowest triplet state of the hydrogen molecule is a dissociative state $^3\Sigma_u^+$. Since it is a dissociative state the lifetime of this state due to the spontaneous emission cannot be measured. The calculation in this section is just to show that the magnetic quadrupole transition can be much greater than the spin-orbit electric dipole transition.

The Heitler-London wave function[9] is well known to give a good approximation for the ground state $^1\Sigma_g^+$ and the lowest triplet state $^3\Sigma_u^+$. A large number of better wave functions are proposed for these states,[9] but for the present purpose of rough estimation the Heitler-London wave function will be good enough.

The Heitler London wave functions are obtained by identifying

$$\begin{aligned} u(i) &= u'(i) = \psi_{1s}(r_{ai}), \\ v(i) &= v'(i) = \psi_{1s}(r_{bi}), \end{aligned} \tag{46}$$

where r_{ai} and r_{bi} are distances between the ith electron and the protons a and b, respectively, and ψ_{1s} is the hydrogen wave function. From Table I it is easy to see that the only finite matrix elements of the magnetic quadrupole moment are

$$\begin{aligned} (^1\Sigma_g^+ 00 | Q_{20}^{(mg)} | ^3\Sigma_u^+ 10) &= 4(e\hbar/2\mu)N_+N_-r_{ab}, \\ (^1\Sigma_g^+ 00 | Q_{21}^{(mg)} | ^3\Sigma_u^+ 1-1) &= 24^{1/2}(e\hbar/2\mu)N_+N_-r_{ab}, \\ (^1\Sigma_g^+ 11 | Q_{2-1}^{(mg)} | ^3\Sigma_u^+ 11) &= 24^{1/2}(e\hbar/2\mu)N_+N_-r_{ab}, \end{aligned} \tag{47}$$

where r_{ab} is the internuclear distance. With the approximation of $N_+ = N_- = 2^{-1/2}$ we obtain

$$\begin{aligned} &P_{20}^{(mg)}(^1\Sigma_g^+ \leftrightarrow {}^3\Sigma_u^+ 0) \\ &\quad = (2/15)\nu\omega_0^5(4\pi c^7\hbar\epsilon_0)^{-1}(e\hbar/2\mu)^2 r_{ab}^2, \\ &P_{2\pm1}^{(mg)}(^1\Sigma_g^+ \leftrightarrow {}^3\Sigma_u^+ \pm 1) \\ &\quad = 5^{-1}\nu\omega_0^5(4\pi c^7\hbar\epsilon_0)^{-1}(e\hbar/2\mu)^2 r_{ab}^2, \end{aligned} \tag{48}$$

which shows that the magnetic quadrupole transition is more effective as the internuclear distance increases, as far as $\omega_0 r_{ab} < c$.

For the spin-orbit interaction one can divide the electric field $\mathbf{E}$ into two parts: The part due to the nucleus to which the electron under consideration is attached and the part due to the other atom. Assuming that the charge distribution is spherical around the other atom we have,

$$\mathbf{E} = \mathbf{E}_a + \mathbf{E}_b = (d\Phi_a/dr_{ai})\mathbf{r}_{ai}/r_{ai} + (d\Phi_b/dr_{bi})\mathbf{r}_{bi}/r_{bi}, \tag{49}$$

where ψ_a and Φ_b are potentials due to each part mentioned above. Now

$$\mathbf{r}_{ai} \times \nabla = (i/\hbar)\mathbf{l}_{ai}, \quad \mathbf{r}_{bi} \times \nabla = (i/\hbar)\mathbf{l}_{ai} + \mathbf{r}_{ba} \times \nabla, \tag{50}$$

where $\mathbf{l}_{ai}$ is the orbital angular momentum of the ith electron with respect to the nucleus a.

Using (46) we have

$$\mathbf{l}_{ai}u(i) = 0, \tag{51}$$

while

$$\begin{aligned} (1s | \mathbf{r}_{ba} \times \nabla | 2p_x) &= (16/2^{1/2}27)(r_{ba}/r_B)\mathbf{j}, \\ (1s | \mathbf{r}_{ba} \times \nabla | 2p_y) &= -(16/2^{1/2}27)(r_{ba}/r_B)\mathbf{i}, \end{aligned} \tag{52}$$

where $\mathbf{i}$ and $\mathbf{j}$ are unit vectors along the x and y axes, respectively, and r_B is the Bohr radius.

If the orbital part of the wave function of the $^1\Pi_u(1s2p\pi)$ state is

$$|^1\Pi_u) = [\psi_{1s}(1)\psi_{2p\pi}(2) + \psi_{1s}(2)\psi_{2p\pi}(1)]/2^{1/2}, \tag{53}$$

we find

$$\begin{aligned} &(^1\Pi_{u\pm} | H_{so} | ^3\Sigma_u^+ 1\pm1) \\ &\quad = (4/27)(e\hbar/2\mu^2)(d\Phi_b/dr_b)r_b^{-1}(r_{ba}/r_B)(\hbar/2) \\ &\quad = (Z/27\pi\epsilon_0)(e\hbar/2\mu c)^2(r_{ab}^2 r_B)^{-1}, \end{aligned} \tag{54}$$

where Z is effective charge of the second atom for the electron in the first atom. Z is less than one and goes to zero as r_{ab} increases. Since

$$(^1\Pi_{u\pm} | Q_{1\pm1}^{(el)} | ^1\Sigma_g^+) = (2^3/3^6)r_B e, \tag{55}$$

we see from (34) that

$$p_{1\pm1\,so}^{(el)} = (Z^2/10^7)\nu\omega_0^3 e^6\hbar^3(\mu^4c^7\epsilon_0^3)^{-1}(\Delta r_{ab}^2)^{-2}, \tag{56}$$

where

$$\Delta = E(^1\Pi_u) - E(^3\Sigma_u^+). \tag{57}$$

In obtaining this formula we assumed that the main contributions come from the mixing of the $^1\Pi_u(1s2p\pi)$ state to the $^3\Sigma_u^+$ state. Note that formula (56) shows that the transition probability in this case decreases as r_{ab} increases as $(Z/r_{ab}^2)^2$.

By comparing (56) to (48) we see

$$\begin{aligned} &P_2^{(mg)}/P_{1\,so}^{(el)} \\ &\quad = (10/Z^2)(\hbar\omega_0/Rch)^2(\Delta/Rch)^2(r_{ab}/r_B)^6, \end{aligned} \tag{58}$$

where R is the Rydberg constant. In our case

$$\begin{aligned} Z^2 &\sim 1/10, \\ \hbar\omega_0/Rch &\simeq 1/2, \\ \Delta/Rch &\sim 1/4, \\ r_{ab}/r_B &= 1.4, \end{aligned} \tag{59}$$

at the equilibrium distance of the ground state. Thus the above ratio is about 10 in favor of the magnetic quadrupole transition over the conventional spin-orbit electric dipole transition. When the internuclear distance r_{ab} increases the ratio will increase very rapidly.

SELECTION RULES

The two comparative mechanisms, the magnetic quadrupole transition and the spin-orbit electric dipole transition have slightly different selection rules. For the case of $\Delta S=\pm 1$ transitions which we are interested in here the selection rules for the magnetic quadrupole transition are just like those of the electric dipole transition, or

$$\Delta L=0, \pm 1, \text{ but } L=0 \leftrightarrow 0; \text{ parity change}, \quad (60)$$

while those for the spin-orbit electric dipole transition are

$$\Delta L=0, \pm 1, \pm 2; \text{ parity change}, \quad (61)$$

in the case of atoms with L–S coupling. Thus, for example, $^1S \leftrightarrow {}^3S$ and $^2S \leftrightarrow {}^4D$ transitions can only be explained by the spin-orbit electric dipole transition.

Transitions with parity no change cannot be explained by either of them, and we have to go to the magnetic octupole transition or the spin-orbit magnetic dipole transition. Their selection rules for $\Delta S=\pm 1$ transitions are

$$\Delta L=0, \pm 1, \pm 2, \text{ but } L=0 \leftrightarrow 0; \text{ parity no change for magnetic octupole}, \quad (62)$$

$$\Delta L=0, \pm 1, \pm 2; \text{ parity no change for spin-orbit magnetic dipole}. \quad (63)$$

Selection rules for molecules can be found by finding those for the electric dipole and the electric quadrupole transitions. The selection rules for the magnetic quadrupole and the magnetic octupole transitions are the same as those respectively. For the benzene molecule, for example, the lowest triplet state $^3B_{1u}$ is known to be able to go to the ground state $^1A_{1g}$ by the spin-orbit electric dipole transition[5,6] but we see that the magnetic quadrupole transition is forbidden for this transition. In the case of the naphthalene and anthracene molecules, on the other hand, the lowest triplet state is assumed[10] to be $^3B_{2u}$, and the magnetic quadrupole transition is allowed from this state to the ground state $^1A_{1g}$. The lowest triplet state of the benzene molecule is observed[11] to have the lifetime of more than 300 sec, while in most aromatic molecules the triplet lifetime is accepted to be about 1 sec. This may be explained by the above conclusion, since our analysis on the hydrogen molecule showed that the magnetic quadrupole transition must be more important than the spin-orbit electric dipole transition in the case of large molecules.

Absolute Electron Excitation Cross Sections of Helium*

ROBERT M. ST. JOHN, FRANK L. MILLER,† AND CHUN C. LIN‡
Department of Physics, University of Oklahoma, Norman, Oklahoma
(Received 16 December 1963)

The absolute apparent electron excitation functions of helium have been measured for the $3\,^1S$, $4\,^1S$, $5\,^1S$, $6\,^1S$, $3\,^1P$, $4\,^1P$, $3\,^1D$, $4\,^1D$, $5\,^1D$, $6\,^1D$, $3\,^3S$, $4\,^3S$, $5\,^3S$, $3\,^3P$, $3\,^3D$, $4\,^3D$, $5\,^3D$, and $6\,^3D$ states at pressures sufficiently low so that the effects of radiation imprisonment and collisional excitation transfer can be neglected. Corrections due to polarization of the radiation and the cascading from the upper excited states have been applied to the experimental data and the true excitation functions obtained. The peak values and the shape of these excitation functions are compared with the results reported from other laboratories. Generally good agreement is found with the previous works where the collisional excitation transfer was properly reduced and allowance was made for the cascading effect. The experimental cross sections show satisfactory agreement with the theoretical values calculated by the Born approximation for the ^1S and ^1P states at high-electron energies, but are about four times larger than the theoretical values for ^1D states. In the case of the triplet series, the experimental cross sections exceed the calculated values by factors of ten to one hundred or more. It is concluded that the population of the triplet states is produced mainly by processes other than direct excitation.

I. INTRODUCTION

RECENT studies of electron excitation of helium atoms indicate that some of the atomic states may be populated to a large extent by collisional excitation transfer and cascading in addition to the usual electron-impact excitation process.[1,2] The excitation transfer and its concommitant effect on cascading may be reduced and even eliminated if measurements of the excitation are made with the helium gas at low pressure, i.e., about 1 μ or less. Furthermore the populations of the ^1P states are affected by imprisonment of resonance radiation at pressures above a few tenths of a micron and therefore

measurements on them should be made below that onset pressure in order that the imprisonment mechanism not obscure the electron-impact excitation process. Cascading effects cannot be entirely removed by reduction of the gas pressure as excitation of the upper levels goes on at all pressures. Thus, in the determination of the electron impact excitation cross section, considerable care must be exercised in subtracting from the total observed (apparent) cross section the contributions from the various other excitation mechanisms. Indeed, the effects of collisional transfer[1-3] and imprisonment are partly responsible for the disagreement of the electron-excitation cross sections reported in the early literature as well as the discrepancy between them and theoretical cross sections.

With the recent improved experimental techniques it is possible to work at pressures low enough to suppress the effect of excitation transfer when observing all but the weakest transitions. In this paper we shall present the apparent excitation functions of 18 excited states of helium measured at low pressure. The cross sections for direct electron excitation are then obtained after the application of a series of corrections. The results of several experimental investigations will be compared. Additionally comparison of these cross sections with the theoretical values will be made and discussed.

II. EXPERIMENTAL METHOD

The apparatus for measuring the relative excitation functions has been described in a previous paper.[4] Absolute values of the excitation functions were obtained by calibration against a standard lamp as previously described.[4,5] The lamp was a tungsten ribbon filament pyrometer supplied and standardized by the General Electric Company. The lamp was operated at 3 temperatures in the range from 1400 to 1700°K and its emission calculated within a small wavelength interval for the wavelength of each transition observed. Emissivity tables for tungsten determined by Larrabee were used.[6] The sensitivity of the detection system was determined with the three-lamp temperatures. The maximum deviation of the sensitivity from the mean value at a given wavelength was generally less than 5%.

The solid angle viewed by the monochromator was determined by the use of a small variable size circular diaphragm which acted as the aperture stop. Transition probabilities used in this paper for evaluating the density of a given excited state by means of observation of the intensity of light emitted from it are those tabulated by Gabriel and Heddle.[7]

III. ANALYSIS

The equation relating population gain and loss rates per unit volume of the jth state of an atomic system is

$$\underset{\text{Electron impact gain}}{Q(j)[I_eN(g)/eS]}+\underset{\text{Cascade gain}}{\sum_i N(i)A(ij)}+\text{transfer gain}$$
$$=\underset{\text{Cascade loss}}{N(j)A(j)}+\text{transfer loss}, \quad (1)$$

where $Q(j)$ is the cross section for excitation by electron impact from the ground state to the jth state, I_e is the electron-beam current passing through the collision tube, S is the cross-sectional area of the electron beam, and e the electronic charge. The symbols $N(g)$ and $N(j)$ stand for the densities of the ground and jth states; $A(ij)$ is the probability of transition from the ith state to the jth state, while $A(j)$ is the total probability of transition from the jth state to lower states. In the above equation we have neglected the effect of imprisonment of radiation. This follows from the assumption that observations of ^1P functions, which are directly affected by imprisonment, are to be made at pressures low enough that imprisonment is negligible.

At low pressure the transfer excitation terms in Eq. (1) can be neglected. When this is done, one obtains

$$Q(j)[I_eN(g)/eS]+\sum_i N(i)A(ij)=N(j)A(j)\,. \quad (2)$$

It is customary to introduce the branching ratio B,

$$B(jk)=A(j)/A(jk)\,, \quad (3)$$

so that Eq. (2) can be rewritten as

$$Q(j)[I_eN(g)/eS]+\sum_i N(i)A(ij)=B(jk)N(j)A(jk)\,. \quad (4)$$

Here $N(j)\ A(jk)$ is the rate at which energy is emitted in connection with transition $j\rightarrow k$ and is determined experimentally from the photomultiplier current $I_P(\theta,j)$ measured at an angle θ relative to the electron beam. Since the radiation generally is not isotropic, a polarization correction factor $f_P(\theta j)$, is introduced so that $I_P(\theta j)f_P(\theta j)$ is proportional to the angular average of the light intensity and thus allows the determination of the entire light flux emitted from the collision chamber. Accordingly we have

$$N(j)A(jk)=C_1(j)I_P(\theta,j)f_P(\theta,j)\,, \quad (5)$$

where $C_1(j)$ is a proportionality constant determined from the calibration proceedure using the standard lamp. For the purpose of comparison with the previous data, we define $Q'(j)$ and $Q''(j)$ as

$$Q'(j)\frac{I_eN(g)}{eS}\equiv Q(j)\frac{I_eN(g)}{eS}+\sum_i N(i)A(ij)\,, \quad (6)$$

$$Q''(\theta,j)\equiv Q'(j)/f_P(\theta,j)$$
$$=eSC_1(j)I_P(\theta,j)B(j)/I_eN(g)\,. \quad (7)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

All the factors making up $Q''(\theta,j)$ are obtained by experimental observation except $B(j)$ which is determined from the theoretical transition probabilities.[7] In fact, $Q''(\theta,j)$ is the cross section which has been reported traditionally by observers of excitation functions. We shall call it the cross section uncorrected for polarization, cascade, and transfer effects; or simply the apparent cross section. Likewise, $Q'(j)$ can be regarded as the observed cross section which has been corrected for polarization but not for cascading and transfer effects, and is obtained from the experimental $Q''(j)$ cross section.

The polarization correction factor[8] is

$$f_P(\theta,j)=\tfrac{1}{3}\{[300-P(j)]/[100-P(j)\cos^2\theta]\}\,, \quad (8)$$

where $P(j)$ is the percentage polarization.

IV. EXPERIMENTAL RESULTS

The apparent excitation functions of 18 states as measured directly from the automatic processing apparatus are shown in Fig. 1. The graphs represent relative values. After the calibration procedure described earlier was followed, the absolute values of the apparent cross sections were obtained; the peak values are listed in Table I.

The apparent excitation function of the $3\,^1P$ level displayed in Fig. 1 was recorded at a pressure of 5.9 μ. The shape of this curve was quite independent of gas pressure. Data obtained at pressures as low as 0.1 μ were used to evaluate the peak apparent cross section of 350×10^{-20} cm^2 listed in Table I.

The excitation function obtained at 4025–6 Å represents the sum of two-line functions. These are 4026 Å ($5\,^3D\rightarrow 2\,^3P$) and 4025 Å ($7\,^1S\rightarrow 2\,^1P$). One can obtain an excellent approximation to the excitation of the $7\,^1S$ level by extrapolation from the 3, 4, 5, and 6 levels of that family; application of the appropriate branching ratio yields the function of the 4025-Å line, with a maximum value of 1.1×10^{-20} cm^2. This, when subtracted from the function representing the sum of the two excitation processes, yields the 4026-Å function which, in turn, yields the $5\,^3D$ apparent excitation function.

TABLE I. Maximum values of the apparent excitation cross sections (low-pressure values).

Level	Transition observed (Å)	Maximum cross section Q^{11} (10^{-20} cm^2)
$3\,^1S$	(7281)	49
$4\,^1S$	(5047)	24
$5\,^1S$	(4438)	9.2
$6\,^1S$	(4170)	4.8
$3\,^1P$	(5016)	350
$4\,^1P$	(3965)	159
$3\,^1D$	(6678)	42
$4\,^1D$	(4922)	17.6

$6\,^1D$	(4144)	4.7
$3\,^3S$	(7065)	107
$4\,^3S$	(4713)	35
$5\,^3S$	(4121)	12.3
$3\,^3P$	(3889)	97
$3\,^3D$	(5876)	31
$4\,^3D$	(4471)	12.0
$5\,^3D$	(4026)	6.2
$6\,^3D$	(3821)	3.9

V. PREVIOUS WORKS

The apparent electron excitation functions of helium have been measured by Lees,[9] Thieme,[10] Yakhontova,[11] McFarland and Soltysik,[12] and Heddle and Lucas.[13] Of these Lees, Thieme, and Yakhontova determined absolute cross sections. Additionally, Stewart and Gabathuler[14] have determined the peak values of the cross sections of several helium levels. Gabriel and Heddle[7] determined the cross sections for 108-eV electrons for a number of helium levels.

The observations by Thieme, Yakhontova, Heddle, and Lucas, Gabriel and Heddle, and Stewart and Gabathuler were at pressures low enough to greatly reduce transfer effects. Of these, Thieme and Stewart and Gabathuler, however, did not work at pressures low enough to eliminate imprisonment of resonance radiation, and thus their absolute determinations of the $3\,^1P$ cross sections are abnormally high. All observers worked at pressures low enough that light emission from ^1S, ^3S, and ^3P states was linear with pressure. All observers cited, including the authors of this paper, observed the excitation chamber in a direction normal to the electron beams. Thus all apparent cross sections determined at low pressures are subject to the same corrections required for polarization and cascade.

Table II shows the peak absolute values of the apparent cross sections of helium levels as measured by the authors of the paper, Yakhontova, Stewart and Gabathuler, Lees, and Thieme.[15] It also shows our values and those of Gabriel and Heddle at an electron energy of 108 eV.

[15] Some of these experimenters published values for cross sections for excitation of a given line transmitted from a given level. By use of the branching factor one can readily obtain the cross section for excitation to the upper level involved. We used the transition probabilities of Gabriel and Heddle for determining the branching factors and thus obtained level cross sections as displayed in Table II. Stewart and Gabathuler listed both line and level cross sections. Due to the fact that they used branching factors differing from those produced by the Gabriel and Heddle transition probabilities, their level cross sections show some slight variation from those we list for them.

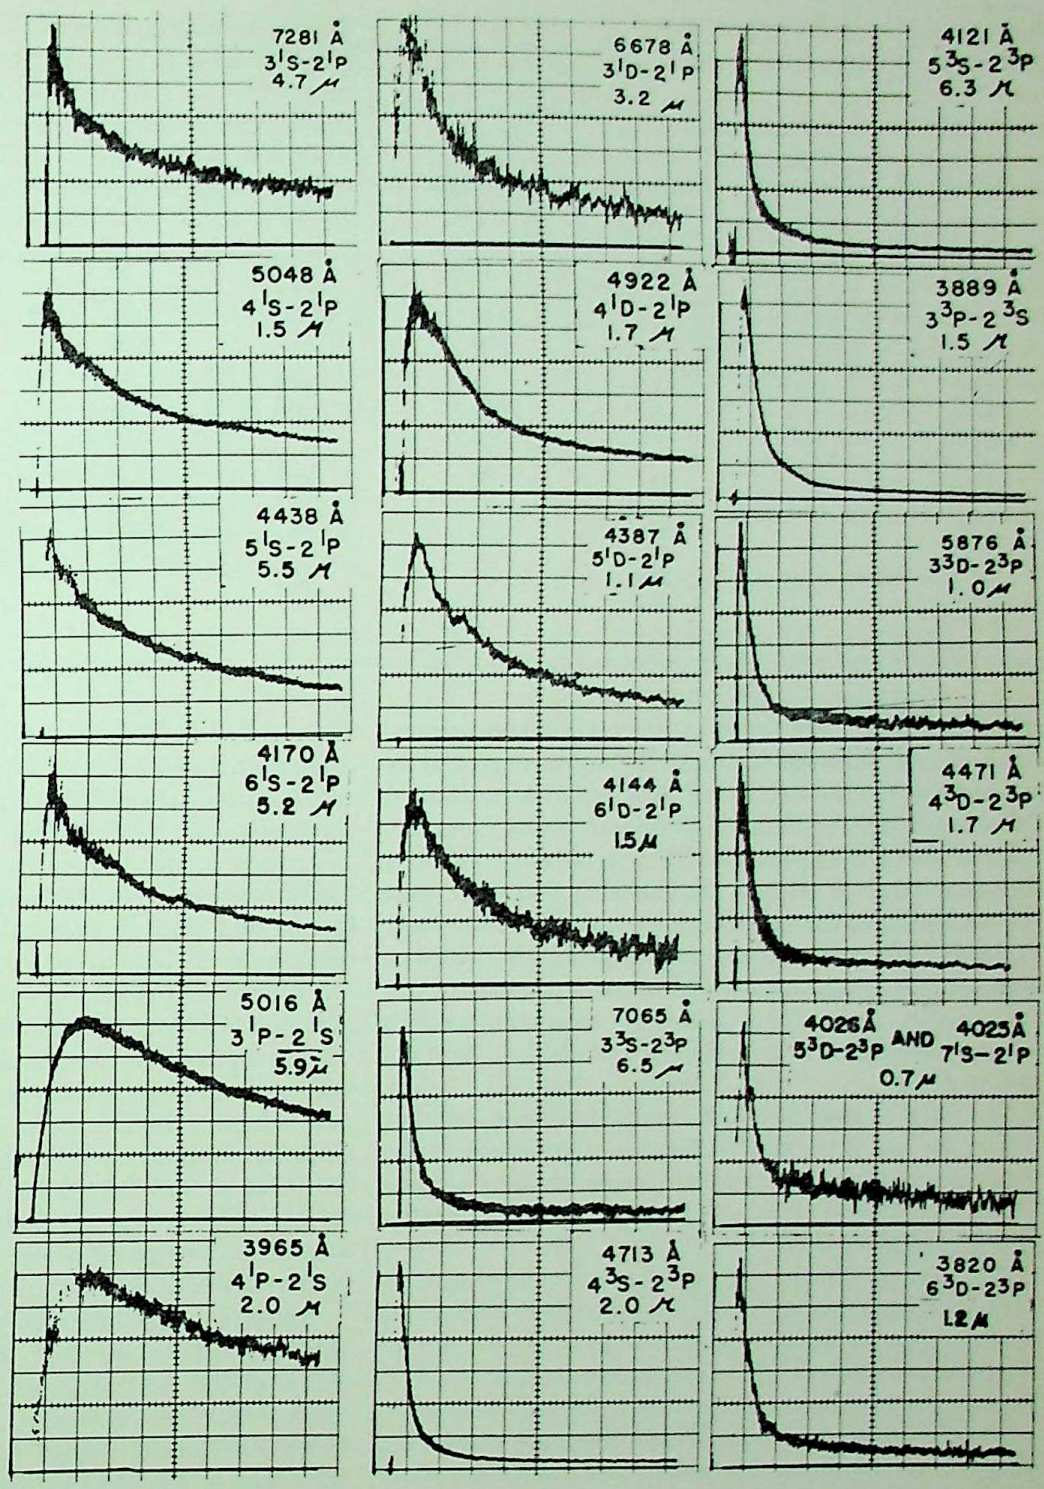

FIG. 1. Apparent excitation functions of 18 helium levels. Cross sections are relative; electron energy varies from 0 to 500 eV.

The measurements of Yakhontova are consistent with those reported herein. The ratio of Yakhontova's peak cross sections to ours averages 0.99 and each lies within the range of 0.83 to 1.16 with the exception of the $4\,^3S$ and $5\,^3D$ cross sections. In those cases the factors were 0.77 and 1.37. This rather good agreement throughout the levels including ^1D, and ^3D verifies that the pressures used in both investigations were below those which cause transfer effects.[16]

[16] Yakhontova determined the absolute value of the peak cross section of lines from the 3 and $4\,^1P$ levels by operating at a gas pressure high enough to cause complete imprisonment (which would yield a value near that of the level cross section) and then determined the line cross sections (5016 and 3965 Å) by dividing by the appropriate branching factor. Due to a spreading of the beam with increasing imprisonment which is concommitant with increasing pressure, the measured line intensity will not increase as much as the branching ratio when imprisonment changes from a nil to its full value. Thus, the line cross sections given by Yakhontova were not converted back to level cross sections and hence are not tabulated in Table II.

Stewart and Gabathuler do not quote directly the pressures used in their determinations of the apparent cross sections, but they were well aware of the pressure

effects, as they gave intensity versus pressure curves. Some of that data was obtained in the 2-μ range, and we can assume the sensitivity of their equipment allowed them to obtain the maxima of the apparent cross sections at about that pressure. Their relative consistancy with our data for ^1D and ^3D indicates that they were able to minimize the transfer of excitation effects. Their values for $3\,^1P$ and $4\,^1P$ are very large and indicates an imprisonment effect as one expects as a pressure of 2 μ. Disregarding the ^1P data, the ratio of their cross sections to ours averaged a 1.26 and varied within the limits of 1.06 to 1.50.

The data of Lees is in serious disagreement with our results for the $3\,^1P$, due to his use of pressures in the 40-μ range. His peak apparent cross sections for the ^1S, ^1D, ^3S, ^3D, and ^3P levels compared to our values by a ratio averaging 0.86.

The data of Thieme compared to ours shows quite a variety of cross-section ratios; his extremely high value for excitation of the $3\,^1P$ level is at least in part due to imprisonment effects. His very large value for the $3\,^3P$ level defies explanation other than through erroneous calibration procedures. Lees' and Thieme's data were obtained by photographic techniques and hence more subject to errors than the photoelectric data of the other investigators cited. The magnitudes of Thieme's data will be given no further consideration.

Gabriel and Heddle measured absolute values of the cross section for 17 helium levels at pressures apparently low for all except the ^3D levels. The ratios of their apparent cross sections to those presented by the present authors averaged 1.12 for ^1S, ^1P, ^1D, ^3S, and ^3P levels, and lay within the range of 0.76 to 1.37. The ^3D ratio varied up to 3.4 indicating a transfer fillin for the cross sections of Gabriel and Heddle.

A comparison of the shapes of the excitation functions is presented in Table III. Each excitation function has been normalized to unity for an electron energy of 100 eV. Included are the data of Yakhontova, Lees, Thieme, McFarland and Solysik, Heddle, and Lucas, and that presented in this paper. It can be seen that there is quite good agreement between the shape data presented herein and that of Yakhontova. This is the result of both sets of data being obtained under low-pressure conditions. The shapes of the ^1D and ^3D curves of Lees are modified by the ^1P fillin due to his use of a relatively high gas pressure. The curves of Thieme are quite similar to those presented herein, a fact derived from the low-helium pressures used by him. McFarland and Soltysik obtained their functions with a gas pressure of 10 to 20 μ, and thus their curves show some transfer effects. The curves of Heddle and Lucas, while obtained at a pressure of about 1 μ, do not show very good agreement with the curves of the other experimenters.

Another factor influencing the shape of an experimentally determined excitation function is that of the shape of the electron beam. If it should undergo any change with electron energy, the light detection system being used could change in sensitivity due to (a) a variation in the light-gathering ability of the optical system with change in the position of the light source and (b) a lack of homogeneity of the response of in the cathode of the photomultiplier. Care was exercised by the authors of this paper to maintain a cylindrical electron beam of constant diameter at all electron energies.

VI. POLARIZATION AND CASCADE CORRECTIONS

Values of the percentage polarization, $P(j)$, have been measured by McFarland and Soltysik[12] for varying pressure and electron energy for several of the transitions reported in this paper, and are used for making

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the polarization corrections reported herein. Since the amount of polarization correction is generally rather small, the values of $P(j)$ given in Ref. 12 were used whenever available, and extrapolations of these values were used for the transitions which were not reported.

To obtain the true cross section of electron excitation, Q' must be corrected for the cascading effect. With the aid of Eqs. (5) and (7), Eq. (6) can be rewritten as

$$Q(j)=Q'(j)-\sum_i Q'(i)A(ij)/A(i)\,. \qquad (9)$$

The true excitation cross section of the jth state can then be determined from a knowledge of Q' of the jth state and of those states that cascade into it.

For our analysis we had available the values of $Q''(i)$ for those states included in Fig. 1 and Table I. These were corrected for polarization effects by the use of the polarization data of McFarland and Soltysik and values of $Q'(i)$ obtained. The shapes of high n values excitation functions corrected for polarization was taken to be the same as that of the low n functions having the same orbital quantum number L. The magnitudes of the high-level $Q'(i)$ functions were assumed to vary as $n^{-\alpha}$ where α is an adjustable parameter. Theoretical transition probabilities have been compiled for $n\leqslant 8$;[7] an extrapolation procedure again was used to find the values for higher states.

The excitation functions corrected for polarization and cascading effects of the levels of helium are shown in Fig. 2. The actual percentage of correction applied to an excitation function for each of the polarization and cascading effects varied with electron energy due to the differences between the energy dependence of the polarization factor, shape of the excitation function of the cascading levels, and the shape of the excitation function being corrected. The variation in the cascading correction was not so prominent for the triplet functions due to the similarity among triplet apparent excitation functions. The maximum percentage by which Q' varied from Q'' was 0 for ^1S levels, 4 to 7% for ^1P levels, 13 to 17% for ^1D levels, 0 for ^3S levels, 5% for the $3\,^3P$ level, and 4 to 5% for the ^3D levels. The higher levels showed less polarization than the low levels and thus received smaller corrections. This situation thus minimized the errors involved in the extrapolation procedure used in procuring the $Q'(j)$ curve from the $Q''(j)$ curve. The cascade contributions were then subtracted from the polarization corrected curves. The maximum cascade contribution to the $3\,^1S$ level was 15% and occurred at an electron energy of 300 eV. Cascade corrections of a similar percentage were obtained for higher ^1S levels. The $3\,^1P$ level sustained a 14% correction at 35 eV and a 4% correction at 100 eV. The $4\,^1P$ level received somewhat smaller percentage corrections and distinctly less absolute corrections. The ^1D functions suffered maximum corrections at 450 eV; they were in the range of 5 to 8%.

The cascade corrections sustained by triplet functions

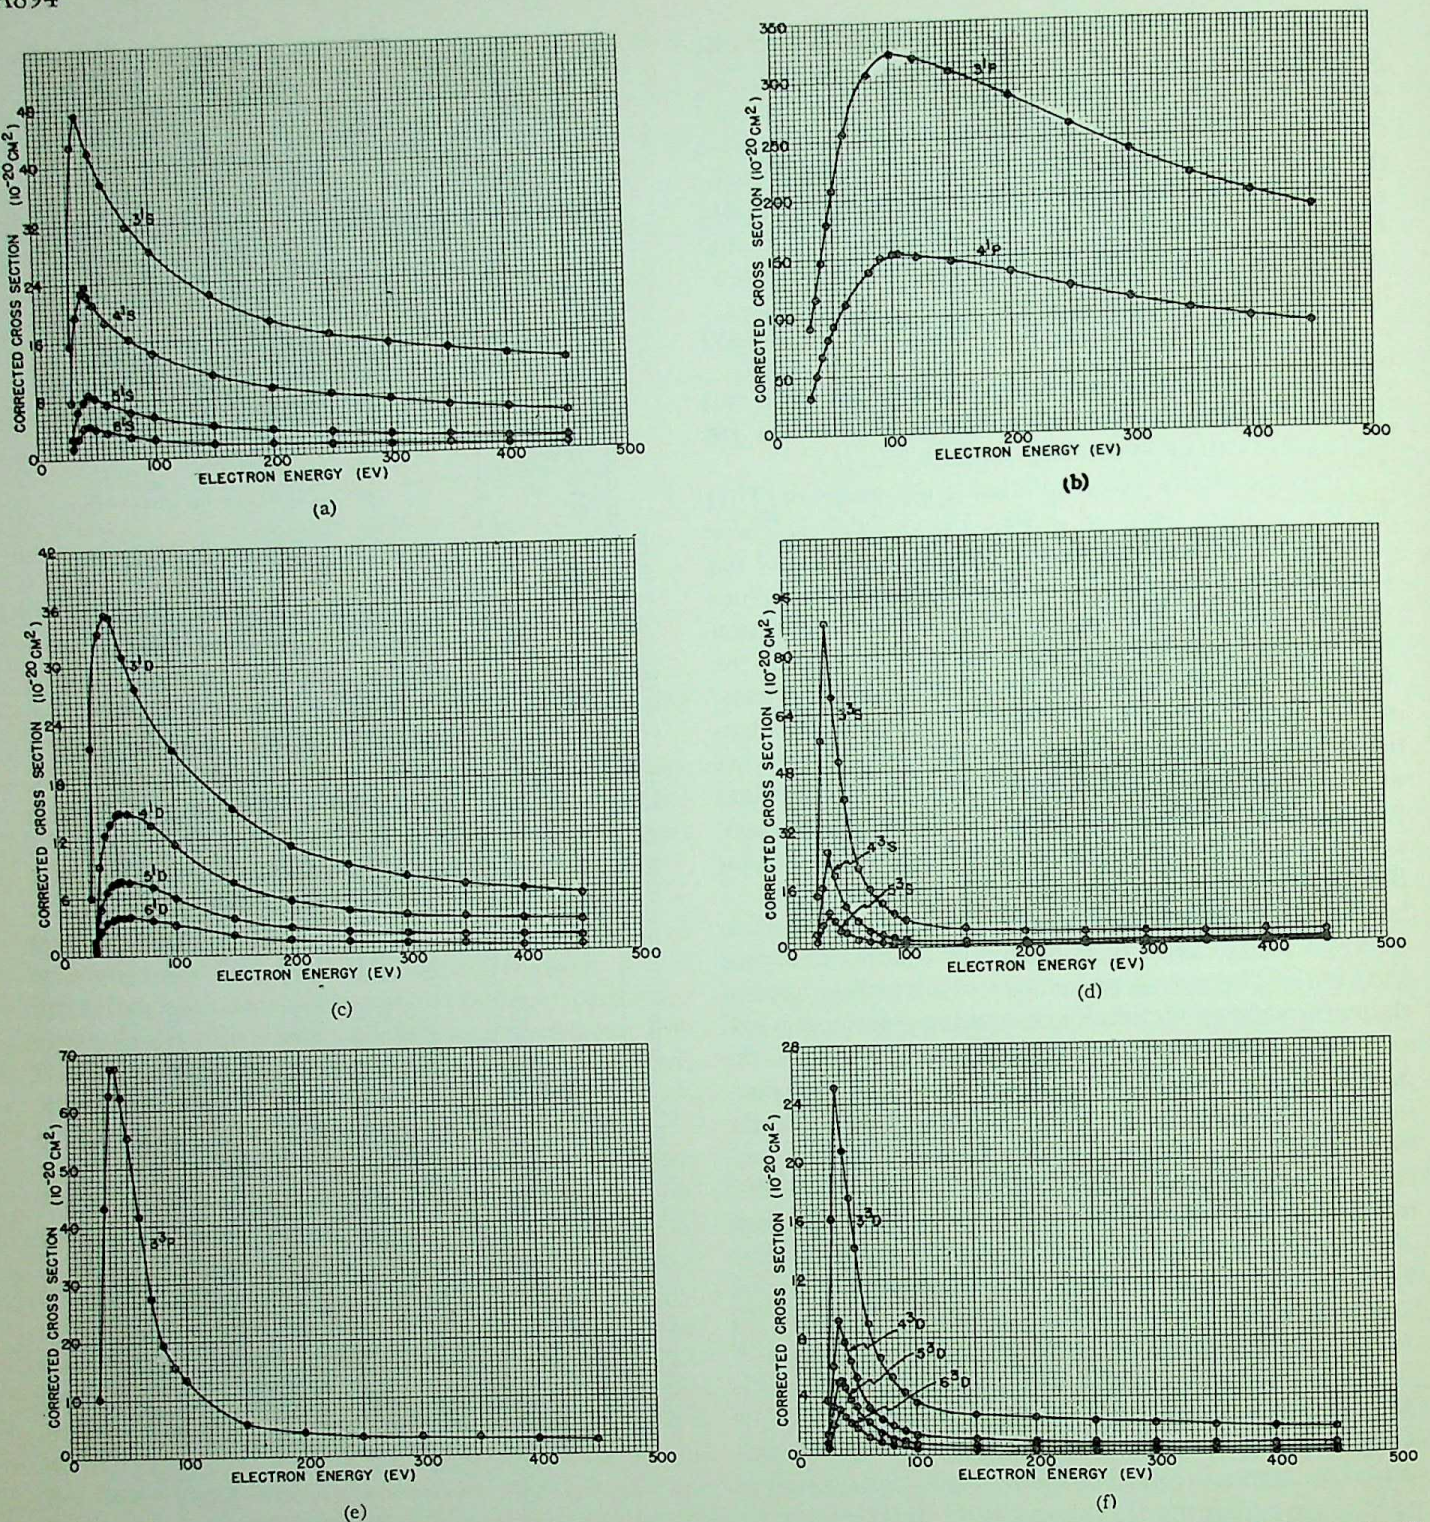

FIG. 2. Families of excitation function corrected for polarization and cascade effects. (a) Singlet S, (b) singlet P, (c) singlet D, (d) triplet S, (e) triplet P, (f) triplet D.

were nearly constant as a function of voltage. The $3\,^3S$, $4\,^3S$, and $5\,^3S$ functions of Q' were 20 to 30% due to cascade. The Q' curve of $3\,^3P$ was 30% due to cascade. The cascade correction for the ^3D functions varied to 10 to 19%.

Fortunately, the errors which might be introduced by the extrapolations processes necessarily are small since the cascading from high states is small. That part of the population of a state coming from levels involved in the extrapolation processes was 7% for the $3\,^1S$ state. The amounts falling to other low-level states by this process[17] were as follows: $3\,^1P$, 1%; $3\,^1D$, 4%; $3\,^3S$, 3%; $3\,^3P$, 4%; $3\,^3D$, 1%. There are additional uncertainties associated with the cascading from the F states. This point is discussed in Sec. VII.

[17] Measurements of the ^3P family were limited to $n=3$. The fall-off cross section with n was determined from the paper of Gabriel and Heddle which supplied cross section data for the 3, 4, and 5 states.

Frost and Phelps[18] made determinations of cascade contributions. They estimated that no correction was necessary for the ^1S and ^1D curves. They obtained a 10% correction for the $3\,^1P$ and $4\,^1P$ levels at 100 eV. The triplet curves, at the peak of the excitation function, were populated by cascade as follows: $4\,^3S$, 4%; $3\,^3P$, 49%; $3\,^3D$, $4\,^3D$, $5\,^3D$ all 10%.

Gabriel and Heddle[7] determined cascade corrections for electron energies of 108 eV. The $4\,^1S$ level population was 2% due to cascading. Higher ^1S level populations were regarded as entirely caused by electron impact. Singlet P populations were assumed free of cascade effects. The $3\,^1D$ level was found to have 4% of its population due to cascade, but higher ^1D unaffected by cascade. The triplets were populated by cascade as follows: $4\,^3S$, 23%; $5\,^3S$, 7%; $3\,^3P$, 34%; $3\,^3D$, 4%; $4\,^3D$, 17%; $5\,^3D$, 17%.

VII. COMPARISON WITH THEORY

The theory of excitation of helium atoms by electron impact has been treated rather extensively in the literature. Massey and Mohr[19] calculated the excitation cross sections for the $2\,^1S$, $3\,^1S$, $2\,^1P$ $3\,^1P$ $4\,^1P$, $5\,^1P$, $3\,^1D$, $4\,^1D$ $5\,^1D$ and $4\,^1F$ states by the Born approximation and for the $2\,^3S$, $3\,^3P$, $4\,^3P$, and $3\,^3D$ states using the Born-Oppenheimer approximation for incident electrons of various energies (60, 100, 200, and 400 eV). Curves for the theoretical excitation functions for the $3\,^1S$, $3\,^1P$, $4\,^1P$, $4\,^1D$, $5\,^1D$ and $2\,^3S$ states were also included in this work. Bates *et al.*[20] have given a critical analysis of the Born and Born-Oppenheimer approximation along with additional results of cross sections for some of the low-n states of He. As an improvement over the Born-Oppenheimer approximation, cross sections for the $1\,^1S \rightarrow 2\,^1S$ $1\,^1S \rightarrow 2\,^3S$, and $1\,^1S \rightarrow 2\,^3P$ transitions have been calculated by Massey and Moiseiwitsch[21] using the method of exchange distorted waves (EDW). Unpublished calculations by Fox on the excitation cross sections of several ^1S states were quoted in the paper of Gabriel and Heddle[7] and by Seaton.[22] In Table IV are listed observed and calculated (Massey and Mohr) excitation cross sections at electron energies of 60, 100, and 200 eV.

TABLE IV. Comparison of observed and calculated cross sections for electrons of various incident energies. Observed cross sections are corrected for polarization and cascading. All cross sections are expressed in units of 10^{-20} cm^2.

[a] The $3\,^3S$ calculated values are extrapolated from $2\,^3S$ calculations.

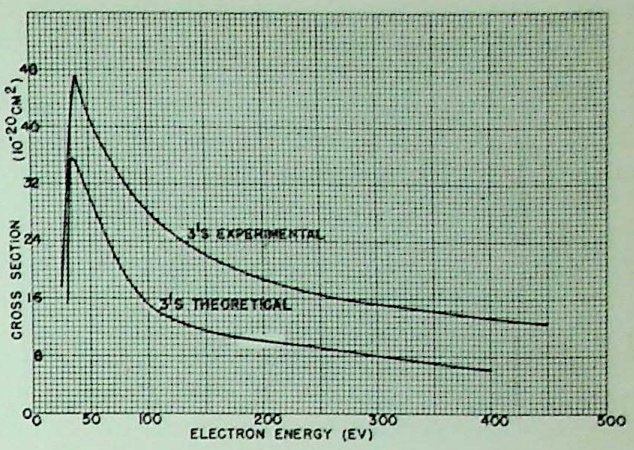

FIG. 3. Experimental and theoretical excitation functions of the $3\,^1S$ level. The experimental curve is corrected for polarization and cascade effects.

The theoretical and observed cross sections of the $3\,^1S$ level show good agreement. The calculated cross sections for the ^1S states are subject to a higher degree of uncertainty than those of the other states, because the wave functions of the $n\,^1S$ states were gotten by orthogonalization of the Slater-like orbitals. A small change of the effective nuclear charge, for instance, may result in a significant variation of the cross sections. Thus Massey and Mohr gave 15×10^{-20} cm^2 for the $3\,^1S$ cross section at 100 eV while the same cross section, according to the work of Fox,[23] is 46×10^{-20} cm^2. In the light of this, the experimental cross section may be considered to lie within the limits of the theoretical calculations. Figure 3 shows the comparison of the experimental and theoretical excitation functions of $3\,^1S$.

Figure 4 shows the comparison between the theoretical and experimental excitation functions of $3\,^1P$ and $4\,^1P$. The discrepancy at voltages below 100 eV is to be expected since the theoretical values were calculated by the use of the Born approximation. Analyses by Altshuler[24] and by Miller and Platzman[25] indicate that the use of approximate helium wave functions may lead to an error in the cross section as large as a factor of two or so. Thus the over-all agreement between the ob-

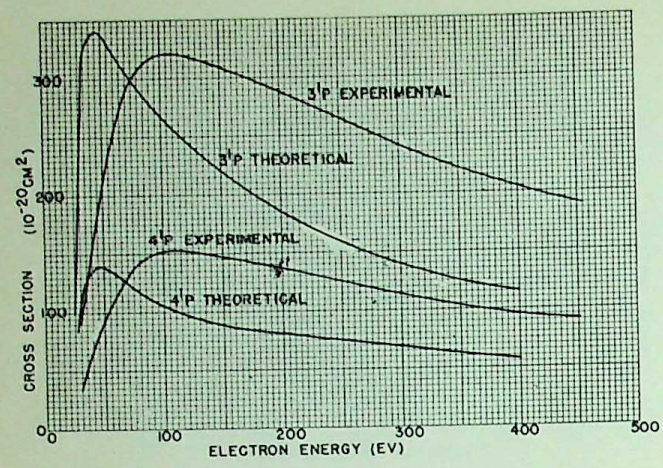

FIG. 4. Experimental and theoretical excitation functions of the $3\,^1P$ and $4\,^1P$ levels. The experimental curves are corrected for polarization and cascade effects.

served and calculated excitation cross sections for $3\,^1P$ and $4\,^1P$ should be considered as good as can be expected at this time.

The evaluation of the absolute cross sections Q from the experimental data for the ^1D states is somewhat complicated by the fact that the amount of cascading from the ^1F to the ^1D states are not known, since no excitation measurements are available for the ^1F states. We shall use the calculated value[19] of $Q(4\,^1F)$ along with an n^{-3} dependence for the higher ^1F states. The cascading from G to ^1F will be neglected, since the populations of the G states are expected to be very small on account of the rapid decrease of the direct excitation cross sections with increasing values of L. Under these assumptions we have calculated $N(n\,^1F)$ and found that the $^1F \rightarrow {}^1D$ cascading contributes less than 1% of the total population of the ^1D state. This result remains essentially the same when the singlet-triplet mixing of the F states are taken into consideration.[3] The absolute cross sections of 3, 4, 5, and $6\,^1D$ are then evaluated from the experimental data on Q'' (see Table I and Fig. 1). They are about four times larger than the theoretical values. At first, one might ascribe this discrepancy to the inaccuracy of our estimated populations of the F states. If we were to assume that $F \rightarrow {}^1D$ cascading is entirely responsible for the deviation of the observed Q from the theoretical values, it would be necessary to increase the concentration of the atoms in the F states. This, in turn, would require cross sections for electron excitation of the ^1F states to be 200 to 300 times as large as the theoretical values. The value of $Q(4\,^1F)$, for example, would have to be about 12×10^{-20} cm^2, a seemingly unreasonable value. Our experimental results for the excitation cross sections of the ^1D states therefore could not be brought into complete agreement with theory in a consistent manner.

Calculation by Fox as quoted by Seaton[22] gives $Q(3\,^1D)=7\times10^{-20}$ cm^2 at 108 eV as compared to 4×10^{-20} cm^2 calculated by Massey and Mohr[19] at 100 eV. The difference between these two values can be taken as an indication of the degree of variation of the theoretical cross section (Born approximation) which can be expected from the use of different approximate helium wave functions. Seaton has pointed out the calculations by B II approximation show that the coupling between $3\,^1D$ and $3\,^1P$ is not important for the cross section of the $3\,^1D$ state. It is very unlikely then that the imperfection of the theory could account for the disagreement between the observed and calculated cross sections for $3\,^1D$ and $4\,^1D$. Nor is it conceivable that errors in the experimental procedure could have caused the observed values to show this mismatch with the calculated cross sections. The measured apparent cross sections are proportional to the output current of the photomultiplier tube; thus, the relative values of the apparent excitation cross sections should be quite accurate. Of course the absolute experimental cross sections are subject to the errors of the light-intensity calibration as well as the cascade corrections. The amount of cascading populations in the ^1P and ^1D are quite small, i.e., less than 14% of the total populations. Errors in the calibration of the photomultiplier output should affect all the cross sections by a constant factor. This leads us to conclude that one cannot have simultaneous agreement between theory and experiment for the $3\,^1P$ $4\,^1P$, $3\,^1D$, and $4\,^1D$ states.

For the $3\,^3P$ and $3\,^3D$ states the calculated cross sections are consistently smaller than the observed values. In fact, the discrepancy is too large to be ascribed to the errors in the theory or experiment or combination of both. In the case of the ^3D states one is again faced with the problem of having to estimate the $F \rightarrow {}^3D$ cascading. Calculations show that the contributions of $F \rightarrow {}^3D$ cascading to the population of the $n\,^3D$ states are less than 1%, i.e., completely negligible.

Finally for the ^3S series, direct comparison between theory and experiment is more difficult since theoretical cross sections are available only for $2\,^3S$, while our experimental results cover $3\,^3S$, $4\,^3S$, and $5\,^3S$. In order to make any comparison it is necessary to extrapolate the experimental data with the assumptions that (i) the shape of excitation functions for all the $n\,^3S$ states is identical, and (ii) the peak values of these functions follow the relation $n^{-\alpha}$ or $(n^*)^{-3}$ as was assumed by Phelps and Frost[18] and by Gabriel and Heddle.[7] Here, n^* is the effective quantum number such that the energy of the state is equal to a negative constant divided by $(n^*)^2$. The extrapolation procedure yielded experimental values of $Q(2\,^3S)$ equal to 180, 69, and 39×10^{-20} at 60, 100, 200 eV, respectively, for the $n^{-\alpha}$ relations, where $\alpha=4.0$. Values of 140, 51, and 30×10^{-20} were obtained for the $(n^*)^{-3}$ relationship where $n^*=n-0.30$. These are to be compared with the theoretical values of 5, 2.4, and 0.5×10^{-20} cm^2 calculated by the Born-Oppenheimer approximation. Massey and Moiseiwitsch[21] have shown that when the distortion of the plane wave is taken into consideration, the calculated

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cross sections become much smaller at low voltages. Thus it is seen that the experimental cross sections for the ^3S series are about 30 times the theoretical values. A comparison of the mismatch of theory and experiment of the ^3S family with that of the ^3P and ^3D can best be made at the $n=3$ level. Since no theoretical cross sections are available for the $3\,^3S$ state they were extrapolated from $n=2$ to $n=3$ by use of the $(n^*)^{-3}$ relationship. These figures are to be found in Table IV. They are used only to provide an estimate of the theoretical values and to draw conclusions of qualitative nature.

An examination of Table IV reveals that the fraction of the observed cross section accounted for by theory is much smaller for the $3\,^3D$ state than for the $3\,^3S$ and $3\,^3P$ states. However, a more important consideration would seem to be that of the magnitude of the unaccounted for cross sections, i.e., $Q(\text{obs})-Q(\text{theory})$. This value is of the same order of magnitude at a given electron energy for the three triplet states under comparison. Thus, the mechanism producing the excessive population in the triplet states does not preferentially populate any one state any more than the others.

VIII. CONCLUSIONS

The electron excitation cross sections for 18 excited states of helium have been determined by measuring the intensities of the radiation originated from these excited states at low pressure. Corrections have been made to allow for the cascading and polarization effects. The agreement between the observed and theoretical cross sections for the $3\,^1P$, $4\,^1P$, and $3\,^1S$ states is satisfactory. The experimental cross sections for $3\,^1D$ and $4\,^1D$ are about four times larger than the theoretical values. For the ^3S, ^3P and ^3D states the experimental results far exceeds (a factor of 10 or more) the calculated cross sections.

The discrepancy in the cross sections of the triplet series with the calculated values is far too large to be explained by experimental uncertainty. Nor can one reasonably expect the Born-Oppenheimer approximation to produce cross sections which are ten to a hundred times too small at electron energies above 60 or 100 eV. This is particularly true in view of the fact that the ^1P and ^1S cross sections calculated by the Born approximation do agree with the experimental values. Furthermore, calculations by Massey and Moseiwitsch[21] show that the excitation cross sections obtained from the Born-Oppenheimer approximation and from the EDW method approach each other at electron voltages above 50 eV. One does not expect the use of more refined method of calculation will change the theoretical cross sections (above 50 eV) significantly. In the case of $3\,^1D$ and $4\,^1D$ although the disagreement between theory and experiment is less severe, it is very unlikely that the cumulative errors of the theoretical calculation and the experimental work including the associated analysis of the excitation data could account for the deviation of a factor of four.

The explanation which seems most plausible to us is that the observed population of the triplet states (and possibly, to some extent, of the ^1D states) is produced mainly by processes other than direct excitation. Results of the measurements of the lifetime of the triplet states by Holzberlein and Fowler[26] also point toward the same conclusion. Of course, the mechanism or mechanisms with which the triplet states are populated must have the correct linear behavior with respect to pressure and electron beam current. Efforts are being made to perform additional experiments to provide further evidence of this "anomalous" behavior of the triplet states as well as to search for the mechanisms which are responsible for the observed populations of these states.

AND
RICHARD D. LEVEE,‡ ROBERT L. PEXTON, AND WALTER ARON
Lawrence Radiation Laboratory, University of California, Livermore, California
(Received 13 September 1963)

A numerical program has been developed for the calculation of atomic photoelectric differential and total cross sections, including all polarization correlations. The program is designed to calculate relativistic Coulomb wave functions in a screened central potential; the outgoing continuum wave function is obtained in a partial-wave series. Results are presented here for K-shell differential and total cross sections in point Coulomb potentials (i.e., unscreened) ranging from charge $Z=13$ to $Z=92$, and covering the range of incident photon energies from 200 keV to 2 MeV. Enough data are presented to permit interpolation throughout these ranges. The total cross sections above 1 MeV are found to be significantly lower than previously accepted values. Further, the angular distributions from heavy elements deviate greatly from the commonly used Sauter distribution. These features are discussed and compared with existing experimental and theoretical work.

I. INTRODUCTION

ACCURATE predictions of the cross sections for the atomic photoelectric effect have in general been unavailable. Except for special limiting cases results must be obtained by numerical methods, even when the electron wave functions are assumed to be hydrogen-like and so available in analytic form. The complexity of these procedures has encouraged the use of extrapolation formulas based on various analytic approximations and indeed, at least for the total cross sections, moderate agreement with experiment has been obtained over a wide energy range.[1] The availability of accurate experimental total cross sections, the increasing need for accurate predictions of the differential cross sections, and the recent interest in the polarization properties of these reactions, have encouraged us to attempt their calculation by numerical means.[2]

We calculate in the central-field approximation, that is, we assume any atomic electron, whether bound or continuum, interacts only with a scalar spherically symmetric potential. Further, we neglect the effects of finite nuclear size, so that for sufficiently small distances this potential must simply reduce to the pure Coulomb Ze^2/r potential. For most applications these assumptions are appropriate.

Under these circumstances the theory of the atomic photoelectric effect is a simple application of first-order radiation theory. We require a fully relativistic treatment, since even at low energies, relativistic effects can be significant in a high-Z element. Then the differential cross section for the photoeffect is[1]

$$d\sigma/d\Omega=(2\pi)^{-2}p\epsilon|H|^2 \tag{1.1}$$

subject to energy conservation, where

$$H=-e(2\pi/k)^{1/2}\int d^3r\psi_{\rm fin}{}^*\boldsymbol{\alpha}\cdot\mathbf{e}e^{i\mathbf{k}\cdot\mathbf{r}}\psi_{\rm in}. \tag{1.2}$$

The absorbed radiation is described by its momentum $\mathbf{k}$ and polarization $\mathbf{e}$. $\psi_{\rm in}$ is a solution of the Dirac equation in a central potential corresponding to an initial bound state and $\psi_{\rm fin}$ is a solution corresponding to an outgoing electron of definite momentum $\mathbf{p}$ and energy ϵ ("plane wave" plus *ingoing* spherical waves).

Given the central potential, the entire problem is to solve the Dirac equation for the desired wave functions and then to integrate to obtain the matrix elements H. We have constructed a code for the IBM-7090 which does this.

In the present paper we present results for photoeffect from the K shell of an atom, obtained using wave functions in the pure point Coulomb field. The range of elements from aluminum ($Z=13$) to uranium ($Z=92$) was investigated for photon energies k from 200 keV to 2 MeV. Enough data were taken to permit interpolation throughout these ranges. For each choice of Z and k we obtained (1) the total cross section, (2) the differential cross section, and (3) all polarization correlations be-

‡ Present address: Physics International, Berkeley, California.

[1] We will make some references to the previous work in this field in succeeding sections. The status of the subject up to 1954 is summarized for instance in W. Heitler, *Quantum Theory of Radiation* (Oxford University Press, New York, 1954), 3rd ed. We, in general, follow the notation of this book, but throughout we shall use the units $\hbar=c=m_e=1$. Thus, distances are measured in units of the electron compton wave length, etc. We will often use $a\equiv Ze^2$.

[2] While this work was in progress, an independent numerical calculation of K-shell photoelectric cross sections was reported by S. Hultberg, B. Nagel, and P. Olsson, Arkiv Fysik **20**, 555 (1961), hereafter referred to as HNO. This calculation, although using a method which cannot be applied to screened potentials and not obtaining results above 662 keV, is very valuable both for the information it provided on photoeffect at the lower energies and because it provides checking points for subsequent calculations, such as the present work.

tween incident photon and ejected electron. Results for differential and total cross sections are given here; the results obtained for the polarization correlations will be reported separately.[3] Most of the information is presented in tabular form. Modifications caused by screening,[4] extensions to lower and higher energies, and photoeffect from higher shells will be discussed in subsequent work.

The organization of the present paper is then as follows. In Sec. II we discuss the general properties of the photoeffect, as revealed by simple analytic approximations, and then develop the complete mathematical formalism for the process. Section III is devoted to a short discussion of the numerical methods for calculating wave functions, some features of which have not previously been published. The accuracy of the numerical calculations is discussed in Sec. IV. The remainder of the paper presents our results and compares them with experiment and previous theory. This is done for the total cross section in Sec. V and for the differential cross sections in Sec. VI.

II. GENERAL PROPERTIES AND FORMALISM

The main purpose of this section is to develop the formalism, based on Eqs. (1.1) and (1.2), needed for the calculation of the photoeffect. The wave function $\psi_{\rm fin}$ for the outgoing electron must be written as a sum over partial waves with appropriate asymptotic properties. Then for each partial wave the integrations over angles of Eq. (1.2) may be performed analytically, leaving a small number of radial integrals to be done numerically. The cross sections and the polarization correlations will be completely specified by these quantities.

It is useful, however, to first have a qualitative understanding of the general features of the process. For this purpose we replace Eq. (1.2) with the corresponding nonrelativistic expression

$$H=-e(2\pi/k)^{1/2}\int d^3r\psi_{\rm fin}{}^*\mathbf{p}\cdot\mathbf{e}e^{i\mathbf{k}\cdot\mathbf{r}}\psi_{\rm in}. \qquad (2.1)$$

We assume a pure Coulomb potential, so that for photoeffect from the K shell $\psi_{\rm in}=(a^3/\pi)^{1/2}e^{-ar}$, where $a\equiv Ze^2$. We also make the Born approximation and replace $\psi_{\rm fin}$ with the plane wave $e^{i\mathbf{p}\cdot\mathbf{r}}$. Then the integral (2.1) is easily done, and the differential cross section for photo effect from *both* K-shell electrons is given as

$$\frac{d\sigma}{d\Omega}=4e^2a^5(e_1e_1{}^*)\frac{p^3}{k^5\epsilon^3}\frac{\sin^2\theta}{(1-\beta\cos\theta)^4}, \qquad (2.2)$$

where θ is the angle between $\mathbf{k}$ and $\mathbf{p}$, and e_1 is the component of the photon polarization vector in the scattering plane which $\mathbf{k}$ and $\mathbf{p}$ define.

This cross section vanishes both in the forward and backward directions. For low energies ($\beta\ll1$) it has a broad maximum centered at $\theta=90°$; as the energy increases the maximum shifts toward smaller angles and its width decreases. Equation (2.2) is independent of any circular polarization of the incident photons, but it is sensitive to linear polarization: If the beam is linearly polarized in the direction $\mathbf{e}$, $e_1=\cos\varphi$, where φ is the angle between the plane of $\mathbf{k}$ and $\mathbf{p}$ and the plane of $\mathbf{k}$ and $\mathbf{e}$; there is no emission perpendicular to the direction of polarization. Integrating over angles, the total cross section for unpolarized photons of low energy (but far above threshold) reduces to

$$\sigma=32\sqrt{2}\pi e^2a^5/3k^{7/2}. \qquad (2.3)$$

We note that this (1) varies as the *fifth* power of Z and (2) decreases rapidly with increasing energy.

These results must be modified both for low and for high energies. Near threshold the Born approximation expansion in a/β is invalid; when the exact nonrelativistic Coulomb wave functions are used it is found[1] that the total cross section (2.3) must be multiplied by

$$f=2\pi\left(\frac{I}{k}\right)^{1/2}\frac{e^{-4\eta\cot^{-1}\eta}}{1-e^{-2\pi\eta}},\quad \eta=[I/(k-I)]^{1/2}, \qquad (2.4)$$

where I is the ionization energy. This causes an appreciable reduction from the Born approximation prediction, which is reached only slowly as the energy increases, in the entire low-energy region; at the K-shell threshold $f=0.12$.[5]

For higher energies a relativistic treatment based on Eq. (1.2) is necessary. Sauter found that, to lowest order in Z, the differential cross section from linearly polarized photons is given by[6]

$$\frac{d\sigma}{d\Omega}=4e^2a^5\frac{p^3}{k^5\epsilon^4}\left[\frac{\sin^2\theta\cos^2\varphi}{(1-\beta\cos\theta)^4}-\frac{1-(1-\beta^2)^{1/2}}{2(1-\beta^2)}\frac{\sin^2\theta\cos^2\varphi}{(1-\beta\cos\theta)^3}+\frac{[1-(1-\beta^2)^{1/2}]^2}{4(1-\beta^2)^{3/2}}\frac{\sin^2\theta}{(1-\beta\cos\theta)^3}\right]. \qquad (2.5)$$

This again vanishes in the forward and backward directions; the maximum narrows and moves toward the forward direction as the energy increases. There is now some emission perpendicular to the direction of polariza-

[3] R. H. Pratt, R. D. Levee, R. L. Pexton, and W. Aron, Phys. Rev. 134, A916 (1964) (following paper).

[4] For K-shell photoeffect, it is believed that screening effects are quite small, typically (in heavy elements) of the order of 1–2%. For all other shells, screening effects are large and the use of hydrogen-like wave functions in a numerical calculation is not justified.

[5] However, in heavy elements relativistic effects are important at threshold. Part of this is simply due to the relativistic shift of the threshold energy. The relativistic K-shell photoeffect at threshold has been discussed by B. Nagel and P. Olsson, Arkiv Fysik 18, 29 (1960), in the approximation of an unscreened point Coulomb potential. However, as the authors note, screening effects are expected to be significant in the threshold region even for K-shell photoeffect.

tion. For very high energies the total cross section from unpolarized photons becomes

$$\sigma=4\pi e^2a^5/k, \tag{2.6}$$

and so still varies with the fifth power of Z but decreases less rapidly with increasing energy.

For high-Z elements the corrections to this lowest order theory can be very large. The high-energy behavior of the total cross section has been obtained exactly,[7] with numerical methods, and for $Z=82$ (lead) the prediction of Eq. (2.6) is too large by a factor of five. The expression

$$\sigma=[4\pi e^2a^5/k]e^{-\pi a}(1-4\pi a/15), \tag{2.7}$$

derived analytically, is in fair agreement with these results, and shows the nature of the suppression of the Z^5 dependence. It has also been shown that the cross section does not vanish in the forward direction when terms of relative order a^2 are considered, and such effects have been observed experimentally.[1]

In relativistic photoeffect there will also be interactions with the electron spin, and hence many more types of polarization correlations are possible. To describe these it is convenient to introduce the usual polarization parameters. We describe photon polarization with the quantities

$$\xi_1=e_1^*e_1-e_2^*e_2,\quad \xi_2=e_1e_2^*+e_2e_1^*,\quad \xi_3=i(e_1e_2^*-e_2e_1^*), \tag{2.8}$$

and we describe the polarization of the ejected electron by the direction ζ of its spin in its rest system. ζ_3 is taken along $\mathbf{p}$, ζ_1 in the scattering plane. Then if we sum or average over the initial polarization states of the bound electron, the differential cross section for photoeffect must be of the form

$$\frac{d\sigma}{d\Omega}=\left(\frac{d\sigma}{d\Omega}\right)_{\text{unpol}}[\tfrac{1}{2}\sum_{i,j=0}^{3}\xi_i\zeta_jC_{ij}], \tag{2.9}$$

where $\xi_0=\zeta_0=C_{00}=1$, and $(d\sigma/d\Omega)_{\text{unpol}}$ is the differential cross section from unpolarized photons, summed over final electron spins. The correlation C_{10} connects linearly polarized photons and unpolarized electrons, and as already noted, occurs in the lowest order cross section. Also occurring in lowest order are C_{33}, connecting longitudinally polarized electrons and transversely polarized photons, and C_{31}. The correlations C_{02}, C_{12}, C_{21}, and C_{23} appear in relative order a. The remaining correlations are forbidden by invariance considerations.

We can now develop the formalism needed for a numerical calculation of these photoeffect cross sections. To begin with, we need wave functions for the electrons. A bound state will be specified by *capital* letters: total angular momentum J, orbital angular momentum L, $(J=L\pm\frac{1}{2})$, the azimuthal quantum number M, and total energy (including rest mass energy) E. Thus, for ψ_{in} in Eq. (1.2) we write

$$\psi_{\text{in}}=\begin{pmatrix}G_\kappa(r) & \Omega_{JLM}(\hat{r})\\ iF_\kappa(r) & \Omega_{JL'M}(\hat{r})\end{pmatrix}, \tag{2.10}$$

where L' and κ are defined by

$$L+L'=2J,\qquad \kappa=\mp(J+\tfrac{1}{2})\text{ as }J=L\pm\tfrac{1}{2},\quad(\text{or }J=L'\mp\tfrac{1}{2}), \tag{2.11}$$

and the spherical spinors Ω_{JLM} are defined in terms of spherical harmonics[8] by

$$\Omega_{JLM}=\begin{pmatrix}C_{JLM}^{+} & Y_{L,M-\frac{1}{2}}\\ C_{JLM}^{-} & Y_{L,M+\frac{1}{2}}\end{pmatrix}, \tag{2.12}$$

where

$$\begin{array}{lll} & J=L+\frac{1}{2} & J=L-\frac{1}{2}\\ C^{+}= & \left[\dfrac{J+M}{2L+1}\right]^{1/2} & \left[\dfrac{J-M+1}{2L+1}\right]^{1/2};\\ C^{-}= & \left[\dfrac{J-M}{2L+1}\right]^{1/2} & \left[\dfrac{J+M+1}{2L+1}\right]^{1/2}.\end{array} \tag{2.13}$$

The radial functions G_κ and F_κ are to be obtained as solutions of the coupled equations

$$\begin{aligned}&[E+1+\varphi]F_\kappa-[dG_\kappa/dr+(1+\kappa)(G_\kappa/r)]=0,\\ &[E-1+\varphi]G_\kappa+[dF_\kappa/dr+(1-\kappa)(F_\kappa/r)]=0.\end{aligned} \tag{2.14}$$

The potential φ must be specified (for the pure Coulomb potential $\varphi=a/r$) and the energy E is then determined from the eigenvalue problem. The wave function will be normalized by requiring

$$\int r^2dr[(F)^2+(G)^2]=1. \tag{2.15}$$

The wave function ψ_{fin} of the outgoing continuum electron is written as a sum over partial-wave solutions with appropriate asymptotic properties:

$$\psi_{\text{fin}}=\sum_{jlm}4\pi(\Omega_{jlm}{}^{+}(\hat{p})U_A)i^le^{-i\delta_\kappa}\begin{pmatrix}g_\kappa\Omega_{jlm}(\hat{r})\\ if_\kappa\Omega_{jl'm}(\hat{r})\end{pmatrix}. \tag{2.16}$$

Equations (2.10)–(2.14) are understood to remain valid with the substitution of the *small* letters j, l, l', m, κ, ϵ, etc., and of course $p^2+1=\epsilon^2$, where $\mathbf{p}$ is the momentum of the outgoing particle. The two-spinor U_A specifies the polarization properties of the electron in its rest frame. Equation (2.15), however, is not appropriate for continuum functions, and is replaced by the requirement that the functions are normalized such that at large

distances

$$g_\kappa \underset{r\to\infty}{\longrightarrow} \left(\frac{\epsilon+1}{2\epsilon}\right)^{1/2}\frac{1}{pr}\sin(pr-\tfrac{1}{2}l\pi+\delta_\kappa),$$
$$f_\kappa \underset{r\to\infty}{\longrightarrow} \left(\frac{\epsilon-1}{2\epsilon}\right)^{1/2}\frac{1}{pr}\cos(pr-\tfrac{1}{2}l\pi+\delta_\kappa). \quad (2.17)$$

Equation (2.17) also defines the phase shifts δ_κ. [For the pure Coulomb potentials δ_κ in Eq. (2.17) but *not* Eq. (2.16) should be replaced by $\delta_\kappa+(a\epsilon/p)\ln 2pr$—this feature arises from the long-range character of the potential.] Note that the sum over j and l subject to $j=l\pm\frac{1}{2}$ in Eq. (2.16) is equivalent to a single sum over κ, where κ ranges over all positive and negative integers.

Substituting the wave functions (2.10) and (2.16) back into Eq. (1.2), H can be written as a summation of terms, each corresponding to a given κ and m in the series for the continuum wave function. It is convenient to remove some constants and write this in the form

$$H=-e(2\pi/k)^{1/2}\sum_\kappa \mathcal{H}_\kappa, \quad (2.18)$$

where each $\mathcal{H}_\kappa$ represents a sum over all m values consistent with that κ.

Now we choose a z axis along the photon direction $\mathbf{k}$ and start performing the angular integrations. In the φ integration nonvanishing contributions come only for $m=M\pm1$, and thus the summation over m implied in $\mathcal{H}_\kappa$ reduces to two terms. This is most conveniently written in terms of the circular polarization coefficients $e_\pm\equiv e_x\pm ie_y$, for then

$$\mathcal{H}_\kappa=4\pi e^{i\delta_\kappa}[(U_A{}^*\Omega_{jlM+1}(\hat{p}))e_-R_\kappa{}^+(M) + (U_A{}^*\Omega_{jlM-1}(\hat{p}))e_+R_\kappa{}^-(M)], \quad (2.19)$$

where the R's, a set of numbers resulting from θ and r integrations contain all the remaining information of the problem. (R's of $\pm M$ are easily related.) To proceed further for an arbitrary bound state one expands the plane wave $e^{i\mathbf{k}\cdot\mathbf{r}}$ of Eq. (1.2) in spherical harmonics and then integrates over products of three spherical harmonics.

For the purpose of this paper we restrict our attention to bound S states ($J=\frac{1}{2}$, $L=0$) and the results are quite simple. All the information of the problem is contained in two sets of numbers, $R_\kappa{}^\pm$, defined by

$$R_\kappa{}^+=\int r^2dr g_\kappa F_\kappa C_{jl+\frac{1}{2}}{}^+\left[\frac{l(l+1)}{2l+1}\right]^{1/2}\times[j_{l-1}(kr)+j_{l+1}(kr)],$$

$$R_\kappa{}^-=\int r^2dr\Big\{g_\kappa F_\kappa C_{jl-\frac{1}{2}}{}^- \times\left[-j_{l-1}(kr)\left(\frac{l^2}{(2l+1)}\right)^{1/2}+j_{l+1}(kr)\left(\frac{(l+1)^2}{2l+1}\right)^{1/2}\right] +\eta_\kappa f_\kappa G_\kappa C_{jl'-\frac{1}{2}}{}^-(2l'+1)^{1/2}j_{l'}(kr)\Big\}, \quad (2.20)$$

where $\eta_\kappa=\pm1$ according as $j=l\mp\frac{1}{2}$. [These R's correspond to $R^\pm(M=+\frac{1}{2})$ of Eq. (2.19).] Then for $M=+\frac{1}{2}$

$$\mathcal{H}_\kappa=4\pi e^{i\delta_\kappa}[(U_A{}^*\Omega_{jl+\frac{1}{2}}(\hat{p}))e_-R_\kappa{}^+ + (U_A{}^*\Omega_{jl-\frac{1}{2}}(\hat{p}))e_+R_\kappa{}^-], \quad (2.21)$$

and for $M=-\frac{1}{2}$

$$\mathcal{H}_\kappa=-4\pi\eta_\kappa e^{i\delta_\kappa}[(U_A{}^*\Omega_{jl-\frac{1}{2}}(\mathbf{p}))e_+R_\kappa{}^+ + (U_A{}^*\Omega_{jl+\frac{1}{2}}(\hat{p}))e_-R_\kappa{}^-]. \quad (2.22)$$

We shall *sum* over the two electrons of a bound S state. Then the differential cross section for a photon with polarization parameter ξ_i [as in Eq. (2.8)] to eject an electron with spin direction ζ (in its rest system, with ζ_3 chosen along the electron, and ζ_1 in the scattering plane) into the solid angle $d\Omega$ may be written

$$\frac{d\sigma}{d\Omega}=\tfrac{1}{2}A\sum_{i,j=0}^{3}\xi_i\zeta_jB_{ij}, \quad (2.23)$$

where

$$\xi_0=\zeta_0=1, \quad A=16\pi e^2p\epsilon/k. \quad (2.24)$$

The only nonvanishing B's are

$$\begin{aligned}
B_{00}&=[|J_-|^2+|K_-|^2+|J_+|^2+|K_+|^2],\\
B_{02}&=2\,\mathrm{Im}[J_-{}^*K_-+J_+{}^*K_+],\\
B_{10}&=2\,\mathrm{Re}[J_-{}^*J_++K_-{}^*K_+],\\
B_{12}&=2\,\mathrm{Im}[J_-{}^*K_++J_+{}^*K_-],\\
B_{21}&=-2\cos\theta\,\mathrm{Im}[J_-{}^*K_++K_-{}^*J_+] +2\sin\theta\,\mathrm{Im}[J_-{}^*J_++K_+{}^*K_-],\\
B_{23}&=-2\cos\theta\,\mathrm{Im}[J_-{}^*J_++K_+{}^*K_-] -2\sin\theta\,\mathrm{Im}[J_-{}^*K_++K_-{}^*J_+],\\
B_{31}&=2\cos\theta\,\mathrm{Re}[J_-{}^*K_--J_+{}^*K_+] -\sin\theta[|J_-|^2-|K_-|^2+|K_+|^2-|J_+|^2],\\
B_{33}&=\cos\theta[|J_-|^2-|K_-|^2+|K_+|^2-|J_+|^2] +2\sin\theta\,\mathrm{Re}[J_-{}^*K_--J_+{}^*K_+],
\end{aligned} \quad (2.25)$$

where

$$\begin{aligned}
J_-&=-(4\pi)^{-1/2}\sum_\kappa\eta_\kappa e^{i\delta_\kappa}\left[\frac{|\kappa-1|}{|\kappa||\kappa+1|}\right]^{1/2}R_\kappa{}^+P_l{}^1(\cos\theta),\\
K_-&=(4\pi)^{-1/2}\sum_\kappa e^{i\delta_\kappa}[|\kappa||\kappa^2-1|]^{-1/2}R_\kappa{}^+P_l{}^2(\cos\theta),\\
J_+&=(4\pi)^{-1/2}\sum_\kappa\eta_\kappa e^{i\delta_\kappa}[|\kappa|]^{-1/2}R_\kappa{}^-P_l{}^1(\cos\theta),\\
K_+&=(4\pi)^{-1/2}\sum_\kappa e^{i\delta_\kappa}[|\kappa|]^{1/2}R_\kappa{}^-P_l{}^0(\cos\theta).
\end{aligned} \quad (2.26)$$

In the sums of Eq. (2.26) terms for which the P_l's do not exist are to be omitted; θ is the angle between photon direction $\mathbf{k}$ and electron direction $\mathbf{p}$. [The last four B's of Eq. (2.25) take their form when a rotation is made so that ζ_3 refers to a spin along the *electron* direction.] To put our result in the form of Eq. (2.9) we finally define the polarization correlations by

$$C_{ij}\equiv B_{ij}/B_{00}. \quad (2.27)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The differential cross section from unpolarized photons, summed over electron spins is then

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{unpol}} = AB_{00} \tag{2.28}$$

and the total cross section

$$\sigma = 2\pi A \int_0^\pi B_{00} \sin\theta d\theta = A \sum_\kappa [(R_\kappa^+)^2 + (R_\kappa^-)^2]. \tag{2.29}$$

Thus, when the quantities $R_\kappa^\pm$ (and the phase shifts δ_κ) have been calculated, all properties of the process may be predicted. And the main work in calculating these quantities lies in the prior calculation of the electron wave functions.

III. METHOD OF SOLUTION OF THE WAVE EQUATIONS

A. The Bound-State Wave Equations

The bound-state wave equations

$$\begin{aligned}(E+1+\varphi)F_\kappa - [dG_\kappa/dr + (1+\kappa)(G_\kappa/r)] = 0,\\ (E-1+\varphi)G_\kappa + [dF_\kappa/dr + (1-\kappa)(F_\kappa/r)] = 0,\end{aligned} \tag{3.1}$$

constitute an eigenvalue problem for the energy eigenvalue E and the bound-state wave functions F_κ, G_κ. Since F_κ and G_κ behave like $r^{\gamma-1}$ near $r=0$ for the Coulomb potential[9] and are therefore singular for $\gamma<1$, it is convenient to make the substitution

$$G_\kappa = \bar{G}_\kappa r^{\gamma-1}, \quad F_\kappa = \bar{F}_\kappa r^{\gamma-1}.$$

Equations (3.1) then become

$$\begin{aligned}(E+1+\varphi)\bar{F}_\kappa - \left[\frac{d\bar{G}_\kappa}{dr} + \frac{(\gamma+\kappa)}{r}\bar{G}_\kappa\right] = 0,\\ (E-1+\varphi)\bar{G}_\kappa + \left[\frac{d\bar{F}_\kappa}{dr} + \frac{(\gamma-\kappa)}{r}\bar{F}_\kappa\right] = 0,\end{aligned} \tag{3.2}$$

where $\bar{F}_\kappa$ and $\bar{G}_\kappa$ are finite at $r=0$.

Although the following analysis for the solution of Eqs. (3.2) applies to a potential φ of any form, we shall in the present paper specify the Coulomb potential $\varphi = a/r$.

The boundary conditions associated with (3.2) with $\varphi = a/r$ are determined at the origin by multiplying through by r and letting $r=0$. We have then

$$\begin{aligned}a\bar{F}_\kappa(0) - (\gamma+\kappa)\bar{G}_\kappa(0) = 0,\\ a\bar{G}_\kappa(0) + (\gamma-\kappa)\bar{F}_\kappa(0) = 0.\end{aligned} \tag{3.3}$$

Since the equations are linear and homogeneous, we may choose $\bar{G}_\kappa(0)$ arbitrarily equal to one. $\bar{F}_\kappa(0)$ is then determined by either of the Eqs. (3.3), and γ is determined by the requirement that

$$\begin{vmatrix} a & -(\gamma+\kappa) \\ \gamma-\kappa & a \end{vmatrix} = 0$$

or

$$\gamma = (\kappa^2 - a^2)^{1/2}, \tag{3.4}$$

where the positive sign is taken to obtain a physically acceptable wave function.

In order to determine E we need to satisfy the boundary condition at $r\to\infty$; that is we must approach the asymptotic solution of (3.2). This solution is determined by letting $r\to\infty$ in (3.2), leading to

$$\begin{aligned}(E+1)\bar{F}_\kappa - \bar{G}'_\kappa = 0,\\ (E-1)\bar{G}_\kappa + \bar{F}'_\kappa = 0,\end{aligned}$$

which have the solution

$$\begin{aligned}\bar{G}_\kappa = C_1 e^{-\lambda r},\\ \bar{F}_\kappa = C_2 e^{-\lambda r},\end{aligned} \tag{3.5}$$

where $\lambda = (1-E^2)^{1/2}$ with $E<1$. Increasing solutions are ruled out since the wave function must be bounded as $r\to\infty$. [In the point Coulomb potential, these forms must be multiplied by $r^{n-|\kappa|}$, where n is the principal quantum number; this has no effect for the K shell.]

In order to numerically integrate (3.2), we must replace them by suitable difference equations. In the difference equations we have chosen, we evaluate the wave functions $\bar{F}$ and $\bar{G}$ (for simplification we have dropped the subscript κ) at the discrete points labeled by integral values of j running from zero at $r=0$ to J at a point r_J. The coordinate r_J is that point where the asymptotic boundary conditions (3.5) are satisfied in appropriate difference form to within some tolerance T_1. The conditions (3.2) are applied at $j+\frac{1}{2}$ and the derivatives are therefore evaluated as the slope of the chords joining values at j and $j+1$. Quantities needed at $j+\frac{1}{2}$ are evaluated by averaging. The resulting finite difference equations are

$$\begin{aligned}(E+1+\varphi_{j+\frac{1}{2}})\frac{(\bar{F}_{j+1}+\bar{F}_j)}{2} - \left[\frac{\bar{G}_{j+1}-\bar{G}_j}{r_{j+1}-r_j} + \frac{(\gamma+\kappa)}{2r_{j+\frac{1}{2}}}(\bar{G}_{j+1}+\bar{G}_j)\right] = 0,\\ (E-1+\varphi_{j+\frac{1}{2}})\frac{(\bar{G}_{j+1}+\bar{G}_j)}{2} + \left[\frac{\bar{F}_{j+1}-\bar{F}_j}{r_{j+1}-r_j} + \frac{(\gamma-\kappa)}{2r_{j+\frac{1}{2}}}(\bar{F}_{j+1}+\bar{F}_j)\right] = 0,\end{aligned} \tag{3.6}$$

with $0\le j\le J-1$.

The basis of the method is the simultaneous solution

[9] L. I. Schiff, *Quantum Mechanics* (McGraw-Hill Book Company, Inc., New York, 1955), 2nd ed., Sec. 44, p. 336.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the complete set of difference equations and boundary conditions. This method has been described for a two-point boundary value problem by Henyey *et al.*[10] The suggestion that the method could also be used for eigenvalue problems was made to one of us by Henyey[11] many years ago and has in fact been used by Levee to solve many problems.

The Eqs. (3.6), although linear in the functions $\bar{F}$ and $\bar{G}$, are nonlinear in the unknowns because of the appearance of the eigenvalue E. They must therefore be solved by an iterative technique such as the Newton-Raphson method described in Henyey *et al.*[10]

Formally we may write (3.6) as

$$\begin{aligned} &Q_{j+\frac{1}{2}}{}^1(\bar{F}_{j+1},\bar{F}_j,\bar{G}_{j+1},\bar{G}_j,E)=0, \\ &Q_{j+\frac{1}{2}}{}^2(\bar{F}_{j+1},\bar{F}_j,\bar{G}_{j+1},\bar{G}_j,E)=0, \\ &\qquad 0\leq j\leq J-1. \end{aligned} \tag{3.7}$$

The Newton-Raphson method when applied to a system

$$f_k(x_1,x_2,\cdots,x_K)=0, \quad k=1, 2, \cdots, K \tag{3.8}$$

corrects an approximate set of values $x_1{}^p$, $x_2{}^p$, $\cdots$, $x_K{}^p$ by variations $\delta x_1{}^p$, $\delta x_2{}^p$, $\cdots$, $\delta x_K{}^p$ to give improved values $x_1{}^{p+1}$, $x_2{}^{p+1}$, $\cdots$, $x_K{}^{p+1}$ where p is the iteration number. The variations are determined from the equations

$$f_k+\sum_{l=1}^{K}\frac{\partial f_k}{\partial x_l}\delta x_l=0, \quad k=1, 2, \cdots, K \tag{3.9}$$

and the iteration is continued until the Eqs. (3.8) are satisfied to within some desired tolerance.

If we define the following two vectors

$$Q_{j+\frac{1}{2}}=\begin{pmatrix} Q_{j+\frac{1}{2}}{}^1 \\ Q_{j+\frac{1}{2}}{}^2 \end{pmatrix}, \quad q_j=\begin{pmatrix} \delta\bar{F}_j \\ \delta\bar{G}_j \end{pmatrix},$$

we may write, in accordance with (3.9), the variational equations derived from (3.6) as

$$A_{j+\frac{1}{2}}q_{j+1}+B_{j+\frac{1}{2}}q_j+C_j\delta E+Q_{j+\frac{1}{2}}=0, \quad 0\leq j\leq J-1, \tag{3.10}$$

where

$$A_{j+\frac{1}{2}}=\begin{bmatrix} \frac{\partial Q_{j+\frac{1}{2}}{}^1}{\partial\bar{F}_{j+1}} & \frac{\partial Q_{j+\frac{1}{2}}{}^1}{\partial\bar{G}_{j+1}} \\ \frac{\partial Q_{j+\frac{1}{2}}{}^2}{\partial\bar{F}_{j+1}} & \frac{\partial Q_{j+\frac{1}{2}}{}^2}{\partial\bar{G}_{j+1}} \end{bmatrix}, \quad B_{j+\frac{1}{2}}=\begin{bmatrix} \frac{\partial Q_{j+\frac{1}{2}}{}^1}{\partial\bar{F}_j} & \frac{\partial Q_{j+\frac{1}{2}}{}^1}{\partial\bar{G}_j} \\ \frac{\partial Q_{j+\frac{1}{2}}{}^2}{\partial\bar{F}_j} & \frac{\partial Q_{j+\frac{1}{2}}{}^2}{\partial\bar{G}_j} \end{bmatrix},$$

$$C_j=\begin{bmatrix} \frac{\partial Q_{j+\frac{1}{2}}{}^1}{\partial E} \\ \frac{\partial Q_{j+\frac{1}{2}}{}^2}{\partial E} \end{bmatrix}.$$

Since the matrix of the coefficients of Eqs. (3.10) is of the form

$$\begin{array}{c} \\ j=0 \\ 1 \\ 2 \\ \vdots \\ J-1 \end{array}\begin{array}{c} \begin{array}{cccccccc} q_0 & q_1 & q_2 & q_3 & \cdots & q_{J-1} & q_J & \delta E \end{array} \\ \begin{bmatrix} x & x & & & & & & x \\ & x & x & & & & & x \\ & & x & x & & & & x \\ & & & \cdot & & & & \\ & & & & & x & x & x \end{bmatrix} \end{array},$$

we have J equations in $J+2$ unknowns. The two additional conditions which are necessary to solve the equations are given by the boundary condition at $j=0$ and the asymptotic condition at $j=J$.

At $j=0$, $\bar{F}_0$ is given by either of (3.3) when we have chosen $\bar{G}_0=1$ arbitrarily. Then $q_0=0$ and the first equation of (3.10) gives q_1 in terms of δE. Using this relation we eliminate q_1 from the second of (3.10) to give q_2 in terms of δE. The elimination process is continued to the final equation which gives q_J in terms of δE. These equations will be of the form

$$\begin{aligned} &q_j=e_j\delta E+f_j, \quad 0\leq j\leq J, \\ &q_0=0. \end{aligned} \tag{3.11}$$

Substituting the first of (3.11) into (3.10) we find recursion relations for the two-vectors e_j and f_j as

$$\begin{aligned} e_{j+1}&=-A_{j+\frac{1}{2}}{}^{-1}(B_{j+\frac{1}{2}}e_j+C_j), \\ f_{j+1}&=-A_{j+\frac{1}{2}}{}^{-1}(B_{j+\frac{1}{2}}f_j+Q_{j+\frac{1}{2}}). \end{aligned} \tag{3.12}$$

Since $q_0=0$, $e_0=f_0=0$ and we may determine all the e_j, f_j from (3.12) for $0\leq j\leq J$.

At $j=J$ we write the asymptotic solution (3.5) in difference form as

$$\bar{G}_J=\bar{G}_{J-1}e^{[-\lambda(r_J-r_{J-1})]}. \tag{3.13}$$

Taking the variation of (3.13) we have

$$\begin{aligned} \delta\bar{G}_J=e^{[-\lambda(r_J-r_{J-1})]}&[\delta\bar{G}_{J-1} \\ &-(r_J-r_{J-1})\bar{G}_{J-1}(d\lambda/dE)\delta E], \end{aligned} \tag{3.14}$$

where

$$d\lambda/dE=-E/(1-E^2)^{1/2} \tag{3.15}$$

from the asymptotic solution.

Now from (3.11) and our definition of q_j we have

$$\delta G_{J-1}=e_{J-1}{}^{(2)}\delta E+f_{J-1}{}^{(2)} \tag{3.16}$$

and

$$\delta G_J=e_J{}^{(2)}\delta E+f_J{}^{(2)},$$

where the superscript "2" refers to the lower element of the e, f two-vectors. Substituting (3.16) into (3.14) and

[10] L. G. Henyey, L. Wilets, K. H. Böhm, R. LeLevier, and R. D. Levee, Astrophys. J. 129, 628 (1959).
[11] L. G. Henyey (private communication to Levee).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

solving for E, we arrive at

$$\delta E=\frac{e^{-\lambda(r_J-r_{J-1})}f_{J-1}^{(2)}-f_J^{(2)}}{e_J^{(2)}+[\bar{G}_{J-1}(r_J-r_{J-1})(d\lambda/dE)-e_{J-1}^{(2)}]e^{-\lambda(r_J-r_{J-1})}}. \tag{3.17}$$

The iteration process may be summarized as follows: (1) From the pth approximation to $\bar{F}_j$, $\bar{G}_j$, and E, compute the elements of $A_{j+\frac{1}{2}}$, $B_{j+\frac{1}{2}}$, C_j and $Q_{j+\frac{1}{2}}$ for $0\leq j\leq J-1$. (2) Using (3.12) compute $e_1, e_2, \cdots, e_J$; $f_1, f_2, \cdots, f_J$ using $e_0=f_0=0$. (3) Compute δE by (3.17). (4) Compute the corrections $\delta\bar{F}_1, \delta\bar{F}_2, \cdots, \delta\bar{F}_J$, $\delta\bar{G}_1, \delta\bar{G}_2, \cdots, \delta\bar{G}_J$ from the first of (3.11). (5) Compute the $p+1$st approximations by

$$\left.\begin{aligned}E^{p+1}&=E^p+\delta E^p\\ \bar{F}_j{}^{p+1}&=\bar{F}_j{}^p+\delta\bar{F}_j{}^p\\ \bar{G}_j{}^{p+1}&=\bar{G}_j{}^p+\delta\bar{G}_j{}^p\end{aligned}\right\}0<j\leq J.$$

This process is repeated until all the unknowns satisfy the inequality

$$|\delta x_k{}^p/x_k{}^{p+1}|<T_2,\quad k=1, 2, \cdots, K$$

and $|\delta E/E|<T_1$ for $x_k>T_3$. For $x_k<T_3$ we do not make a test.

In addition to satisfying the above tolerance tests, we must also have chosen r_J such that the asymptotic solution is indeed valid. To check this we compute

$$\hat{\bar{F}}_{J-1}=\bar{F}_{J-2}e^{-\lambda(r_{J-1}-r_{J-2})}$$
$$\hat{\bar{G}}_{J-1}=\bar{G}_{J-2}e^{-\lambda(r_{J-1}-r_{J-2})}$$

and require that

$$|(\hat{\bar{F}}_{J-1}-\bar{F}_{J-1})/\bar{F}_{J-1}|<T_1$$

and that

$$|(\hat{\bar{G}}_{J-1}-\bar{G}_{J-1})/\bar{G}_{J-1}|<T_1.$$

If these inequalities are satisfied we are finished. If they are not, we advance J by 10 and resolve the equations. This procedure is repeated until all tests are satisfied.

In order to normalize our solutions we require that

$$N^2\int_0^\infty r^{\gamma+1}(\bar{F}^2+\bar{G}^2)dr=1=N^2\int_0^\infty H(r)dr.$$

This quadrature was performed by Bessell's formula

$$\int_0^\infty H(r)dr=\sum_{j=0}^{4}C_j(H_j+H_{J-j})+\sum_{j=5}^{J-5}H_j+\int_{r_J}^\infty H(r)dr$$

where the C_j take on the values

$$C_0{}^1=0.32986,\quad C_1{}^1=1.32083,\quad C_2{}^1=0.76667,$$
$$C_3{}^1=1.10139,\quad C_4{}^1=0.98125.$$

The final values of the wave functions for the bound state are given by

$$\left.\begin{aligned}F_j&=Nr^{\gamma-1}\bar{F}_j\\ G_j&=Nr^{\gamma-1}\bar{G}_j\end{aligned}\right\}0\leq j\leq J.$$

In the results reported here we have taken $T_1=10^{-4}$, $T_2=10^{-5}$, $T_3=10^{-5}$. The actual iteration error is much smaller since the tests involve comparison with values from the preceding iteration. In fact, since Newton's method doubles the number of significant figures when within the linear range, iteration errors are probably less than 10^{-8}.

B. The Continuum-State Wave Equations

The continuum-state wave equations

$$\begin{aligned}(\epsilon+1+\varphi)f_\kappa-[(dg_\kappa/dr)+(1+\kappa)(g_\kappa/r)]&=0\\ (\epsilon-1+\varphi)g_\kappa+[(df_\kappa/dr)+(1-\kappa)(f_\kappa/r)]&=0\end{aligned} \tag{3.18}$$

constitute an initial value problem since ϵ, the energy of the ejected electron, is determined by the sum of the incident photon energy and the energy of the bound state determined in the previous section.

As in the case of the bound state, it is convenient to make a change of variables here also.

$$f_\kappa=\bar{f}_\kappa r^{\gamma-1},\quad g_\kappa=\bar{g}_\kappa r^{\gamma-1}.$$

Equations (3.18) then become

$$\begin{aligned}(\epsilon+1+\varphi)\bar{f}_\kappa-[d\bar{g}_\kappa/dr+[(\gamma+\kappa)/r]\bar{g}_\kappa]&=0\\ (\epsilon-1+\varphi)\bar{g}_\kappa+[d\bar{f}_\kappa/dr+[(\gamma-\kappa)/r]\bar{f}_\kappa]&=0\end{aligned} \tag{3.19}$$

where $\bar{f}_\kappa$ and $\bar{g}_\kappa$ are finite at $r=0$.

In a manner similar to the bound state we determine at $r=0$ for a Coulomb potential a/r

$$a\bar{f}_\kappa(0)=(\gamma+\kappa)\bar{g}_\kappa(0) \tag{3.20a}$$

or

$$a\bar{g}_\kappa(0)=-(\gamma-\kappa)\bar{f}_\kappa(0). \tag{3.20b}$$

Thus $\gamma^2=\kappa^2-a^2$ and since Eqs. (3.20) are linear we may again choose $\bar{g}_\kappa(0)$ arbitrarily equal to 1. We then may determine $\bar{f}_\kappa(0)$ from either of (3.20). In practice we use (3.20a) for $\kappa>0$ and (3.20b) for $\kappa<0$ to insure the greatest accuracy.

In order to normalize the continuum solution properly, it is necessary to find the asymptotic solution. This is done by matching the solutions of (3.18) with φ not zero to general solutions of (3.18) with φ equal to zero,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and evaluating the asymptotic behavior from the zero-φ solutions beyond the range of the potential.

Let the matching of solutions be done at a point r_0. Let $p^2=\epsilon^2-1$. Then

$$\begin{aligned} f_\kappa(r_0)&=[(\epsilon-1)/pr_0]^{1/2} \\ &\quad\times[A_+J_{\kappa-\frac{1}{2}}(pr_0)+A_-J_{-(\kappa-\frac{1}{2})}(pr_0)] \\ g_\kappa(r_0)&=[(\epsilon+1)/pr_0]^{1/2} \\ &\quad\times[A_+J_{\kappa+\frac{1}{2}}(pr_0)-A_-J_{-(\kappa+\frac{1}{2})}(pr_0)]. \end{aligned} \tag{3.21}$$

These two equations serve to determine the constants A_+ and A_-. The asymptotic behavior of f_κ and g_κ is then determined by the asymptotic form of the Bessel functions.

$$\begin{aligned} f_\kappa(r)&\sim\left(\frac{2(\epsilon-1)}{\pi}\right)^{1/2}\frac{1}{pr}\left[A_+\cos\left(pr-\frac{\pi\kappa}{2}\right)\right. \\ &\quad\left.+A_-\cos\left(pr+\frac{\pi\kappa}{2}-\frac{\pi}{2}\right)\right], \\ g_\kappa(r)&\sim\left(\frac{2(\epsilon+1)}{\pi}\right)^{1/2}\frac{1}{pr}\left[A_+\cos\left(pr-\frac{\pi\kappa}{2}-\frac{\pi}{2}\right)\right. \\ &\quad\left.-A_-\cos\left(pr+\frac{\pi\kappa}{2}\right)\right]. \end{aligned} \tag{3.22}$$

The normalization factor A and the phase shift δ_κ are given by

$$\begin{aligned} A&=(A_+^2+A_-^2)^{1/2}, \\ \cos\delta_\kappa&=A_+/A, \\ -\sin\delta_\kappa&=(-1)^\kappa A_-/A. \end{aligned} \tag{3.23}$$

The asymptotic forms of f_κ and g_κ are then

$$\begin{aligned} f_\kappa(r)&\sim\left(\frac{2(\epsilon-1)}{\pi}\right)^{1/2}\frac{A}{pr}\cos\left(pr-\frac{\kappa\pi}{2}+\delta_\kappa\right), \\ g_\kappa(r)&\sim\left(\frac{2(\epsilon+1)}{\pi}\right)^{1/2}\frac{A}{pr}\sin\left(pr-\frac{\kappa\pi}{2}+\delta_\kappa\right). \end{aligned} \tag{3.24}$$

In using this with a true Coulomb potential, the phase shifts δ_κ will not become constant with increasing r, but rather will continue to increase, behaving like $(a\epsilon/p)\ln 2pr+$constant. This must be taken into account when checking whether the asymptotic form is attained. For potentials that die out more rapidly than the Coulomb potential, the δ_κ's should become constants in r.

The numerical solution of either (3.18) or (3.19) is straightforward except near $r=0$. Because of the singularity exhibited in (3.18) at $r=0$ we use (3.19), but even here we have a starting problem.

Let us write Eqs. (3.19) in the vector notation

$$\omega_\kappa'=A_\kappa\omega_\kappa, \tag{3.25}$$

where ω_κ has components $\bar{f}_\kappa$, $\bar{g}_\kappa$ and where

$$A_\kappa=\begin{bmatrix} -\dfrac{\gamma-\kappa}{r} & -\left(\epsilon-1+\dfrac{a}{r}\right) \\ \left(\epsilon+1+\dfrac{a}{r}\right) & -\dfrac{(\gamma+\kappa)}{r} \end{bmatrix}. \tag{3.26}$$

Consider now the finite difference representation of (3.25) based on the Euler approximation

$$(\omega_{j+1}-\omega_j)/h=A_j\omega_j, \quad j>0, \tag{3.27}$$

where $h=r_{j+1}-r_j=$a constant, and where we have for simplicity dropped the subscript κ. Equation (3.27) is restricted to $j>0$ since the elements of A_j are singular for $j=0$. In practice ω_1 would be determined from ω_0 by a series expansion. Equations (3.27) may be written

$$\omega_{j+1}=(I+hA_j)\omega_j.$$

The first-order error equation will then be

$$\delta\omega_{j+1}=(I+hA_j)\delta\omega_j, \tag{3.28}$$

where we have neglected errors in A_j. Equation (3.28) may be simplified to

$$\delta\omega_{j+1}=B_j\delta\omega_j, \tag{3.29}$$

with

$$B_j=\begin{bmatrix} 1-\dfrac{h}{jh}(\gamma-\kappa) & -h\left(\epsilon-1+\dfrac{a}{jh}\right) \\ h\left(\epsilon+1+\dfrac{a}{jh}\right) & 1-\dfrac{h(\gamma+\kappa)}{jh} \end{bmatrix} \tag{3.30}$$

and where we have replaced r by $r_0+jh=jh$.

If individual errors in ω_j are to remain bounded, we must require that the eigenvalue of the matrix B_j be less than or equal to 1 in absolute value. The eigenvalues of (3.30) are determined from

$$\begin{bmatrix} 1-\dfrac{(\gamma-\kappa)}{j}-\lambda & -h\left(\epsilon-1+\dfrac{a}{jh}\right) \\ h\left(\epsilon+1+\dfrac{a}{jh}\right) & 1-\dfrac{(\gamma+\kappa)}{j}-\lambda \end{bmatrix}=0.$$

The argument holds in the limit of $h\to 0$ which leads to

$$[1-(\gamma-\kappa)/j-\lambda][1-(\gamma+\kappa)/j-\lambda]+a^2/j^2=0. \tag{3.31}$$

Remembering that $\gamma^2=\kappa^2-a^2$ we solve (3.31) to give $\lambda=1,\ 1-(2\gamma/j)$. Since we require $|\lambda|\leq 1$ we have $-1\leq 1-(2\gamma/j)\leq 1$. Now γ and j are always greater than zero and therefore the right-hand inequality is always satisfied. The left-hand inequality will be satisfied if $j>\gamma$. The conclusion is that if we want errors to decrease in the solution of (3.19) by numerical integration, we must begin the integration at a value of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$j \geq \gamma$. The maximum value of γ in our calculations was 20 corresponding to $\kappa = \pm 20$ and it is therefore necessary to use the starting series described below for the first 20 steps. Although the above analysis is applied to the simple Euler method it leads to the same result where applied to the Runge-Kutta method. In fact, it was using the Runge-Kutta method for starting that led to the observations of the error growth and the analysis.[12] It has been pointed out to the authors by J. Scofield[13] that the modified Euler scheme, $\omega_{j+1} = [(I + \frac{1}{2}hA_{j+\frac{1}{2}})/(I - \frac{1}{2}hA_{j+\frac{1}{2}})]\omega_j$ has eigenvalues $\lambda = 1$, $[1 - \gamma/(j+\frac{1}{2})]/[1 + \gamma/(j+\frac{1}{2})]$ in the limit as $h \to 0$. Therefore errors in this scheme will be bounded since $\gamma > 0$.

The power-series solution to (3.19) around the point r_n is of the form

$$\begin{aligned} \bar{f}(r) &= \sum c_i (r - r_n)^i, \quad i = 0, 1, 2, \cdots, \\ \bar{g}(r) &= \sum b_i (r - r_n)^i, \quad i = 0, 1, 2, \cdots. \end{aligned} \tag{3.32}$$

Substituting into (3.19) we arrive at the recursion relations

$$\begin{aligned} r_n(i+2)b_{i+2} + (i+1)b_{i+1} + (\gamma+\kappa)b_{i+1} \\ - [(\epsilon+1)r_n + a]c_{i+1} - (\epsilon+1)c_i = 0, \\ r_n(i+2)c_{i+2} + (i+1)c_{i+1} + (\gamma-\kappa)c_{i+1} \\ + [(\epsilon-1)r_n + a]b_{i+1} + (\epsilon-1)b_i = 0, \end{aligned}$$

where $c_0 = \bar{f}(r_n)$, $b_0 = \bar{g}(r_n)$. These relations allow the determination of the c_i, b_i for $i > 0$ for successive expansions about $r_n = 0$, $r_n = h$, $r_n = 2h$, $\cdots$, $r_n = jh$. Since we are always expanding about the previous point, $r - r_n = h$.

The series solutions (3.32) and similar equations for the derivatives of $\bar{f}$ and $\bar{g}$ were computed out to $j = JJ$. The series at each j were terminated when the percentage error in f' and g' was less than one part in 10^8. Using the functions and derivatives thus determined, the numerical solution of (3.32) was then continued by the Runge-Kutta method. In the case of a general potential where the series solution is not easily arrived at, we plan using the modified Euler scheme for starting the integration.

At this point in j we switched back to using f and g instead of $\bar{f}$ and $\bar{g}$ so that our numbers would not become too small. In addition it was necessary to add a scale factor, SF, in both f and g in certain cases to keep numbers within machine limits. Using the values

$$\begin{aligned} f_{JJ} &= \bar{f}_{JJ}(SF \cdot r_{JJ})^{\gamma-1} \\ g_{JJ} &= \bar{g}_{JJ}(SF \cdot r_{JJ})^{\gamma-1} \\ f_{JJ'} &= \bar{f}_{JJ'}(SF \cdot r_{JJ})^{\gamma-1} + (\gamma-1)f_{JJ}/r_{JJ} \\ g_{JJ'} &= \bar{g}_{JJ'}(SF \cdot r_{JJ})^{\gamma-1} + (\gamma-1)g_{JJ}/r_{JJ}, \end{aligned}$$

the numerical integration of (3.32) was continued by the standard Runge-Kutta method.

[12] This difficulty had been observed and resolved previously by Levee in a problem in controlled thermonuclear reactions.

[13] J. Scofield (private communication).

Although our analysis in this section indicates that we should take $JJ = 20$, we actually used $JJ = 10$. This allowed small errors to appear in the normalization factors and wave functions for $\kappa > 10$. These errors were of the order of 4% in the normalization factor at $\kappa = 16$. However, the high values of κ contributed very little to the cross sections and the cross sections show no error due to using $JJ = 10$ instead of 20.

We require f and g to be normalized such that

$$\begin{aligned} f &\sim \left(\frac{\epsilon-1}{2\epsilon}\right)^{1/2} \frac{1}{pr} \cos\left(pr - \frac{l\pi}{2} + \delta\right) \\ g &\sim \left(\frac{\epsilon+1}{2\epsilon}\right)^{1/2} \frac{1}{pr} \sin\left(pr - \frac{l\pi}{2} + \delta\right). \end{aligned} \tag{3.33}$$

From (3.23) and (3.33) we then have the following relation for the normalization factor N_1: $N_1 = 2A(\epsilon/\pi)^{1/2}$ where A is determined from (3.21) and the first of (3.23).

The phase δ must now be determined. For a potential which falls off more rapidly than $1/r$ the phase will be given by (3.23) as $\delta = \arctan|A_-/A_+|$, but for the pure Coulomb potential $\delta = \arctan|A_-/A_+| - (a\epsilon/p)\ln 2pr$.

In the program reported here we have computed A at each step of the integration and required that

$$\left| 2\frac{A_{j+10} - A_j}{A_{j+10} + A_j} \right| < T_4.$$

It turned out that for the very small T_4 chosen, the integration was always carried out to the predetermined maximum at $r = 120$. At this point the normalizations and phases were determined.

IV. ACCURACY OF THE NUMERICAL CALCULATION

We have seen that we will have all the information needed to specify the properties of S-state photoeffect when we have calculated the quantities $R_\kappa^\pm$ given by Eq. (2.20). We have not discussed how many of these quantities we need to calculate, i.e., the convergence properties of the series in Eqs. (2.24) and (2.27). We follow usual practice, and will judge the convergence by the size of successive $R_\kappa^\pm$. Practical considerations force us to choose a limit for $|\kappa|$ in advance, since the methods employed for calculating functions and organizing the numerical program for machine purposes depend on this choice; in the present paper we consider $|\kappa| \leq 20$.

Then first of all the calculation of a given R_κ requires bound-state radial functions F_κ, G_κ, continuum radial functions f_κ, g_κ, and spherical Bessel functions $j_l(kr)$. Also, in calculating angular distributions we will need the associated Legendre functions $P_l^m(\cos\theta)$, for $m = 0$, 1, 2. The accuracy of the calculations of these *components* of the general program are discussed in separate subsections. We can then estimate the accuracy with which each R_κ has been computed, and the accuracy this implies for the cross sections. And we must also judge

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the error which has been made due to the restriction $|\kappa| \leq 20$.

Checks for the component programs will be discussed separately. A number of checks are available for the final results: We can compare with analytic results for low Z and we can compare with numerical results which have previously been obtained for photoelectric cross sections. These comparisons are made in the subsequent sections where we present our results. In all cases the proper agreement was obtained, so that we have full confidence in our numerical program. It should perhaps also be mentioned that with the present program some ten minutes of IBM-7090 time were required to obtain the differential and total cross sections and polarization correlations for a given choice of element and energy; it is expected that further improvements in the program will appreciably reduce this figure.

A. Component Programs

i. Bound-State Wave Functions

The accuracy of the bound-state calculation can be tested for the pure Coulomb potential by comparison with analytic results. It is particularly simple to check the eigenvalue and the normalization of a calculated wave function. The energy levels are obtained with considerable accuracy. However, the normalization coefficient, i.e., the constant which multiplies the known small r dependence, probably gives a better indication of the over-all accuracy of the wave function. For given $h \equiv r_{i+1} - r_i$, the error in mormalization increases with Z. With $h=0.05$, the smallest value used, the error is negligible for $Z=26$ or 50 but 0.4% for $Z=82$ and 0.6% for $Z=92$. To obtain 1% accuracy in the cross sections for heavy elements we have taken results for $h=0.1$, 0.075, and 0.05 and extrapolated to $h=0$. [*Note:* It has since been established that these small errors result from a minor error in programming; once this is corrected, the error in bound-state normalizations becomes completely negligible.]

ii. Continuum-State Wave Functions

The two parameters of a continuum-state solution which are easily compared with the analytical results of the pure Coulomb potential are normalization and phase. The accuracy of the normalizations calculated with $h=0.05$ for some typical partial waves in low-Z (26) and high-Z (82 and 84) elements are shown for various energies in Table I. The errors in the higher partial waves are nearly independent of energy (away from threshold) and Z, but increase rapidly with κ. These arise from the use of the same switching point $JJ=10$ from power series to numerical integration for all κ. Except at the highest energy (2 MeV), the errors are not sensitive to choices of h in the range from 0.05 to 0.1. The error in normalization also increases rapidly as the threshold energy is approached. This type of error is insensitive to h and may be connected with the very long periods of low-energy continuum states. In Table II we give the analogous errors in phase shifts, expressed both in radians and in percent.

TABLE I. Accuracy of continuum normalizations.

	Energy (MeV) \ κ	+1 (%)	+5 (%)	+9 (%)	+15 (%)

	1.131	0.0011(0.3%)	0.0009(0.1%)	0.0011(0.1%)	0.0014(0.1%)

iii. Spherical Bessel Functions

The spherical Bessel functions j_l, $0 \leq l \leq 20$, were computed by the method of Corbató and Uretsky[14] and were checked against the NBS Tables[15] for selected values of l. The errors were less than one part in 10^6.

iv. Legendre Polynomials

The Legendre and associated Legendre functions were computed in double precision arithmetic directly from the polynomials given by Tallquist.[16] These were compared with double precision values computed from the recursion relations and found to agree to at least one part in 10^{12}. Rough comparisons can be made to the tables of Mursi[17] and NBS.[18]

B. The Main Program

i. Partial-Wave Integrals R_κ

The errors in an R_κ are due first to the errors of the component programs and second to the errors of the

integration procedures. The errors in integration arise from the choice of h and r_{max}, the upper limit of the integration.

Table III summarizes, for representative parameters, the distance in r which it was necessary to integrate to hopefully reduce the residual contribution to less than one part in 10^6. The needed distance increases slowly with increasing κ; in heavy elements it is nearly independent of energy and is determined by the decreasing exponential of the bound-state wave function. Since this exponential scales as Z the required distance greatly increases as Z decreases. In light elements this has the consequence that an energy dependence persists in the energy range of concern, and the rapid oscillations of a high-energy continuum-state work to reduce the needed distance.[19] Since such a stringent criterion was applied in the table, it is possible to obtain satisfactory results from the present calculation for a Z as low as 10 or 13, even with the restriction $r_{max} \leq 120$ required in the machine program.

The error in integration arising from the choice of h can be estimated by noting the change in the values of R_κ resulting from changes in h and subtracting out the portion of this which is due to change in component programs with h. As already noted, up to 1.5 MeV, the only component program which is sensitive to choices of h in the range 0.05–0.10 is the bound-state wave function. When the estimated error from this source is subtracted, the residual error to be attributed to error from h in integration is generally small and, with one exception,[20] completely independent of κ. The typical error begins to increase at higher energies: the difference between R_κ of $h=0.05$ and 0.10, still negligible at 662 keV, is about 0.4% at 1.131 MeV, both for $Z=26$ and 82, and 1.5% at 1.5 MeV.

TABLE IV. Number of κ's needed for accuracy to one part in 10^n.

E \ n	1	2	3	4	5	6
0.140	2	3	4	4	5	5
0.200	3	4	5	6	7	8
0.279	3	4	6	7	8	9
0.354	4	5	7	9	10	12
0.400	4	6	8	9	11	13
0.662	5	8	10	13	14	
1.131	7	12	15			
1.1368	8	13	16			
2.0	11	≈17				
2.754	14					

[19] It should be noted that the distance required for very high accuracy has a different dependence on parameters from the distance which characterizes the main region of the integrand. It is the latter distance which is discussed in the various analytic approximations.

ii. Number of κ's Contributing to Cross Section

The number of κ's needed to determine the total cross section to any desired accuracy increases with energy, but it is almost independent of Z. One or two more κ's are needed to obtain the same accuracy for $Z=26$ as for $Z=84$. In Table IV we summarize as a function of energy (for heavy elements) the number of κ's needed to obtain an accuracy of one part in 10^n. The restriction to $|\kappa|<20$ results in a limitation to energies below about 2 MeV if it is desired to obtain the total cross section to 1%.

TABLE V. Estimates of total error in numerical calculation.

	Energy	Error in σ_{total} (%)
Low Z	0.354	0.2
	1.131	0.6
High Z	0.200	1.1
	0.354	0.5
	0.600	0.5
	1.131	0.8
	1.368	0.8
	2.00	2.0

iii. Estimate of Total Error in Cross Sections

We assume that a fit is made to the results for different h and extrapolated to $h=0$, and we assume that, in agreement with our analysis, this renders errors associated with h (bound-state normalization, integration, etc.) negligible, i.e. 0.1%. Then the error in R_κ is dominated by the error in the continuum wave function. From this estimate of the error in each R_κ, and from the information just presented on the contribution of each κ to the cross section, we can get an estimate of the total error of the cross section. Some rough estimates of this kind are summarized in Table V. The main conclusion is that the present calculation obtains total cross sections accurate to 0.8% in the energy range from 300 to 1400 keV; the accuracy decreases rapidly toward threshold and at high energies.

V. TOTAL CROSS SECTIONS

Theoretical predictions for the total K-shell photoelectric-effect cross section have been based on four

[20] The exception is for $\kappa=1$, for which R_κ changes by as much as 0.5% between $h=0.05$ and 0.10.

main calculations: (1) The exact nonrelativistic solution of the problem, usually associated with Stobbe,[21] (2) Sauter's relativistic calculation,[6] valid to lowest order in $Z\alpha/\beta$, (3) numerical calculations of Hulme *et al.*[22] for a few selected energies and elements, (4) the high-energy limit of the relativistic problem for arbitrary Z as given by Hall.[23] Extrapolation procedures, based on these four results, can be used to estimate the cross section for arbitrary Z and energy; tables of these predictions have been given by Grodstein[24] (NBS tables). Experimental results have generally yielded satisfactory agreement with these tables.

Since 1955 there has been substantial improvement in all four of these calculations, and one of them has actually been found to contain an error. Namely, although Hall's expression for the high-energy limit in the form of a double integral is correct, the analytic formula with which he approximated the integral is not, and overestimates the cross section by a factor of two in heavy elements. The exact high-energy limit was obtained numerically by Pratt[7] and later confirmed by Hall[25]; as already noted, Eq. (2.7) gives a fairly good analytic representation. It is then at first hard to understand why the extrapolation between Sauter and Hall is in good agreement with Hulme. The work of Gavrila[26] and Nagel,[27] who extended Sauter's result to next order in $(Z\alpha/\beta)$, explains the puzzle. Hall's error essentially involved omission of the factor $(-4\pi a/15)$ in Eq. (2.7), but the energy dependence of this term is such that it is large only at very high energies. [Recently, a complicated analytical expression for still another order in $Z\alpha/\beta$ has been given by Gorshkov and Mikhailov.[28]]

K-shell photoeffect at threshold has been calculated for the relativistic problem, both analytically and numerically, by Nagel and Olsson.[5] In the low-energy region screening effects are expected to be important, however, and this has recently been examined in the nonrelativistic problem by Cooper.[29] Since, as already noted, the numerical techniques of the present paper require modification at low energies, we will not discuss this energy region further.

The numerical calculations of Hulme *et al.* provided the reference points which Sauter-Stobbe and Sauter-Hall extrapolations are forced to fit. The accuracy of Grodstein's predictions for intermediate energies rests almost entirely on the accuracy of these numerical results obtained for 0.3543 and 1.131 MeV, estimated at 4% for heavy elements and 8% for lighter elements. Since this is the main energy region of experimental interest, it is important to verify and extend these

calculated points, and this is the purpose of the present section.

While the present work was in progress a new numerical calculation was reported by Hultberg, Nagel, and Olsson (HNO).[2] Like the work of Hulme *et al.*, the method used applies only to the pure Coulomb potential; HNO treated two heavy elements in the energy range 0.120–0.662 MeV. Moderately good agreement was obtained with the values derived from the NBS tables, confirming the low-energy high-Z point of Hulme *et al.*[30]

The K-shell total cross sections obtained in the present numerical calculations are summarized in Tables VI and VII. The Z's of Table VI corresponds to those of

[30] It should also be noted that in principle, another series of photoeffect total cross sections is available in the numerical calculations on the coherent scattering of photons from K-shell electrons carried out by Brown and collaborators: G. E. Brown, R. E. Peierls, and J. B. Woodward, Proc. Roy. Soc. (London) **A227**, 51 (1954); S. Brenner, G. E. Brown, and J. B. Woodward, *ibid.* **A227**, 59 (1954); G. E. Brown and D. F. Mayers, *ibid.* **A234**, 387 (1955); **A242**, 89 (1957). As the authors note, the photoeffect cross sections can be obtained from the imaginary part of the scattering amplitude in the forward direction for the coherent process, and results are presented for Hg at photon energies of 0.32, 0.64, 1.28, and 2.56 (all in units of mc^2). A similar calculation was later reported by H. Cornille and M. Chapdelaine, Nuovo Cimento **14**, 1386 (1959) for photons of energy 5.12 mc^2 on Hg. Unfortunately, results of these papers pertaining to the photoeffect are not presented as cross sections. We do not wish to now enter into a detailed discussion, but if our interpretation of these results is correct they are in fair accord with our numerical work and the highest energy results show the suppression from previous values reported here.

Hulme *et al.* and those of Table VII to HNO; in each case the appropriate comparisons with earlier work are made. The first striking feature is the excellent agreement, far better than the accuracy which had been claimed, with the calculations of Hulme *et al.* This means that interpolations, such as Grodstein's, based on the Hulme values would be expected to be good and need no major revision in this energy range (however, see below). The errors which remain are of the same magnitude as screening effects; such effects must be included before the change in the cross section from the Hulme values is significant. Agreement with the HNO results is also excellent, and within the estimated error of the present calculation. The first result of this section is then the establishment of the accuracy of the values of Hulme *et al.*

In Table VII we have also given the corresponding cross section as obtained in the NBS tables.[31] The com-

[31] Since the NBS values are for total absorption cross sections, the contribution from higher shells is removed by dividing out the simple multiplicative factor which Grodstein used to put it in. Another smaller correction is also needed to obtain a K-shell cross section without screening.

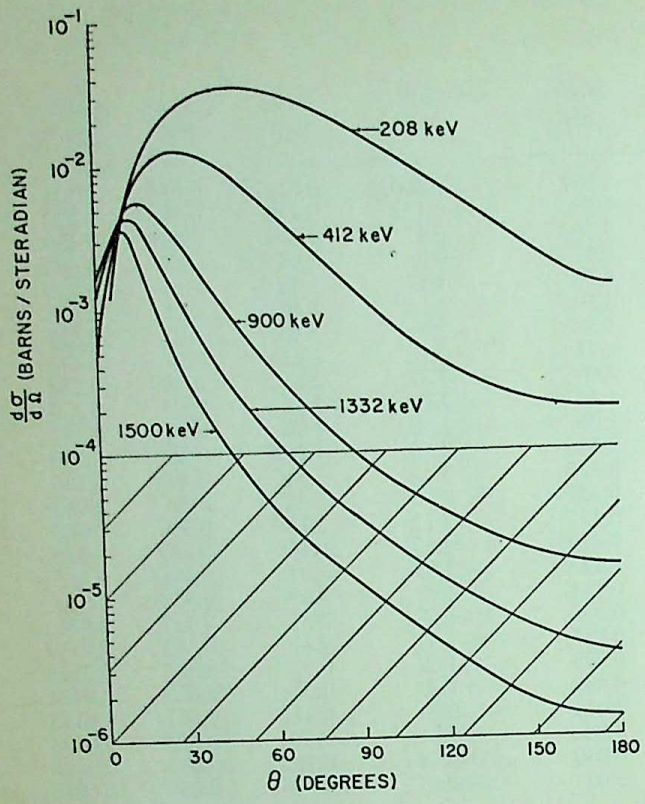

FIG. 1. K-shell angular distributions for U in barns/steradian. The small cross sections in the shaded region of the graph are of low accuracy.

parison is rather surprising; even in the 1-MeV region, the present results are 5–10% lower than corresponding interpolations from the NBS tables. It is hard to understand this, since the present results agree with Hulme *et al.* and the NBS tables are based on Hulme *et al.* By 2 MeV, the difference has reached 25%. Further proof that this difference is real is provided by a new calculation[32] which HNO have undertaken to check our results; it appears that they have obtained complete agreement with our cross section for $Z=92$ at 1.332 MeV.

A comparison with the extrapolation formula of Pratt[7] is given in Table VIII for $Z=82$. This formula, which is exact at very high energies and exact for light elements at all energies, is in good agreement with the Hulme values and so also with the present calculation in the 1-MeV range. However Table VIII suggests that the very close agreement at 1 MeV is misleading, since for the higher energy of 2 MeV the two differ by 10%.

The recent experimental measurements[33–36] of the total cross section from the K shell are given in Table IX.[37] These results were all reported as in good accord with the NBS tables, which again says that the experimental results above 1 MeV are higher than the theoretical values of the present calculation.

The second result of this section is then the finding of significantly lower cross sections in the energy region above 1 MeV than are given in the NBS tables or in two recent experiments. We have previously outlined the evidence for the accuracy of the present calculations. If these arguments are correct we see no theoretical explanation for the discrepancy. It is true that screening effects will modify the pure Coulomb calculations, but for the K shell such corrections are expected to be only 1–2%, and in the wrong direction.

VI. ANGULAR DISTRIBUTIONS

Until quite recently the only theoretical result for the angular distribution of relativistic K-shell photoeffect was that of Sauter,[6] Eq. (2.5), and there was no experimental information. When corrections of relative $0(a)$ were computed by Banerjee,[38] Gavrila,[26] and Nagel[27] it was found that they did not significantly change the predicted angular distributions, including the prediction of a vanishing cross section in the forward direction. On the other hand, the experiments of Hultberg[39–41] indicated some striking deviations from the Sauter distribution: A nonvanishing forward cross section, a shifting of the maximum in the cross section toward *larger* angles, and a tendency of the cross section to hold up at large angles. We shall return to the theoretical discussion of these matters following the presentation of our numerical calculations and their comparison with HNO and experiment.

The K-shell angular distributions obtained in the present numerical calculations are summarized in Tables X and XI. We present these results in some detail, despite their limited accuracy, since they do display the significant deviations from the Sauter distribution and so provide more nearly correct predictions. The very small large-angle cross sections are not tabulated. For qualitative purposes we also show in Fig. 1 the $Z=92$ distributions for several energies. Forward scattering increases with increasing energy, the maximum moves in, and backward scattering remains finite but decreases with increasing energy.

For the lower energies we may again compare these results with those of HNO which become available (although they have not been published) in the course of the present calculation. The comparison for U is given in Table XII, where the HNO values, which are normalized to unity at the angle of maximum emission, are read from their graphs and normalized to agree with our absolute results at the underlined angles. The two calculations are in good agreement.

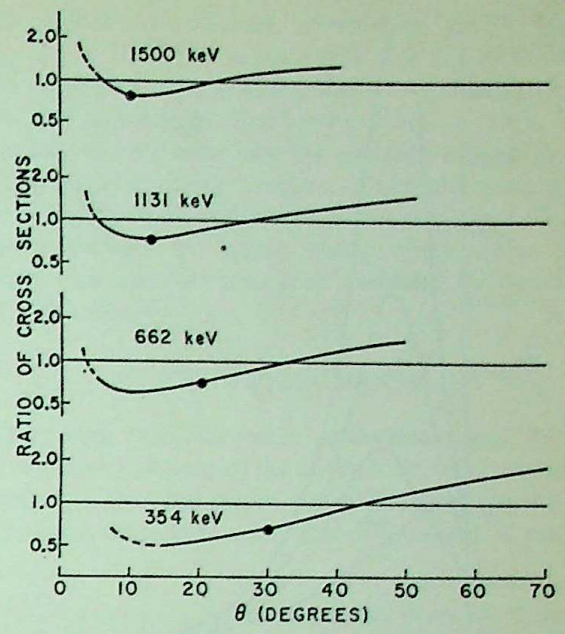

FIG. 2. Comparison with the Sauter angular distribution from $Z=84$ for a series of energies. The ratio R of the present distribution to the Sauter distribution is plotted, where both distributions have been normalized to their respective total cross sections. The approximate angles of maximum emission are marked.

Experimental results for K-shell angular distributions have been obtained for uranium by Hultberg[39] (412, 662, and 1332 keV) and by Sujkowski[40] (279 keV); no other true K-shell distributions are known to us, excepting the early work of Hultberg.[37–38] In Table XIII we give, for a few selected angles, the ratio of experiment to theory. The experimental results are available at quite fine angular intervals, and the 279- and 662-keV cases have elsewhere[2,42] been compared with the HNO predictions in graphical form. Except at forward angles the 279-keV result of Sujkowski seems to be in good agreement with theory, and it should be noted that at this low energy the forward cross section is very small. The higher energy data of Hultberg shows more marked deviations from theory; now that fairly good theoretical estimates are available, further experimental data in this energy region would be desirable. Note that at higher energies theory predicts a *larger* forward cross section than was observed. [Angular distributions for Au at 412 keV in the range 20°–90° have now been obtained by Bergkrist and Hultberg[43] in excellent agreement with theory.]

Let us next compare these new theoretical results with the much-used Sauter distribution. This has been done for a series of energies in Fig. 2. What is plotted is the ratio R of the present distribution to the Sauter distribution, with both distributions normalized to their respective total cross section $[(d\sigma/d\Omega)/\sigma]$. Thus, the

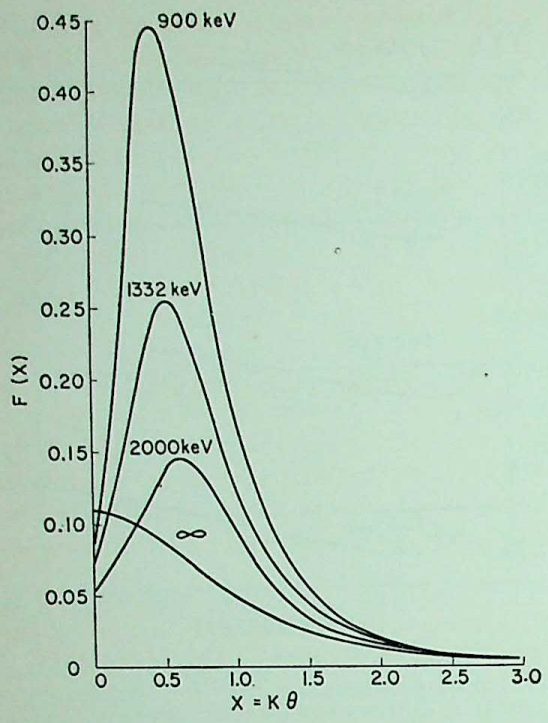

FIG. 3. High-energy behavior of angular distribution. $F(x) = (4e^2a^5\epsilon)^{-1}(d\sigma/d\Omega)$ is plotted against $x=k\theta$ for $Z=82$ at three energies and compared with its form in the high-energy limit.

straight line $R=1$ corresponds to the Sauter distribution; an angular region in which $R=$constant is a region in which the distribution locally has the Sauter shape. The only case shown is for $Z=84$. For $Z=26$ the curves essentially follow the straight lines $R=1$ and even for $Z=50$ the deviations are barely significant within the errors of the calculation This was why, as was elucidated by later theoretical work, it was possible to get along with a Sauter distribution for many years—the shape was much better than the normalization. Roughly speaking, the error in the Sauter total cross section is $0(\pi a)$ (from omission of the characteristic $e^{-\pi a}$ factor) but the significant errors in the Sauter distribution are only $0(a^2)$. But Fig. 2 does show that in the heaviest elements the deviations from the Sauter distribution become significant. The rise in R at small angles occurs because the Sauter distribution, unlike an exact calculation, vanishes in the forward direction. If this were the only region which deviated from Sauter form the curve would elsewhere behave as $R=$constant. Instead, at larger angles it falls off more slowly than the Sauter form, and indeed there is no sizeable angular region of Sauter shape. These qualitative features were first remarked in the experiments. Finally, the angle $\theta_{\max}$ of maximum emission, roughly indicated on the graphs, occurs in the region in which R is rising, so the cross section is staying up in comparison to Sauter, and so $\theta_{\max}$ is being shifted toward larger angles in comparison to the Sauter distribution. This too was first noted in the experiments.

The relative $0(a)$ corrections, mentioned earlier, do not shed much light on these properties—they appear to be $0(a^2)$ effects. This arises, as was noted by Nagel,[27] both because at intermediate energies the $0(a)$ term is not large and because its distribution is similar to the Sauter form. There is a tendency for a maximum at larger angles and for a larger cross section at back angles, but especially for the latter effect the increase is insufficient. Nagel also pointed out that the reason the $0(a)$ distribution vanishes in the forward direction is that it arises as a cross term with the Sauter matrix element. The lowest order nonvanishing cross section in the forward direction $I(0)$ is relative $0(a^2)$, and this Nagel obtained.[43a] It has been conventional to express this in terms of the ratio $\kappa \equiv I(0)/I(\theta_{\max})$. From Table XI we would estimate that at 1332 keV, this ratio is 0.30 for Pb and 0.38 for U. These compare with the theoretical values 0.27 obtained for Pb by Sauter and Wüster[44] in a numerical calculation and 0.42 obtained by Nagel for Pb from the relative $0(a^2)$ term above. Hultberg's experimental value for κ in U at 1332 keV was 0.245, which again reflects the fact that the experimental forward cross section at the higher energies lies below theory.[45] (Some new measurements of κ have recently been reported by Rimskii-Korsakov *et al.*[46])

It is finally of some interest to discuss the behavior of the K-shell angular distribution in the high-energy limit. At high energies, the significant angles are $0(1/k)$, and in analytic work it is appropriate to expand in $1/k$ and θ, but for arbitrary $x \equiv k\theta$. Neglecting $0(a^2)$, Nagel[27] writes the distribution in this limit as

$$\sim \frac{x^2}{(1+x^2)^3}\left[1-a\frac{\pi}{2}\frac{1}{(1+x^2)^{1/2}}\right], \qquad (6.1)$$

including the $0(a)$ correction to the Sauter distribution which has its maximum at $x=1/\sqrt{2}$. Nagel (and also Mork and Olsen[47]) find that in this limit forward scattering is characterized by $\kappa=5.85a^2$ to lowest nonvanishing order in a. Mork and Olsen also obtained an exact expression for the forward scattering in the high-

[43a] This result was also independently obtained by Arne Reitan, Physica Norvegica 1, 113 (1961).

[44] F. Sauter and H. O. Wüster, Z. Physik 141, 83 (1955). Actually these authors obtained $I(0°)$ numerically and took $I(\theta_{\max})$ from the usual Sauter distribution, a procedure which certainly becomes invalid at high energies as will be seen shortly.

[45] Nagel (Ref. 27) compares the Sauter-Wüster 0.27 value with Hultberg's 0.245, calling the agreement rather good, apparently assuming that for large Z, κ does not change appreciably with Z. The present results do not support this assumption, and we conclude there is a significant difference between theory and experiment.

energy limit; such an expression was also later obtained by Weber and Mullin,[48] who graph $F(0)$ against Z, where

$$F(\theta)=\frac{1}{4e^2a^5\epsilon}\frac{d\sigma}{d\Omega} \tag{6.2}$$

in dimensionless units. In the high-energy limit, F is independent of energy. For Pb we would compute $\kappa=2.1$, an absurd result ($\kappa\leq 1$) which could be interpreted as a gross failure of the expansion of $F(0)$ in a. In fact, the error lies in the supposition that the position of the maximum is given by the Sauter maximum, whereas numerical calculations of Boyer[49] and Nagel[50] show that in heavy elements the maximum occurs for forward emission and the distribution decreases monotonically. Using Nagel's calculation[50] we find that the ratio of forward emission to emission at the Sauter angle is 1.6. In Fig. 3 we plot $F(x)$ for $Z=82$ for three of the energies of our numerical calculation and also show the high-energy limit from Nagel's work. This again makes very clear how far removed 2 MeV is from the asymptotic energy region. Even the manner in which the minimum at forward angles gets filled remains to be calculated by higher energy work. (The high-energy limit has now also been discussed by Gorshkov and Mikhailov.[51])

Polarization Correlations in Atomic Photoeffect*

R. H. PRATT,†

RICHARD D. LEVEE,‡ ROBERT L. PEXTON, AND WALTER ARON
Lawrence Radiation Laboratory, University of California, Livermore, California
(Received 13 September 1963)

The seven possible polarization correlations between incident photon and ejected electron in K-shell photoeffect have been obtained with numerical methods for the range of elements from $Z=13$ to $Z=92$ and the range of energies from 200 keV to 2 MeV. The photoeffect can serve as a polarizer of electrons, a transmitter of polarization from photons to electrons, or an analyzer of polarized radiation. In heavy elements at suitable angles of emission all these correlations can be large. Previous work on the correlations is discussed.

I. INTRODUCTION

THE atomic photoelectric effect can serve as an analyzer of polarized radiation, a transmitter of polarization from photons to electrons, or a polarizer of electrons. The preferential ejection of photoelectrons in the plane defined by the momentum $\mathbf{k}$ and polarization vector $\mathbf{e}$ of linearly polarized photons has long been known.[1] In recent years the high degree of correlation between circularly polarized photons and longitudinally polarized electrons has been discussed.[2–6] The photoeffect can also serve as a polarizer, producing transversely polarized electrons from unpolarized radiation.[5] In practice not too much use has been made of the photoeffect for these purposes, due both to experimental problems and to the lack of precise knowledge of the expected correlations.[7]

We have recently completed a numerical calculation of K-shell photoelectric cross sections, covering the range of elements from $Z=13$ to $Z=92$ and the range of energies from 200 keV to 2 MeV, neglecting electron screening. Our numerical methods and the resulting differential and total cross sections have been reported elsewhere[8]; the purpose of this paper is to present and discuss the results which we have obtained for all the possible polarization correlations between incident photon and ejected electron. For a qualitative understanding of the nature of the correlations we give a set of figures showing the energy dependence of the correlations in a high-Z element; these are found in the separate sections in which we discuss each correlation. We have appended to this paper a representative set of tables for the element $Z=84$; a complete set of tables is also available.[9]

To define these correlations we need to introduce the usual polarization parameters. We describe photon polarization with the quantities

$$\xi_1=e_1^*e_1-e_2^*e_2\,,\quad \xi_2=e_1e_2^*+e_2e_1^*\,,\quad \xi_3=i(e_1e_2^*-e_2e_1^*)\,. \tag{1}$$

Here e_1 is the component of the photon polarization vector $\mathbf{e}$ which lies in the plane of the incoming photon $\mathbf{k}$ and outgoing electron $\mathbf{p}$, and e_2 is the component perpendicular to the plane (along $\mathbf{k}\times\mathbf{p}$), so that $(e_1,e_2,\mathbf{k})$ form a righthanded set. Photons linearly polarized parallel or perpendicular to the production plane are characterized by a nonvanishing ξ_1, circularly polarized photons by nonvanishing ξ_3. Similarly, we describe the polarization state of the ejected electron in terms of the direction $\boldsymbol{\zeta}$ of its spin in its rest system; ζ_3 is taken along the *electron* direction $\mathbf{p}$, ζ_1 in the scattering plane, and ζ_2 perpendicular to the scattering plane (along $\mathbf{k}\times\mathbf{p}$), so that $(\zeta_1,\zeta_2,\zeta_3)$ again form a right-handed set. Longitudinally polarized electrons are characterized by nonvanishing ζ_3. It should be noted that the coordinate systems used for the description of photon and electron polarizations are different.

In terms of these parameters the differential cross section for K-shell photoeffect, summed over both K-shell electrons, is of the form

$$\frac{d\sigma}{d\Omega}=\left(\frac{d\sigma}{d\Omega}\right)_{\text{unpol.}}\left[\tfrac{1}{2}\sum_{i,j=0}\xi_i\zeta_jC_{ij}\right], \tag{2}$$

where $\xi_0=\zeta_0=C_{00}=1$, and $(d\sigma/d\Omega)_{\text{unpol.}}$ is the differential cross section from unpolarized photons, summed over final electron spins. The quantities C_{ij}, satisfying $|C_{ij}|\leq 1$, are the polarization correlations with which this paper is concerned.

It would appear from Eq. (2) that, not counting $C_{00}\equiv 1$, there are fifteen polarization correlations. But in fact invariance considerations permit only seven nonzero correlations. This follows most directly from the fact that the matrix element

$$H=-e(2\pi/k)^{1/2}\int d^3r\psi_{\text{fin}}{}^{\dagger}\boldsymbol{\alpha}\cdot\mathbf{e}e^{i\mathbf{k}\cdot\mathbf{r}}\psi_{\text{in}} \tag{3}$$

is invariant under the substitutions

$$\psi\rightarrow\sigma_2\psi\,,\quad (e_1,e_2)\rightarrow(-e_1,e_2)\,. \tag{4}$$

For we may absorb these substitutions into the polarization parameters by

$$(\xi_1,\xi_2,\xi_3)\rightarrow(\xi_1,-\xi_2,-\xi_3)\,,$$
$$(\zeta_1,\zeta_2,\zeta_3)\rightarrow(-\zeta_1,\zeta_2,-\zeta_3)\,, \tag{5}$$

and similarly for the bound-state polarization parameters which are summed out. If Eq. (2) is to be invariant under the substitutions (5), then we conclude that, not counting $C_{00}\equiv 1$, the only nonzero correlations are

$$C_{02},\,C_{10},\,C_{12},\,C_{21},\,C_{23},\,C_{31},\,C_{33}\,. \tag{6}$$

These seven correlations are indeed all nonzero, and they will be discussed in the subsequent sections. C_{02} produces transversely polarized electrons from unpolarized photons, C_{10} is the well-known correlation which analyzes linearly polarized photons, and C_{33} converts circularly polarized photons to longitudinally polarized electrons.

We have written down in Eqs. (2.25)–(2.27) of Ref. 8 expressions for the C_{ij} in terms of reduced partial-wave matrix elements R_κ and continuum wave-function phase shifts δ_κ; it is from these equations that the results presented in this paper were calculated. Some information which can be deduced from these equations concerning the behavior of the correlations at small angles should be mentioned. First of all, since the angular distribution $(d\sigma/d\Omega)_{\text{unpol.}}$ does not vanish for forward (and backward) angles (unlike the Sauter distribution,[1,10] valid only to lowest order in $a\equiv Z\alpha$), one sees that all correlations except C_{33} vanish in the forward and backward directions, and $C_{33}(0°)=+1$, $C_{33}(180°)=-1$. Further, for small angles the correlations C_{02}, C_{12}, C_{21}, and C_{31} go as θ, while C_{10} and C_{23} go as θ^2. And finally, for small angles one has the identity $C_{12}=-C_{21}$. However, one can see from the figures and tables that small angles, at these energies, means much less than 5°, and indeed all the correlations undergo very rapid and violent changes over this region of very small angles, in contrast with their comparatively slow variations through the main angular regions. Indeed, in the figures, we have not attempted to draw in the variation of the correlations between 0 and 5°.

Before proceeding to the specific correlations we may also discuss their behavior at low and at high energies and as a function of Z. In the nonrelativistic theory, $\boldsymbol{\alpha}\cdot\mathbf{e}$ in Eq. (3) is replaced by $\mathbf{p}\cdot\mathbf{e}$, and all dependence on electron spin disappears. This leads to a differential cross section proportional to $(1+\xi_1)$, so that $C_{10}=1$ for all angles and all other correlations vanish. Of course even at threshold there are relativistic corrections of relative order a^2 [which for example cause $C_{10}(0°)=0$], and away from threshold there are relativistic corrections of relative $O(1)$, as given by Sauter,[1,10] which in fact for the larger angles cause the preferred direction of emission to be perpendicular to rather than in the plane of $\mathbf{k}$ and $\mathbf{e}$. In the relativistic theory correlations with the electron spin can occur. In addition to C_{10} the correlations C_{31} and C_{33} are also $O(1)$, while the remaining correlations are $O(a)$ and so mainly important only in heavy elements. At very high energies one can show[6,11] that for angles of significant electron emission the only nonvanishing correlations are C_{12}, C_{21}, and C_{33}, and further $C_{33}=+1$ and $C_{12}=-C_{21}$.

II. THE CORRELATION C_{02}

The correlation C_{02} permits the production of transversely polarized electrons from unpolarized photons; the resulting electron spin is perpendicular to the production plane. The correlation vanishes both in the nonrelativistic and extreme relativistic limits and is $O(a)$. Figure 1 shows C_{02} for $Z=92$ at some representative energies. Like the more familiar correlation C_{10}, C_{02} exhibits a "crossover" feature: For energies above some minimum energy the spin direction $\mathbf{k}\times\mathbf{p}$ is favored at smaller angles and $-\mathbf{k}\times\mathbf{p}$ at larger angles. Previous work on this correlation is due to Kolbenstvedt and Olsen[12] and Nagel,[5] who obtained the analytic expression for the correlation to lowest nonvanishing order in a, and show curves which are qualitatively similar to ours. [These curves fail near the forward direction where the angular distribution itself is $O(a^2)$ rather than $O(1)$; the same comment will apply to all the analytical calculations subsequently mentioned.] Numerical results at threshold have been reported by Nagel and Olsson.[13] In the report on their numerical calculation of K-shell cross sections Hultberg, Nagel, and Olsson[14] show one representative curve for C_{02}

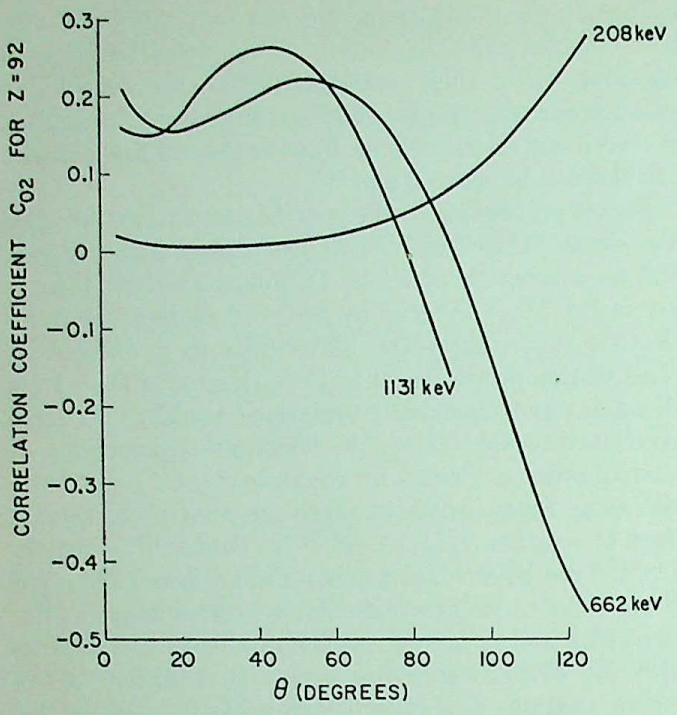

FIG. 1. Correlation C_{02} for the production of transversely polarized electrons from unpolarized photons, as a function of angle for $Z=92$ at several energies.

(P_1 in their notation), and in unpublished work[15] they have given curves for $Z=82$ and $Z=92$ over a range of energies up to 662 keV, which are in good agreement with the corresponding results of our tables. As has been noted,[5,12] the electron polarization which C_{02} implies is analogous to that produced in relativistic Coulomb scattering with unpolarized electrons, and can be analyzed in the same way; this correlation has the advantage[12] of not vanishing as rapidly at high energies.

III. THE CORRELATION C_{10}

The correlation C_{10}, as already noted, reflects the fact that the photoeffect can serve as an analyzer for photons linearly polarized parallel or perpendicular to the production plane. In the nonrelativistic theory[1] $C_{10}=+1$, which says no electrons are emitted perpendicular to the polarization direction of the photons. Of course, even at threshold there are relativistic corrections of $O(a^2)$, which, for example, cause $C_{10}(0°)=0$. The calculation of C_{10} to lowest order in a in the relativistic theory was made by Sauter,[1,10] and like C_{02} it exhibits a crossover feature: Above a minimum energy, emission in the plane of $\mathbf{k}$ and $\mathbf{e}$ (as predicted by the nonrelativistic theory) is favored for smaller angles of emission, whereas emission *perpendicular* to the plane is favored at larger angles. As discussed by Olsen,[2] in lowest order in a the minimum electron energy for the crossover feature is $\epsilon=\frac{5}{3}$ (in units $\hbar=c=m_e=1$), i.e., ≈ 340 keV for the photon, and at higher energies the crossover angle θ_c is determined from

$$k(k+1)(1-\beta\cos\theta_c)=2, \qquad (7)$$

where k is the photon energy in the same units. Olsen also noted that in the same approximation, at the crossover angle θ_c such that $C_{10}(\theta_c)=0$, electrons from *circularly* polarized photons are *completely* polarized along the *photon* direction. We shall return to this feature in our discussion of C_{31} and C_{33}. We should also note that the analytical corrections to C_{10} of order a were obtained by Gavrila[16] and Nagel.[5]

Results of our numerical calculation of C_{10} are given in the tables appended to this paper and in Fig. 2. We also give in Table I some information on the crossover angle θ_c as a function of k and Z. At low energies, the correlation is quite close to its nonrelativistic value except at large angles (and extremely close to the forward direction). As the energy increases the correlation appears to decrease monotonically for the angles of significant electron emission, and it will vanish in the high-energy limit. However, C_{10} can still be quite sizeable at 2 MeV. Table I shows that in heavy elements the crossover angle θ_c begins to vary significantly from the lowest order prediction Eq. (7); the crossover occurs significantly *later*.

Among the seven photoeffect polarization correlations, only C_{10} appears to have so far been the subject

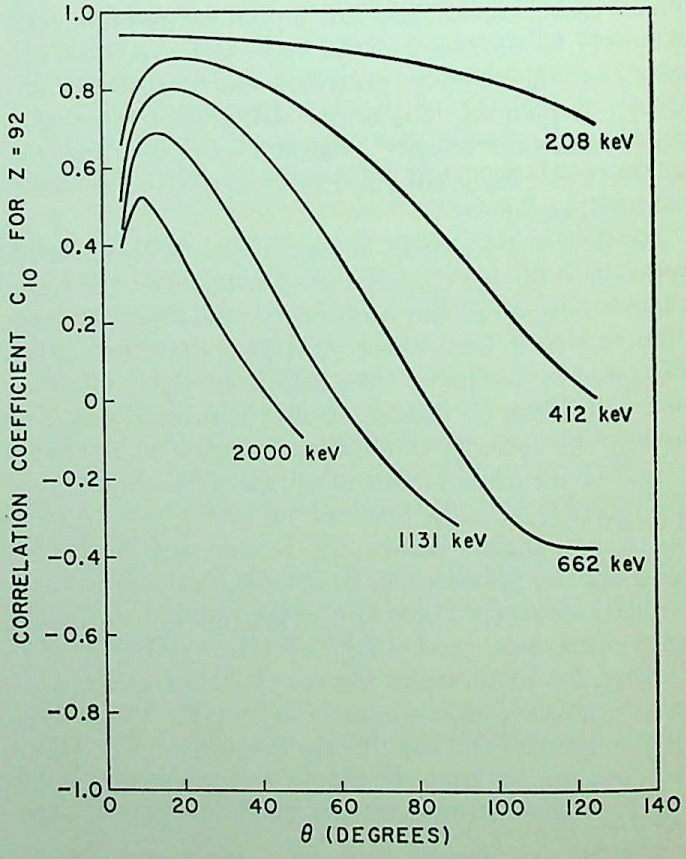

FIG. 2. Correlation C_{10} for the analysis of linearly polarized photons, as a function of angle for $Z=92$ at several energies.

[15] S. Hultberg, B. Nagel, and P. Olsson (unpublished). (Dr. Nagel now informs me that they have made calculations for all seven polarization correlations.)

of experimental investigations. In the energy range of interest there are experiments by Hereford and coworkers[17] and by Brini *et al.*[18] In both cases the objective was to test the predicted crossover feature of Sauter's relativistic theory; the first group appeared to see such a feature while the second group did not. Now that a more precise theory is available, and especially in view of the shift of the predicted θ_c as shown in Table I, further experiments on this question would seem desirable.

IV. THE CORRELATION C_{12}

The correlation C_{12} alters the production of transversely polarized electrons from that given by C_{02} in the case that the initial photons are linearly polarized parallel or perpendicular to the production plane. To determine C_{12} will require also determining C_{02} and C_{10}, or at least designing a set of experiments which subtract out their effect; C_{12} is the only one of the seven correlations which cannot in this sense be determined independently. Like C_{02}, the correlation C_{12} vanishes in the nonrelativistic limit and is $O(a)$; unlike C_{02} it remains finite in the extreme relativistic limit. Connections between C_{12} and C_{21} have already been mentioned: $C_{12}=-C_{21}$ for very small angles and also for all angles of significant electron emission (which are also small angles, but not as small) in the extreme relativistic limit.[6,11] There does not appear to be any discussion of the general analytic form of C_{12}, although an expression to lowest nonvanishing order in a could be extracted from Nagel's work.[5] An expression for the lowest order result valid in the extreme relativistic limit was obtained by Banerjee.[3] The complete analytical expression for the relativistic limit has now been given by Nagel,[11] and he has evaluated it numerically for three choices of Z. Results of our calculation of C_{12} are detailed in the Appendix and in Fig. 3. Since the correlation is $O(a)$ it is most important in heavy elements, but it can become quite sizeable for intermediate Z at back angles (and Nagel's work[11] indicates that in the extreme relativistic case it is greater for intermediate than for large Z). C_{12} is always positive in the regions considered here, but

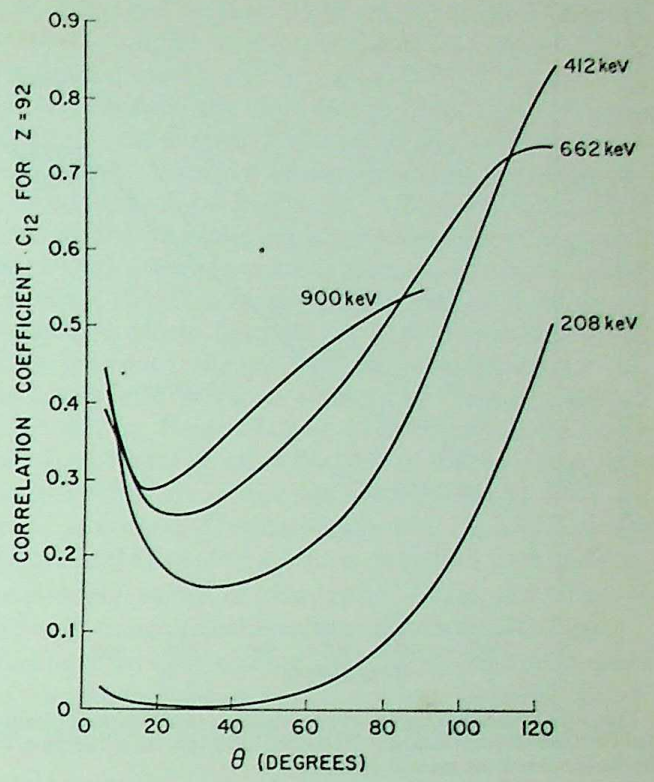

FIG. 3. Correlation C_{12} for the production of transversely polarized electrons from linearly polarized photons, as a function of angle for $Z=92$ at several energies.

Nagel's work[11] indicates that for very heavy Z and high energies there will be a crossover. Finally, for heavy Z and intermediate energies C_{12} is large, especially at the more backward angles, and so produces major effects in the production of transversely polarized electrons from linearly polarized photons.

V. THE CORRELATION C_{21}

The correlation C_{21}, like C_{12}, produces transversely polarized electrons from linearly polarized photons. However this correlation, also $O(a)$, is between electrons polarized *in* the production plane and photons polarized at 45° to the production plane. As we have said before, $C_{12}=-C_{21}$ for very small angles and also in the extreme relativistic limit. The remarks on previous work also apply to both processes: from Nagel's work[5] one can extract an analytic expression for the lowest nonvanishing order in a and from his more recent work[11] one of course has the extreme relativistic limit ($C_{21}=-C_{12}$, note there is a difference in sign and in his choice of coordinate system). Results for C_{21} are in the Appendix and in Fig. 4. Remarks on magnitudes apply to both correlations and need not be repeated here. However, the correlation C_{21} exhibits, even at the lowest energies, a crossover feature; the crossover angle increases with energy, unlike C_{02} or C_{10}. Since C_{21} is large at intermediate energies for back angles the photoeffect provides a fairly efficient mechanism for the transfer of these polarizations.

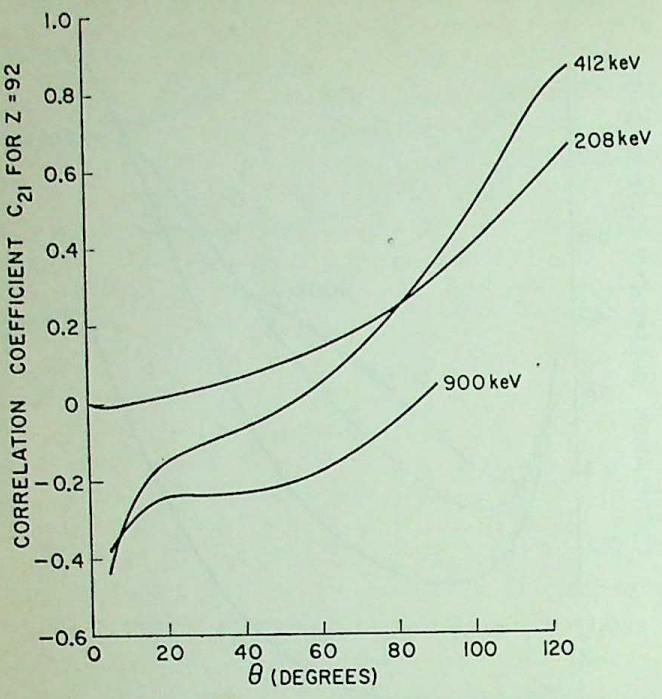

FIG. 4. Correlation C_{21} for the production of transversely polarized electrons from linearly polarized photons, as a function of angle for $Z=92$ at several energies.

VI. THE CORRELATION C_{23}

The correlation C_{23}, which is $O(a)$, produces longitudinally polarized electrons from linearly polarized photons. The photon polarization should again be at 45° to the production plane. There does not appear to have ever been any analytical discussion of this correlation, although the result to lowest order in a can again be extracted from Nagel's work.[5] Results for C_{23} are given in the Appendix and in Fig. 5. In the range considered here the correlation is always negative. And although C_{23} is $O(a)$ and vanishes in the nonrelativistic and extreme relativistic limits, for intermediate and large Z at intermediate energies it becomes quite sizeable at large angles and so provides a fairly efficient mechanism for the transfer of these polarizations.

VII. THE CORRELATION C_{31}

The correlation C_{31} produces electrons transversely polarized in the production plane from circularly polarized photons. The correlation vanishes in both the nonrelativistic and extreme relativistic limits, but it is $O(1)$ and very large for intermediate energies and angles. Figure 6 shows C_{31} for $Z=92$ at some representative energies; further results are given in the Appendix. At very forward angles the correlation is positive, but it soon crosses over and remains negative through most of the angular range, with a broad minimum at intermediate angles. (The curves suggest that there could actually be an energy, near 600 keV, and angle, near 80°, for which $C_{31}=-1$.) Analytical expressions for C_{31} to lowest order in a were obtained by Olsen[2] and Banerjee[3]; Nagel[5] also obtained terms of relative order a. Numerical results obtained by Hultberg, Nagel, and Olsson[14,15] (in their notation $C_{31}=-P_3$) are in good accord with the corresponding values of our tables. Numerical results at threshold were given by Nagel and Olsson.[13]

TABLE II. $D(\theta_c)$ as defined by Eq. (8) for $Z=84$ as a function of photon energy k (in MeV).

k	0.662	1.131	1.5	2.0
$D(\theta_c)$	0.963	0.972	0.965	0.961

It was noted by Olsen[2,4] that, to lowest order in a, at the crossover angle θ_c for which $C_{10}(\theta_c)=0$, electrons from circularly polarized photons are completely polarized along the *photon* direction, i.e.,

$$D(\theta_c)\equiv C_{33}(\theta_c)\cos\theta_c - C_{31}(\theta_c)\sin\theta_c = 1. \quad (8)$$

For this to be true requires that, in the language of Eqs. (2.25)–(2.27) of Ref. 8,

$$|K_-|^2=|J_+|^2=0 \text{ when } \mathrm{Re}[J_-{}^*J_+ + K_-{}^*K_+]=0; \quad (9)$$

it does not seem that this can in general be true. We show, however, in Table II the calculation of $D(\theta_c)$ for $Z=84$ from our results; the deviations from Olsen's prediction are very small, and almost within the errors of the calculation.

VIII. THE CORRELATION C_{33}

The correlation C_{33} is a transmitter of helicity, producing longitudinally polarized electrons from circularly polarized photons. The only one of the seven correlations which does not vanish in forward and backward directions [$C_{33}(0°)=-C_{33}(180°)=1$], it vanishes in the nonrelativistic limit, but becomes 1 for all angles of significant electron emission in the extreme relativistic limit.[6] We show results for C_{33} in the tables appended to the paper and in Fig. 7. Even at intermediate energies the correlation is large; it appears to approach one at high energies somewhat more rapidly in the lighter elements. Since C_{33} ranges from $+1$ to -1 it exhibits a crossover, which, however, at high energies moves to very backward angles. Analytical expressions for C_{33} to lowest order in a were obtained by Olsen,[2] by Banerjee,[3] and by Fano, McVoy, and Albers[4]; Nagel[5] also obtained terms of relative order a. The extreme relativistic limit of C_{33} was discussed by Pratt.[6] Like C_{02} and C_{31}, numerical results obtained for C_{33} by Hultberg, Nagel, and Olsson[14,15] are in good accord with the corresponding values of our tables. Nagel and Olsson[13] have given numerical results at threshold. The connection between the crossover angle for C_{10} and production of completely polarized electrons from circularly polarized photons has been discussed in the previous section.

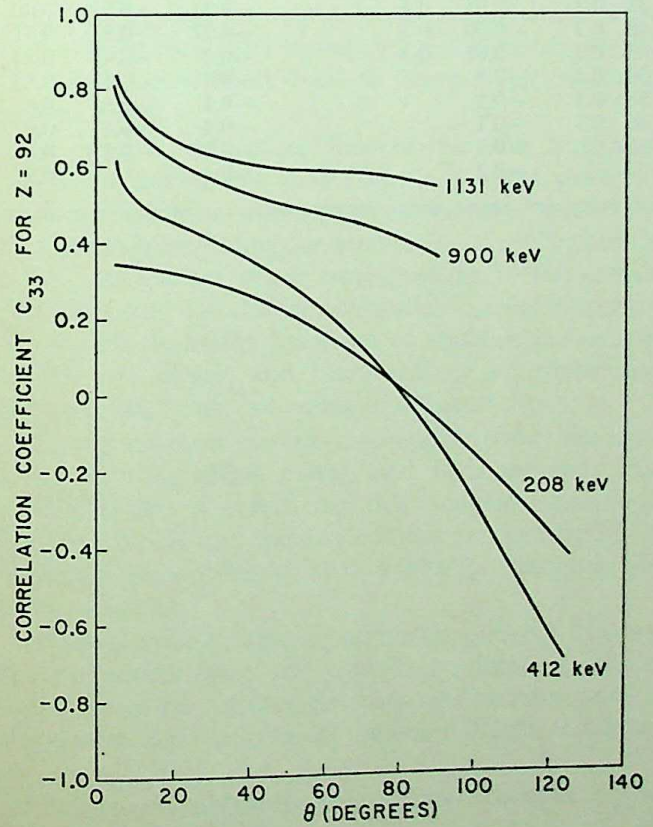

FIG. 7. Correlation C_{33} for the production of longitudinally polarized electrons from circularly polarized photons, as a function of angle for $Z=92$ at several energies.

ACKNOWLEDGMENTS

This work was suggested and encouraged by Dr. Harvey Hall, to whom all the authors are much indebted. Thanks are also due to Dr. Sölve Hultberg, for helpful discussions, correspondence, and prepublication results.

Effect of Correlation on the Ferromagnetism of Transition Metals

MARTIN C. GUTZWILLER

*IBM Zurich Research Laboratory, Ruschlikon, Zurich, Switzerland**

(Received 17 October 1963; revised manuscript received 13 December 1963)

The wave function for the electrons is investigated when a set of narrow bands (valence states) has its energies within a wide band (conduction states). The valence states are linear combinations of localized states which are attached to each lattice site. The intra-atomic Coulomb and exchange integrals for the localized states are much larger than the bandwidths of the valence states. Some of the narrow bands are neither completely empty nor completely filled. The wave function is therefore expected to be correlated, because it is disadvantageous for the electrons to crowd into the same lattice site, or take up some configuration contrary to Hund's rule. This correlation is important in transition metals, where it is considered to be the cause of ferromagnetism. The correlated wave function is obtained by applying to the uncorrelated antisymmetrized product of Bloch functions an operator which provides each configuration of localized valence states with an appropriate amplitude and phase factor. The procedure is worked out in detail for the case of few particles (electrons or holes) in the narrow bands with the help of a diagram analysis. The localized orbits of different lattice sites do not have to be orthogonal to on another, and the computational rules are actually simplified thereby. The example of a twofold degenerate band such as the upper part of the $3d$ band in Ni is treated, and the conditions for the occurrence of ferromagnetism are stated in the case of few $3d$ holes per lattice site.

INTRODUCTION

THE present work studies the correlation of electrons in a situation which is considered as typical for the $3d$ electrons in a transition metal. The characteristic features of the valence and the conduction electrons in the transition metals are not obtained from first principles, but they are assumed according to a number of experimental facts and their intuitive interpretation in order to yield a model Hamiltonian. The aim is therefore to find an approximate ground-state wave function for the model Hamiltonian, and to investigate the mechanisms which tend to favor a ferromagnetic ground state.

In accord with other theories for the transition metals[1] it is assumed that there is a fairly clear cut distinction between three types of electronic states: the core states representing the atomic $1s$, $2s$, $2p$, $3s$, and $3p$ orbits, the valence states corresponding to the atomic $3d$ orbits, and the conduction states corresponding to the atomic $4s$ orbits. Each set of states is orthogonal to the two others, and there will be no correlation between two orbits belonging to different sets.

This is the most obvious assumption about the electrons in a transition metal, and it is certainly not definitive. But it is felt that this complete separation between the $3d$ and the $4s$ electrons can be lifted in a later, refined model without basically changing the present results.

There is some striking experimental evidence in favor of the independence and completely different orbital character of the valence electrons on one hand and of the conduction electrons on the other. Neutron diffraction in iron[2] has shown that the magnetization density in the lattice is mostly concentrated very tightly around the lattice sites, whereas a small fraction of the total magnetization is distributed uniformly throughout the lattice. The simple linear dependence of magnetization on the alloy composition, e.g. in the Ni-Cu system,[3] seems to indicate that the Bloch states which carry most of the magnetization are being filled quite independently from the presence of conduction electrons.

The conduction electrons are formally included in the present investigation. Unlike the valence states which are defined in terms of tightly localized orbits, the conduction states may best be thought of as plane waves which were orthogonalized to the core and valence states. The lowest conduction state is assumed to lie well below all the valence states, and the highest conduction state well above. The noncrossing rule makes it inevitable to introduce bands which are conduction like in part of their Brillouin zone and valence like in the remaining part. In the transition region the Bloch states are a mixture of the two kinds, but all these transition regions together will be assumed to occupy a volume in reciprocal space which is small compared to the volume of one Brillouin zone. With this hypothesis all the actual computations will bear out the kinematic and dynamic independence of the conduction states from the valence states. The presence of the conduction electrons in the crystal manifests itself then mainly through the seemingly arbitrary number of valence electrons even in a "simple" metal, such as pure Fe, Co, and Ni. Other effects of the conduction electrons are harder to evaluate and will be either implicitly contained or completely neglected. The screening of the

nuclear charge by the conduction electrons is implicitly taken into account through the effective crystal potential, but the coupling of the spins of $3d$ electrons through the conduction electrons is not mentioned at all since its treatment belongs to a more refined model.

The $3d$ electrons are characterized by the localized (at each lattice site) states which they occupy. No precise description of these atomic states is needed besides their transformation properties under the symmetry operations of the lattice, and the crucial assumption that two such localized orbits at different lattice sites have a small overlap integral. The smallness of this overlap is not a consequence of a clever choice, such as in a Wannier function, but a genuine expression for the tightness of the $3d$ orbits around their lattice site. Therefore, the matrix elements for a transition of a localized $3d$ electron to a neighboring lattice site due to kinetic energy and the crystal potential, are always smaller (by a factor of the order of the overlap integral) than the matrix elements for a transition within the same lattice site. The transitions between lattice sites due to the Coulomb repulsion or exchange between electrons are smaller by the square of the overlap integral than the transition within one lattice site. The only transitions between lattice sites which are admitted by the model Hamiltonian are therefore the ones due to the kinetic energy and the crystal potential. Those terms determine the band structure of the $3d$ electrons. The bandwidth is then smaller than the intra-atomic Coulomb and exchange integrals.

There are three terms in the model Hamiltonian: (i) kinetic energy and crystal potential terms, (ii) Coulomb repulsion terms at the same lattice site, (iii) exchange terms at the same lattice site. Terms involving the integral over four orbits at the same lattice site, but not of the ordinary Coulomb repulsion or the ordinary exchange type, are neglected. They are not necessarily small, but it is believed that the important ordering of atomic levels at one particular lattice site can already be understood on the basis of the Coulomb repulsion and exchange integrals. In particular Hund's rule for an atomic system follows already from such a reduced Hamiltonian.

Since the two particle terms (ii) and (iii) are larger than the one particle terms (i), the resulting problem is one of strong interaction. It is, however, complicated by the nonvanishing overlap between orbits on different lattice sites. The usual formulation in terms of creation and annihilation operators for the localized states has to be modified. The destruction operator for a given state is not exactly the Hermitian conjugate of its creation operator. Although this complication does not arise in the usual formulation, it does not really make the computations more awkward. It turns out that the various expectation values for the correlated wave function can be evaluated only in the limit of few particles (electrons or holes) compared to the number of lattice sites. The nonvanishing overlap integrals help to simplify the general rules in the diagrammatic analysis, although the number of diagrams is increased.

The present investigation amplifies considerably a short account published earlier.[4] The main idea is still the same. The uncorrelated antisymmetrized product of Bloch states is modified by applying operators which essentially project the uncorrelated wave function into a subspace of configurations with the appropriate correlations. The resulting correlated wave function is believed to be a good approximation to the ground state for all densities of electrons or holes. Practical results, however, i.e., the calculation of various expectation values, have been possible only in the limit of low-particle densities (with the exception of one statement concerning the occupation probability for valence states inside the Fermi surface in the case of a nondegenerate band, cf. Ref. 4). In the earlier account there was neither the possibility of nonvanishing overlap, nor of degenerate bands, nor of conduction states, nor of combining configurations according to Hund's rule. All these new features are brought out in the example of a twofold degenerate band, where ferromagnetism is favored by both terms, (ii) and (iii).

For the nonferromagnetic state the intra-atomic Coulomb-repulsion terms (ii) are more effective in scattering the particles into Bloch states of high energy, because two uncorrelated particles crowd more often into the same lattice site if their spins are antiparallel. Although this effect is probably not serious enough to induce ferromagnetism, it may come close to canceling the loss in band energy which particles of the same spin experience due to the exclusion principle. The dependence of this mechanism on the density of states was shown in the earlier account, and is again found in the example at the end of this report. But now, there is also the effect of the intra-atomic exchange which had been pointed out by Slater[5] and which is due to the terms (iii). Whereas one may hope to show some day that the terms (ii) can never induce ferromagnetism at all by themselves, it would still seem highly arbitrary to neglect them altogether in the discussion of ferromagnetism and consider only the terms (iii).

A brief account of the following sections will now be given. The first- and second-order density functions are defined in Sec. 1 together with the relevant overlap integrals. The creation and destruction operators are introduced in Sec. 2 and the important projection operators for the localized valence states are studied. The basic idea for the definition of a correlated wave function is explained in Sec. 3 by studying the correlation energy due to intra-atomic Coulomb repulsion in the simplest possible case of all Coulomb integrals being equal. The correlated wave function is defined in Sec. 4 quite generally by applying a suitable set of operators (projections operators for the various states of the whole

ion of each lattice site) to the uncorrelated antisymmetrized product of Bloch states. The same idea is realized in Sec. 5 in a slightly different manner, which will then help to expand all expectation values in powers of the particle density.

The computation of expectation values for the correlated wave function is outlined in Sec. 6; it leads to evaluating the expectation value of a product of creation and destruction operators for the uncorrelated wave function. The latter expectation values are represented in Sec. 7 by diagrams which contain vertices, solid lines for particle propagators, and dotted lines for overlap integrals. The usual breaking up of a diagram into closed linked diagrams is performed in Sec. 8; also it is shown how to obtain diagrams with external points from closed linked diagrams.

The first-order density function is studied in Sec. 9 in order, first to eliminate a number of simple diagrams which lead to a renormalization of the initial uncorrelated wave function, and second, to obtain all the terms up to second order in the particle density. The second-order density function is similarly treated in Sec. 10. The main correlation parameters occur at most quadratically and can therefore easily be determined by minimizing the expectation value for the total energy. This procedure is applied in Sec. 11 to the twofold-degenerate band characteristic of the upper end of the $3d$ band. The conditions for ferromagnetism are then stated. The density of states per unit interval of energy at the upper end of the valence band has to be larger than the average density in the limit of very strong localized Coulomb repulsion. The degeneracy of the valence band is important in the more realistic case where the Coulomb repulsion is not infinitely larger than the bandwidth so that two holes can occasionally crowd into the same lattice site.

The results of the last section are derived for a small density of valence holes and are based on the assumed correlated wave function. This wave function constitutes a guess which may not be particularly good for low densities, because the correlation may spread over many neighbors for low-particle densities as opposed to densities of about 1 per atom. Since the low-density case can be treated directly with the help of the ladder approximation, the present investigation may be viewed as an attempt to propose a wave function for all densities and to treat it in the limit where exact results can be obtained.

1. THE SINGLE-ELECTRON WAVE FUNCTIONS

The lattice is made up of L identical atoms in some elementary arrangement, say face-centered cubic. The lattice sites are labeled by the letters f, g, or h. To each site belongs a set of single-electron wave functions, which we shall divide into three categories: core states (corresponding to $1s$, $2s$, $2p$, $3s$, $3p$ levels); valence states (corresponding to $3d$ levels); and conduction states (corresponding to $4s$ levels).

The core states are assumed orthogonal to the valence and conduction states of all atomic sites. Also, the core states are uncorrelated, so that they contribute only through the first-order density function $\rho_1(x,y)$, namely

$$\rho_1(x,y)=N\int dx_2\cdots\int dx_N \times\Psi(x,x_2,\cdots,x_N)\Psi^*(y,x_2,\cdots,x_N) =\sum\chi(x)\chi^*(y)+\text{contribution from valence states and conduction states,} \quad (1)$$

where the first term on the right is from the core states.

In this formula the core states χ may be either localized or Bloch-like. The contribution of the valence and conduction states to ρ_1 is complicated because of correlation. The contribution of the core states to the second-order density function $\rho_2(\xi,x;\eta,y)$ is then already contained in

$$\rho_2(\xi,x;\eta,y)=\tfrac{1}{2}N(N-1)\int dx_3\cdots dx_N \times\Psi(\xi,x,x_3,\cdots,x_N)\Psi^*(\eta,y,x_3,\cdots,x_N) =\tfrac{1}{2}[\rho_1(\xi,\eta)\rho_1(x,y)-\rho_1(\xi,y)\rho_1(x,\eta)] +\text{properly correlated part arising from valence and conduction states.} \quad (2)$$

Since the effects of the core states are completely described by (1) and (2) together with their orthogonality to the valence and conduction states, it is quite feasible not to mention the core states any more in working out a correlated wave function for the valence and conduction states. Therefore, the first term in (1) will be mentioned again only when it comes to computing the total energy of the crystal. In keeping with this procedure we shall now call N the number of electrons in valence and conduction states only, and the total wave function Ψ will have only as many variables x as there are electrons in valence and conduction states. Formulas (1) and (2) are interpreted henceforth without the first term on the right-hand side of (1). The eventual inclusion of core states is easily performed.

The localized valence and conduction states are $\varphi_{\beta g}(x)$, where g is the label of the atomic site, β is the band index (including spin index), and x is the combination of spatial and spin variable. The band index is sometimes labeled α or γ. Bloch states are constructed by

$$\psi_{\kappa k}(x)=(1/L^{1/2})\sum_{\beta g}V_{\kappa k,\beta g}\varphi_{\beta g}(x). \quad (3)$$

k is a wave vector of the first Brillouin zone and κ is the index of the band. The coefficient $V_{\kappa k,\beta g}$ depends on the lattice site g through a factor $\exp(ikg)$, but the dependence on the indices κ and β may be quite complicated. In particular, $\psi_{\kappa k}$ may contain, for certain combinations

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of κ and k, contributions from both valence and conduction states. The exact values of $V_{\kappa k,\beta g}$ will result from some secular problem, exactly as the band structure is obtained in the tight-binding approximation. The variety of Bloch states $\psi_{\kappa k}$ depends directly on the initial choice of localized valence and conduction states $\varphi_{\beta g}$.

Formula (3) can be inverted by writing

$$\varphi_{\beta g}(x)=(1/L^{1/2})\sum_{\kappa k} U_{\beta g,\kappa k}\psi_{\kappa k}(x)\,, \tag{4}$$

where one has the relations

$$\begin{aligned}(1/L)\sum_{\kappa k} U_{\alpha f,\kappa k}V_{\kappa k,\gamma h}&=\delta_{\alpha\gamma}\delta_{fh}\,,\\ (1/L)\sum_{\beta g} V_{\lambda l,\beta g}U_{\beta g,\kappa k}&=\delta_{\lambda\kappa}\delta_{lk}\,.\end{aligned} \tag{5}$$

The coefficients $U_{\beta g,\kappa k}$ depend on g through the factor $\exp(-ikg)$.

The Bloch functions $\psi_{\kappa k}(x)$ will be assumed orthonormal to one another, i.e.,

$$\int \psi_{\lambda l}^{*}(x)\psi_{\kappa k}(x)dx=\delta_{\lambda\kappa}\delta_{lk}\,. \tag{6}$$

But the localized orbitals $\varphi_{\beta g}(x)$ will not be assumed orthonormalized, and this makes it necessary to introduce their overlap integrals

$$\begin{aligned}R(\alpha f,\gamma h)&=\int \varphi^{*}_{\alpha f}(x)\varphi_{\gamma h}(x)dx\\ &=(1/L)\sum_{\kappa k} U^{*}_{\alpha f,\kappa k}U_{\gamma h,\kappa k}\,.\end{aligned} \tag{7}$$

The only restriction which may be imposed for convenience is

$$R(\alpha f,\gamma f)=\delta_{\alpha\gamma}\,, \tag{8}$$

so that the localized orbits belonging to the same lattice site are orthonormalized. Also, the values of $R(\alpha f,\gamma h)$ differ from zero only when the sites of f and h are close to each other, and then they are small compared to 1 in all cases except when the indices α and γ refer both to conduction states.

Two remarks are in order at this point. First, it is convenient to introduce the nonorthogonality integrals R, even if they should be ultimately assumed to vanish. Indeed, the results of the diagrammatic analysis of Sec. 7 are more easily expressed if the values of $R(\alpha f,\gamma h)$ are not immediately simplified to $\delta_{\alpha\gamma}\delta_{fh}$. Second, it may be that certain simple types of correlations, special cases of the ones to be introduced in Sec. 4, do not necessitate the assumption of $R(\alpha f,\gamma h)$ being different from $\delta_{\alpha\gamma}\delta_{fh}$. Indeed the nonorthogonality of the valence states may be taken fully into account by a proper choice of the correlation parameters. An example is the Heitler-London theory of the hydrogen molecule. But no such equivalence between correlation parameters and nonorthogonality integrals has been found in the more general case to be discussed in the following sections for the Ni-Cu alloys.

2. SECOND QUANTIZED FORMALISM

The many-electron wave functions may be treated most conveniently in the formalism of second quantization. Therefore, we introduce creation operators $c^{\dagger}_{\kappa k}$ and annihilation operators $c_{\kappa k}$ corresponding to the Bloch functions $\psi_{\kappa k}(x)$ of (3). These operators satisfy the anticommutation relations

$$\begin{aligned}c^{\dagger}_{\kappa k}c_{\lambda l}+c_{\lambda l}c^{\dagger}_{\kappa k}&=\delta_{\kappa\lambda}\delta_{kl}\,,\\ c_{\kappa k}c_{\lambda l}+c_{\lambda l}c_{\kappa k}&=0\,,\\ c^{\dagger}_{\kappa k}c^{\dagger}_{\kappa k}+c^{\dagger}_{\kappa k}c^{\dagger}_{k}&=0\,.\end{aligned} \tag{9}$$

The localized states $\varphi_{\beta g}(x)$ are created by

$$a^{\dagger}_{\beta g}=\frac{1}{L^{1/2}}\sum_{\kappa k} U_{\beta g,\kappa k}c^{\dagger}_{\kappa k}\,, \tag{10}$$

and they are destroyed by the operators

$$b_{\beta g}=\frac{1}{L^{1/2}}\sum_{\kappa k} V_{\kappa k,\beta g}c_{\kappa k}\,. \tag{11}$$

It is important to notice that $b^{\dagger}_{\beta g}\neq a^{\dagger}_{\beta g}$ because the localized orbits are not orthonormalized. However, one has

$$\begin{aligned}a^{\dagger}_{\alpha f}b_{\gamma h}+b_{\gamma h}a^{\dagger}_{\alpha f}&=\delta_{\alpha\gamma}\delta_{fh}\,,\\ a^{\dagger}_{\alpha f}a^{\dagger}_{\gamma h}+a^{\dagger}_{\gamma h}a^{\dagger}_{\alpha f}&=0\,,\\ b_{\alpha f}b_{\gamma h}+b_{\gamma h}b_{\alpha f}&=0\,.\end{aligned} \tag{12}$$

These relations follow from (9) and (5). Other anticommutators between a's and b's can be expressed in terms of the overlap integral R of (7).

A one-particle operator $Q_1(x,y)$ with matrix elements

$$\langle\kappa k|Q_1|\lambda l\rangle=\int\psi^{*}_{\kappa k}(x)dx\int\psi_{\lambda l}(y)dyQ_1(x,y)\,, \tag{13}$$

is given in second quantized formalism by

$$Q_1=\sum_{\kappa k,\lambda l} c^{\dagger}_{\kappa k}\langle\kappa k|Q_1|\lambda l\rangle c_{\lambda l}\,. \tag{14}$$

In terms of the matrix elements

$$\langle\alpha f|Q_1|\gamma h\rangle=\int\varphi^{*}_{\alpha f}(x)dx\int\varphi_{\gamma h}(y)dyQ_1(x,y)\,, \tag{15}$$

the operator Q_1 becomes in the second quantized formalism

$$Q_1=\sum_{\alpha f,\gamma h} b^{\dagger}_{\alpha f}\langle\alpha f|Q_1|\gamma h\rangle b_{\gamma h}\,, \tag{16}$$

which is obtained directly from (13) and (14) by inserting (3) and (11).

In the same manner, a two-particle operator

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$Q_2(\xi,x;\eta,y)$ with matrix elements

$$\langle\alpha_1 f_1\alpha_2 f_2|Q_2|\gamma_1 h_1\gamma_2 h_2\rangle=\tfrac{1}{2}\int d\xi\int dx\int d\eta\int dy \times\begin{vmatrix}\varphi^*_{\alpha_1 f_1}(\xi) & \varphi^*_{\alpha_2 f_2}(\xi)\\ \varphi^*_{\alpha_1 f_1}(x) & \varphi^*_{\alpha_2 f_2}(x)\end{vmatrix} Q_2(\xi,x;\eta,y) \times\begin{vmatrix}\varphi_{\gamma_1 h_1}(\eta) & \varphi_{\gamma_2 h_2}(\eta)\\ \varphi_{\gamma_1 h_1}(y) & \varphi_{\gamma_2 h_2}(y)\end{vmatrix} \quad (17)$$

is given in second quantized form by the formula

$$Q_2=\sum_{(\alpha_1 f_1,\alpha_2 f_2)}\sum_{(\gamma_1 h_1,\gamma_2 h_2)} b^\dagger_{\alpha_2 f_2} b^\dagger_{\alpha_1 f_1} \times\langle\alpha_1 f_1\alpha_2 f_2|Q_2|\gamma_1 h_1\gamma_2 h_2\rangle b_{\gamma_1 h_1} b_{\gamma_2 h_2}. \quad (18)$$

The summation goes only over different pairs $(\alpha_1 f_1,\alpha_2 f_2)$ and $(\gamma_1 h_1,\gamma_2 h_2)$. The formulas (16) and (18) have been derived because in this work the assumption of orthonormality is not made for the localized states, so that there remains the question whether the a or the b operators are to be used in representing Q_1 and Q_2.

The operator $a^\dagger_{\beta g} b_{\beta g}=P_{\beta g}$ destroys the electron in the localized state $\varphi_{\beta g}(x)$ and then creates right back again. This operator acting on an arbitrary many electron state isolates that part which has an electron in the localized state $\varphi_{\beta g}(x)$. In view of

$$P^2_{\beta g}=a^\dagger_{\beta g} b_{\beta g} a^\dagger_{\beta g} b_{\beta g}=a^\dagger_{\beta g} b_{\beta g}=P_{\beta g}, \quad (19)$$

the operator $P_{\beta g}$ is indeed a projection operator. However, it is not a Hermitian operator, and has to be handled with some care. One way of examining it in more detail is to express $a^\dagger_{\beta g}$ in terms of $b^\dagger_{\beta g}$. With the help of (5), (10), and (11) one finds

$$a^\dagger_{\beta g}=\sum_{\alpha f} b^\dagger_{\alpha f} R(\alpha f,\beta g), \; =b^\dagger_{\beta g}+\sum_{\alpha f\neq g} b^\dagger_{\alpha f} R(\alpha f,\beta g). \quad (20)$$

The last step is a consequence of the orthonormalization (8) for the localized states belonging to the same lattice site. If the index β refers to a valence state, the second term on the right hand side of (20) is small to the extent that the overlaps between a localized valence state and all localized states on neighbors are small. The overlap between a valence and a conduction state is small because of the different angular symmetry, and the overlap between two valence states is small because of their tight localization. In this sense the operator $P_{\beta g}$ is approximately Hermitian for the localized valence states.

Since the projection operator $P_{\beta g}$ is not Hermitian we cannot associate a measurable quantity with it. As long as $P_{\beta g}$ is only used to construct some correlated wave function for the whole crystal, the lack of Hermiticity is not a drawback. But $P_{\beta g}$ cannot be used to answer the question as to the probability of finding the localized valence state $\varphi_{\beta g}$ occupied. Such detailed knowledge may be of no interest. However, one may find it useful to answer the more general question as to the average number of electrons in localized valence states. A Hermitian operator whose expectation value answers the last question can be constructed under certain additional assumptions which do not seem unduly restrictive. For instance, the conduction states may be defined as plane waves which were orthogonalized not only to the core states but also to the valence states. An operator can then be constructed whose expectation value gives the average number of electrons in conduction states, and therefore the difference between the total number of electrons and the number of electrons in conduction states gives the number of electrons in valence states. We shall use such a number in the future whenever this seems convenient.

3. ABOUT THE CORRELATION IN THE VALENCE STATES

With the help of the projection operator $P_{\beta g}$ the contribution of the localized valence state $\varphi_{\beta g}$ to the wave function Ψ of the whole crystal can be investigated. More generally, one can speak about the configurations Φ which contribute to Ψ. A configuration is a set of localized valence states, and it can be described by enumerating the index pairs βg which make up the configuration. To each configuration Φ belongs a projection operator which is just the product of $P_{\beta g}$ for the indices belonging to the configurations Φ, and of $(1-P_{\beta g})$ for the indices of valence states not belonging to the configuration Φ.

The total wave function Ψ can now be written as a sum over all possible configurations Φ of localized valence states in the crystal. The terms in this sum are not mutually orthogonal, but for the discussion of that part of the Hamiltonian which refers to the valence states of one particular atom only, the lack of orthogonality may be temporarily forgotten.

The largest contributions to these intra-atomic energy terms, besides the kinetic energy and the potential energy in the field of the nucleus and the core electrons, come from the mutual Coulomb repulsion of the valence states (since the core states are always occupied, their repulsion provides merely a constant shift). Indeed all the Coulomb repulsion integrals between valence states contain one term which is the largest and identical in all of them.[6] It is the Coulomb repulsion between two spherically symmetric charge distributions, each with total charge equal to one electronic charge, and a radial dependence equal to that of the valence states. If ν of the valence states at a particular atom are occupied, this term in the Coulomb repulsion becomes simply $C\nu(\nu-1)/2$.

For some arbitrary wave function Ψ, the number ν of occupied valence states at some particular atom is, in general, not fixed. Ψ may contain configurations Φ

[6] John C. Slater, *Quantum Theory of Atomic Structure* (McGraw-Hill Book Company, Inc., New York, 1960), Vol. I, pp. 311, 490.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which have different numbers of occupied valence states at the particular atom under examination. To the approximation where the configurations Φ are considered mutually orthogonal, a probability p_ν can be defined for Ψ, to have exactly ν occupied valence states at the particular atom. p_ν is simply the sum of the squares of all those configurations Φ which occur in the expansion of Ψ and have exactly ν occupied valence states at the particular atom.

Since the Coulomb repulsion $C\nu(\nu-1)/2$ is the largest among the many two-particle terms, it is important for the wave function Ψ to minimize the quantity

$$\tfrac{1}{2}\sum \nu(\nu-1)p_\nu=q, \tag{21}$$

with the summation going over the possible occupation numbers of the valence states, e.g., ν goes from 0 to 10 for the entire set of $3d$ states. There are two obvious conditions to be satisfied for the set of probabilities p_ν. The normalization condition is

$$\sum p_\nu=1, \tag{22}$$

and the total number of valence electrons is given by, say, $\bar{n}$ per atom on the average, so that

$$\sum \nu p_\nu=\bar{n}. \tag{23}$$

The solution to this simple minimization problem is found most easily in the following way. $\bar{n}$ is assumed to lie between two integers μ and $\mu+1$, i.e.,

$$\mu<\bar{n}<\mu+1. \tag{24}$$

q can then be expressed with the help of (22) and (23) as

$$q=(\mu/2)(2\bar{n}-\mu-1)+\tfrac{1}{2}\sum(\mu-\nu)(\mu+1-\nu)p_\nu. \tag{25}$$

The coefficients of p_μ and $p_{\mu+1}$ vanish, whereas the coefficients of all the other p's are positive. Therefore, q reaches its minimum for the values

$$p_\mu=\mu+1-\bar{n},\quad p_{\mu+1}=\bar{n}-\mu,$$
$$p_\nu=0 \quad \text{for} \quad \nu\neq\mu \quad \text{and} \quad \nu\neq\mu+1. \tag{26}$$

The values of p_μ and $p_{\mu+1}$ are obtained from (22) and (23) after all the other p_ν's have been set equal to zero.

The statement expressed in (26) has some striking consequences. For example, in the case of iron we have $\mu=7$, and it follows that any reasonable wave function Ψ for the whole iron crystal should contain only configurations which have either 7 or 8 occupied valence states on each atom. Similarly, in Ni we have $\mu=9$ and there ought not to be any configuration with less than 9 valence ($3d$) electrons at any lattice site.

The requirement (26) is generally violated by the itinerant electron model. Let us consider for example the Ni-Cu alloy with $100p$ atomic percent Cu substituted for Ni. We shall assume that $0.6-p$ holes per atom have to be distributed equally over two degenerate valence bands in the ferromagnetic ground state, and over four degenerate valence bands in the nonferromagnetic ground state. In terms of the numbers ν of holes we then have

$$p_\nu=\binom{2}{\nu}\left(1-\frac{0.6-p}{2}\right)^\nu\left(1+\frac{0.6-p}{2}\right)^{2-\nu} \text{ ferromagnetic,}$$

$$p_\nu=\binom{4}{\nu}\left(1-\frac{0.6-p}{4}\right)^\nu\left(1+\frac{0.6-p}{4}\right)^{4-\nu} \text{ nonferromagnetic.}$$

The second term in (25) becomes equal to $(0.6-p)^2/4$ for the ferromagnetic and $3(0.6-p)^2/8$ for the nonferromagnetic case.

The Coulomb repulsion C can be estimated as follows. The outermost $3d$ electrons see at least 1.6 unscreened nuclear charges. But since there are at least two of these outermost $3d$ orbits, the average unscreened nuclear charge in these orbits must be at least 2 so that such an outermost $3d$ orbit can be thought of as a hydrogenic $3d$ orbit in the field of an He nucleus. If we think of one of the two mutually repelling electronic charge distributions as completely concentrated at the nucleus (this tends to overestimate the value of C, but the hydrogenic $3d$ orbit has been chosen rather conservatively), C becomes equal to 4/9 Ry. The Coulomb repulsion energy is, therefore, $(0.6-p)/9$ Ry per hole for the ferromagnetic and $(0.6-p)/6$ Ry per hole for the nonferromagnetic case.

The surplus of Coulomb-repulsion energy for pure Ni, i.e., $p=0$, corresponds, according to our rough estimate, to about 10 000°K in the ferromagnetic and to about 15 000°K in the nonferromagnetic itinerant model, whereas the Curie temperature in Ni is found to be 650°K. It seems futile to discuss the itinerant model further without a serious attempt to find a modified wave function which is not beset by the large surplus of Coulomb repulsion in either the ferromagnetic or the nonferromagnetic state.

Since there are many configurations Φ with not more than $\mu+1$ and not less than μ occupied valence states on any lattice site, a good wave function Ψ for the whole crystal is expected to be a linear combination of all such configurations. Indeed any configuration Φ by itself does not give a particularly low expectation value for the kinetic energy and crystal potential terms in the Hamiltonian which correspond to a single electron moving in an effective potential of the lattice symmetry. Exactly these last terms were minimized by the itinerant model. They constitute the first order if the terms in the Hamiltonian are arranged in ascending powers of the overlap R between valence orbits on neighboring sites. The Coulomb repulsion C belongs to the zero order in such an expansion.

The basic idea is then to enforce the result (26) upon the itinerant model wave function by eliminating those configurations which violate the requirement (26) at some particular lattice site. Such a correlation corresponds exactly to the correlation in the Heitler-London wave function for the hydrogen molecule. But since we have now to do with $3d$ orbits the requirement (26) still

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

leaves many configurations at each lattice site, so that some additional correlation beyond the Heitler-London type (26) seems indicated. In particular Hund's rule should now be enforced at each lattice site.

4. A CORRELATED WAVE FUNCTION FOR THE VALENCE ELECTRONS

The ground state Ψ_0 in the itinerant electron model is obtained from the vacuum state Φ_0 by creating N electrons in Bloch states $\psi_{\kappa k}(x)$. Therefore, we have

$$\Psi_0 = \prod_{(\kappa k)} c^\dagger_{\kappa k} \Phi_0 , \tag{27}$$

where the set (κk) of occupied Bloch states is chosen in some manner, e.g., such as to minimize the expectation value of the total energy. The particular choice of the Bloch functions $\psi_{\kappa k}$ and the set (κk) is not under discussion right now, and we shall assume that both the functions $\psi_{\kappa k}(x)$ and the set (κk) have been determined once for all.

Ψ_0 is now expanded into configurations Φ of localized valence states by the method described at the beginning of the last section. The new (correlated) wave function Ψ is then obtained by transforming each configuration $\Phi(\alpha_1 f_1, \cdots, \alpha_M f_M)$ in the expansion of Ψ_0 into a linear combination of related configurations $\Phi(\gamma_1 h_1, \cdots, \gamma_M f_M)$. Most generally this transformation is described by an operator whose matrix elements give the coefficient of the configuration $\Phi(\gamma_1 h_1, \cdots, \gamma_M h_M)$ in the transformation of the configuration $\Phi(\alpha_1 f_1, \cdots, \alpha_M f_M)$.

A more specific assumption has to be made. As the most stringent assumption we will assume that the above operator O does not transfer electrons from one lattice site to another. Then it is helpful to simplify matters by assuming O to effect transfers of electrons within one atom independently of the transfers of electrons in neighboring atoms. We have, therefore, a set of operators $O^{(0)}$, $O^{(1)}$, $O^{(2)}$, $\cdots$ applicable to lattice sites which are occupied by 0, 1, 2, $\cdots$ electrons in the valence shell. The determination of these operators O is essentially equivalent to bringing about the necessary correlation of the valence states. In terms of the creation and annihilation operators we can write

$$O^{(\nu)} = \sum_{(\gamma_1 \cdots \gamma_\nu)} \sum_{(\alpha_1 \cdots \alpha_\nu)} \langle \gamma_1 \cdots \gamma_\nu | O^{(\nu)} | \alpha_1 \cdots \alpha_\nu \rangle$$
$$\times a^\dagger_{\gamma_\nu} \cdots a^\dagger_{\gamma_1} b_{\alpha_1} \cdots b_{\alpha_\nu} (1 - P_{\alpha_{\nu+1}}) \cdots (1 - P_{\alpha_{10}}) , \tag{28}$$

to be summed over all different groups of ν indices $(\alpha_1 \cdots \alpha_\nu)$ and $(\gamma_1 \cdots \gamma_\nu)$. In the case of $3d$ bands there is a maximum of 10 different indices.

For example the requirement (26) is enforced by setting all $O^{(\nu)} = 0$, except $O^{(\mu)} = O^{(\mu+1)} = 1$. This constitutes the generalization of the Heitler-London model for the hydrogen molecule. A somewhat weaker correlation is brought about by allowing the $O^{(\nu)}$ to deviate from the above value, but keeping each $O^{(\nu)}$ a multiple of the unit matrix.

It is now evident how Hund's rule can be favored. The configuration at each lattice site can be expanded into the states corresponding to the various spectral levels. The operators O can now be chosen so as to eliminate certain unfavorable spectral levels, or at least to reduce their contributions, whereas the levels which are lowest according to Hund's rule can be left unreduced. Therefore, the operators O may have off-diagonal elements. The values of the matrix elements of O can be determined variationally.

5. ALTERNATIVE FORMULATION FOR THE CORRELATED WAVE FUNCTION

If one is interested in a metal with only few electrons in the valence band, it is natural to expand all the results in powers of the density of valence electrons in the lattice. The operator O of the previous section is then best replaced by a slightly different expression which will be defined in this section.

The operator O will be expressed in terms of matrix elements $\vartheta_0 = 1, \vartheta_1(\gamma,\alpha), \vartheta_2(\gamma_1\gamma_2,\alpha_1\alpha_2)$, etc. These matrix elements are numbers out of which $\langle \gamma_1 \cdots \gamma_\nu | O^{(\nu)} | \alpha_1 \cdots \alpha_\nu \rangle$ can be computed by taking all kinds of combination of $\vartheta_0, \vartheta_1, \vartheta_2, \cdots$ and summing them.

First there is a summation over ν from 0 to 10 and for each ν a summation over all different ν-tuples $(\alpha_1 \cdots \alpha_\nu)$. Second, for each ν there is a summation over all partitions $P^{(\nu)}$ of the integer ν. Third, for each partition there is a summation over all possible groupings of the ν-tuple $(\alpha_1 \cdots \alpha_\nu)$ according to P, and over all permutations of $(\gamma_1 \cdots \gamma_\nu)$. A particular grouping of $(\alpha_1 \cdots \alpha_\nu)$ is written as $(\alpha^1 \cdots \alpha^\nu)$ where $\alpha^1 \cdots \alpha^\mu$ are associated with the 1's of the partition P, $(\alpha^{\mu_1+1}\alpha^{\mu_1+2})$, $(\alpha^{\mu_1+3}\alpha^{\mu_1+4})$, $\cdots$ with the 2's, etc. The permutation of $(\gamma_1 \cdots \gamma_\nu)$ is written $(\gamma^1 \cdots \gamma^\nu)$. With these preliminaries one can now write

$$O = -\frac{1}{\omega} \sum_{\nu=0}^{10} \sum_{(\alpha_1 \cdots \alpha_\nu)} \sum_{(\gamma_1 \cdots \gamma_\nu)} \sum_{P^{(\nu)}} \sum_{\substack{\text{groupings} \\ \text{of } (\alpha_a \cdots \alpha_\nu)}} \sum_{\substack{\text{permutations} \\ \text{of } (\gamma_1 \cdots \gamma_2)}}$$
$$\times \vartheta_1(\gamma^1\alpha^1)\vartheta_1(\gamma^2\alpha^2) \cdots \vartheta_2(\gamma^{\mu_1+1}\gamma^{\mu_2+1}\alpha^{\mu_1+1}\alpha^{\mu_1+2}) \cdots$$
$$\times a^\dagger_{\gamma_\nu} \cdots a^\dagger_{\gamma_1} b_{\alpha_1} \cdots b_{\alpha_\nu} . \tag{29}$$

The term $\nu = 0$ is put equal to 1.

The factor $1/\omega$ expresses the fact that the same wave function Ψ results, if the left-hand and the right-hand sides of (29) are just multiples of each other with the same factor for all operators.

Since the operators $O^{(\nu)}$ have an intuitive interpretation according to the preceding section, the problem arises of finding the matrix elements ϑ from known operators O by solving Eq. (29). The special case of the O's being chosen according to the requirement (26) is treated in the Appendix A. We shall assume that $\omega = 1$ from now on. This implies that $O^{(0)} = 1$, or in other words, that a configuration will not be discriminated against for having no electrons at all at some particular lattice site. Such an assumption is only reasonable if

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

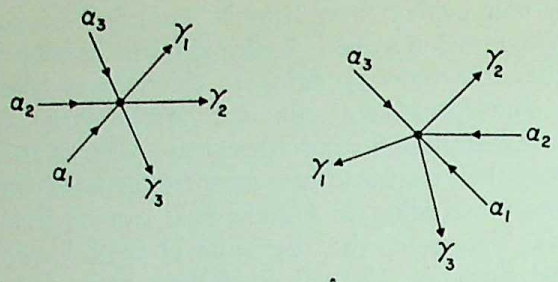

FIG. 1. Two equivalent vertices corresponding to ϑ_3.

there are fewer valence electrons on the average in the lattice than lattice sites.

The theory has been phrased in terms of electrons, but in the case of almost-filled bands it is more appropriate to consider the holes in the valence bands. This is done simply by switching the positions of $a^\dagger$ with respect to b in (28) and (29). The projection operator $1-P=1-a^\dagger b=ba^\dagger$ appearing in (28) then goes into $a^\dagger b=P$, which tests the absence of a hole exactly as $1-P$ tested the absence of an electron. Again, an equivalence between (28) and (29) can be established only in the cases where there is no physical reason to discriminate against a configuration for having no holes at all at some particular lattice site. Since the present investigation is directed mostly toward the understanding of the Ni-Cu alloys, all the following calculations will be done for the case of an almost-full valence band.

A picture can be associated with any particular term in (29), if each factor ϑ_ν is represented by a heavy dot, called a vertex, with ν directed lines across. The endpoints of the lines are labeled on the incoming end by α, and on the outgoing end by γ. A combination of such representations of ϑ's is called a picture. Two pictures are called equivalent if they can be brought to congruence including the labeling of lines, by shifting their parts. Figure 1 shows two equivalent vertices.

Conversely, given a picture, i.e., a combination of vertices with labeled ingoing and outgoing lines, one associates a product of ϑ's and operators $a^\dagger$, b with it. To each vertex corresponds a factor $\nu!\vartheta_\nu$ with the arguments occurring in the picture. Formula (29) can then be expressed as a sum over all pictures to be made with two sets of labels $(\alpha_1\cdots\alpha_{10})$ and $(\gamma_1\cdots\gamma_{10})$.

6. CALCULATION OF EXPECTATION VALUES

The correlated wave function Ψ is now given by

$$\Psi=\prod_g O_g\Psi_0, \tag{30}$$

where O_g is the operator (29) belonging to the lattice site g. Since Ψ_0 represents almost filled valence bands, $a^\dagger$ is replaced formally by b everywhere, and vice versa, everything else in (29) remaining at its place. The first thing to be done is the computation of the absolute value $(\Psi|\Psi)$ of the correlated wave function Ψ.

Formula (29) is inserted in (30) by attaching an additional index g to the ϑ_μ, b_γ, and $a^\dagger_\alpha$. The product over the lattice sites is worked out for both Ψ and Ψ^*, the scalar product is taken term by term, and the results are added up. Each term in this last sum can be represented by a picture in the following way:

To each $\vartheta_{\mu g}$ or $\vartheta^*_{\mu g}$ associate a heavy dot called a vertex, to be labeled by the lattice site g. Each operator $a^\dagger_{\alpha g}$ associated with $\vartheta_{\mu g}$ is represented by a solid line with an arrow going into the vertex of $\vartheta_{\mu g}$, and each operator $a_{\alpha g}$ associated with $\vartheta^*_{\mu g}$ is represented by a solid line with an arrow coming out of the vertex of $\vartheta^*_{\mu g}$. Each operator $b_{\gamma g}$ associated with $\vartheta_{\mu g}$ is represented by a dotted line leaving the vertex of $\vartheta_{\mu g}$, and the operator $b^\dagger_{\gamma g}$ associated with $\vartheta^*_{\mu g}$ is represented by a dotted line going into the vertex of $\vartheta^*_{\mu g}$. The lines are labeled exactly as the operators they represent. Figure 2 is an example of such a picture representing a term in $(\Psi|\Psi)$. Two pictures like Fig. 2 are called identical if they can be brought to congruence including labels and directions by merely shifting the parts of the picture without ever detaching a line from its vertex. If one permutes the arguments $\gamma_1\cdots\gamma_\mu$ in $\vartheta_{\mu g}$ the same picture arises according to this definition.

Conversely, given a picture like Fig. 2, it is immediately possible to write down the corresponding term in the evaluation of $(\Psi|\Psi)$. For each vertex with μ incoming solid lines one writes an operator

$$\mu!\vartheta_{\mu g}(\gamma_1\cdots\gamma_\mu\alpha_1\cdots\alpha_\mu)b_{\gamma_1 g}\cdots b_{\gamma_{10}g}a^\dagger_{\alpha_1 g}\cdots a^\dagger_{\alpha_\mu g}$$

with the corresponding labels, and analogously for each vertex with μ outgoing solid lines. All operators belonging to a ϑ^* are written to the left of all operators belonging to a ϑ. The order of operators belonging to different lattice sites is immaterial. Operators belonging to the same lattice site have to be pulled together in the order suggested by (29). A particular label βg on $a^\dagger$ can then not occur more than once, and similarly any particular label on b, $b^\dagger$, or a cannot occur more than once. The freedom left in ordering the operators belonging to different lattice sites cannot change the expectation value of the whole operator product because of the simple anticommutators (12) for $a^\dagger$ and b.

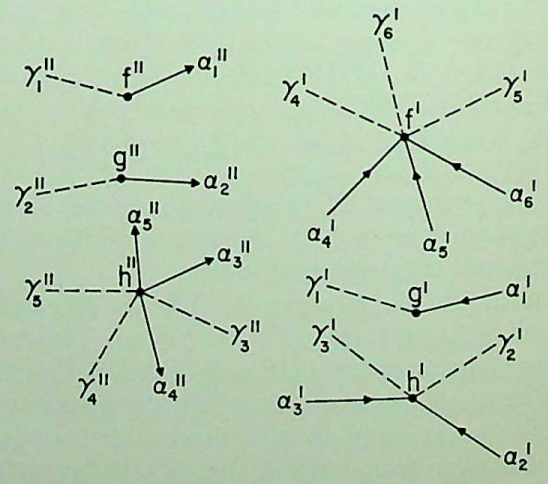

FIG. 2. Example of a picture for a term in (30).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The absolute value $(\Psi|\Psi)$ becomes now a sum over all different pictures like Fig. 2, where one associates an operator with each picture according to the rules of the previous paragraph, and then computes the expectation values of that operator with the wave function Ψ_0.

The computation of an expectation value like $(\Psi|b^\dagger_{\alpha f}b_{\gamma h}|\Psi)$ which arises from the one particle operator (16) is done in almost the same way. $b^\dagger_{\alpha f}$ is represented by a small cross labeled αf with an ingoing dotted line, and $b_{\gamma h}$ is represented by a small cross labeled γh with an outgoing dotted line, in addition to all the features in the pictures for $(\Psi|\Psi)$. Everything stays the same as with $(\Psi|\Psi)$ except the operators associated with ϑ^* have to be written to the left of $b^\dagger_{\alpha f}b_{\gamma h}$, and the operators associated with ϑ stand to the right. The small crosses associated with $b^\dagger_{\alpha f}$ and $b_{\gamma h}$ are called external points to distinguish them from the vertices (heavy dots).

7. EVALUATION IN TERMS OF DIAGRAMS

The expectation value of the operator associated with a picture like Fig. 2 can be evaluated for the uncorrelated wave function Ψ_0 with the help of Wick's theorem. According to this theorem one has to run through all complete systems of contractions, that is through all ways of grouping the annihilation and creation operators into pairs. The contribution of such a complete system of contractions is given by the product of the expectation values of each pair in the contraction for the wave function Ψ_0. The order of the operators in each pair has to be the same as in the original operator, and there is a sign to be determined from the number of permutations necessary in order to bring the partners of each pair together.

In the case of the uncorrelated wave function Ψ_0 only the pairs consisting of one annihilation and one creation operator give a nonvanishing result. There are four types of such pairs and their expectation values are easily computed with the help of the definitions (10) and (11), as well as the relations (5). They are

$$\begin{aligned}
&(\Psi_0|a_{\alpha f}a^\dagger_{\gamma h}|\Psi_0)=W(\alpha f,\gamma h),\\
&(\Psi_0|b_{\alpha f}a^\dagger_{\gamma h}|\Psi_0)=\sum_{\beta g}S(\alpha f,\beta g)W(\beta g,\gamma h),\\
&(\Psi_0|a_{\alpha f}b^\dagger_{\gamma h}|\Psi_0)=\sum_{\beta g}W(\alpha f,\beta g)S(\beta g,\gamma h),\qquad (31)\\
&(\Psi_0|b^\dagger_{\alpha f}b_{\gamma h}|\Psi_0)=S(\gamma h,\alpha f)\\
&\quad-\sum_{\beta' g'\beta'' g''}S(\gamma h,\beta'' g'')W(\beta'' g'',\beta' g')S(\beta' g',\alpha f),
\end{aligned}$$

where W and S are defined by

$$\begin{aligned}
W(\alpha f,\gamma h)&=\frac{1}{L}\sum_{(\kappa k)}U^*_{\alpha f,\kappa k}U_{\gamma h,\kappa k},\\
S(\alpha f,\gamma h)&=\frac{1}{L}\sum_{\kappa k}V_{\kappa k,\alpha f}V_{\kappa k,\gamma h}.\qquad (32)
\end{aligned}$$

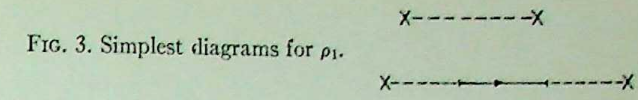

FIG. 3. Simplest diagrams for ρ_1.

The summation over (κk) means that only those indices κk are included in the summation which correspond to empty Bloch states of Ψ_0. It is easily checked that the matrix $S(\alpha f,\gamma h)$ is just the inverse of the overlap matrix $R(\alpha f,\gamma h)$ defined in (7).

It is immediately evident from writing down the operator corresponding to a picture like Fig. 2 that a and $a^\dagger$, as well as $b^\dagger$ and b, have always to be paired in the sequence in which they appear in the first and last formula of (31). However, the pairs made up of b and $a^\dagger$, or of a and $b^\dagger$, may occur in either sequence, except if the two partners of such a pair belong to the same lattice site. In that case b always precedes $a^\dagger$, and a precedes $b^\dagger$, exactly as in the second and third formula of (31). If b and $a^\dagger$, or a and $b^\dagger$ do not belong to the same lattice site, the commutation relations (12) tell us that only the sign of the expectation value changes when the order of the partners in the pair is changed. But this sign change is accounted for when the over-all sign to be attached to the product of the quantities (31) is determined.

A complete system of contractions can be represented with the help of pictures like Fig. 2 in the following way. A pair of the type $aa^\dagger$ is represented by simply connecting the two solid lines representing a and $a^\dagger$, the arrow points from a to $a^\dagger$. Similarly a pair of type $ba^\dagger$ is represented by tying the dotted line of b to the solid line of $a^\dagger$, inserting a short cross line such as in Fig. 3 at the point where the dotted and the solid lines meet. This short cross line marks the end of the dotted and the beginning of the solid line, and corresponds to the summation over βg which appears in the formula (31) for $(\Psi_0|b_{\alpha f}a^\dagger_{\gamma h}|\Psi_0)$. A similar treatment is given to a pair $ab^\dagger$. Finally, since a pair $b^\dagger b$ gives rise to two terms as shown in (31), it will be represented in two ways as shown in Fig. 3, first by simply connecting the two dotted lines of $b^\dagger$ and b, and second by joining the dotted line of $b^\dagger$ with the dotted line of b through the intermediary of a directed solid line. The arrows go from b to $b^\dagger$ which is reflected in the inverted arguments of the last formula in (31) as compared to the preceding formulas in (31). The minus sign appearing in the last part of $(\Psi_0|b^\dagger_{\alpha f}b_{\gamma h}|\Psi_0)$ will be absorbed in the general rules determining the overall sign. This pictorial representation of a particular complete system of contractions by connecting the appropriate lines in a picture like Fig. 2 is called the diagram associated with that system of contractions. Two diagrams are identical if they can be brought into complete congruence (including labels and arrows) by shifting the lines in the drawing without ever breaking any of them.

In the present formulation the particle lines (solid or dotted) run from one vertex to another, but they do not

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

run through a vertex. None of the solid lines at some vertex is in a particular relationship with any given dotted line belonging to the same vertex, and vice versa. However, if one starts from a given diagram in order to write its contribution to $(\Psi|\Psi)$, the result depends on the order in which the arguments α and γ are listed in the ϑ corresponding to some particular vertex. In establishing the over-all sign to be attached to the contribution, it is convenient to adopt the following rule: The particle line ending in α_i at some vertex ϑ_μ continues on the other side with the particle line labeled γ_i, and the particle line ending in γ_j in ϑ^*_ν continues with α_j. In this manner all particle lines are joined two by two to form so-called loops. A closed loop closes itself in the diagram, an open loop ends at external points, which are the ones represented by small crosses. The over-all sign to be associated with a particular diagram is obtained in the following manner. The solid and dotted lines are organized into loops according to the rules of the previous paragraphs. A factor (-1) is now inserted for each segment of solid line in the diagram and for each closed loop.

In the original picture, e.g., in Fig. 2, the labels associated with outgoing solid lines were all different from one another; similarly, the labels of the incoming solid lines were all different; and similarly for the dotted lines, excepting the labels of dotted lines attached to external points. The expectation value associated with a picture like Fig. 2 is the sum over the contributions from all different diagrams to be drawn from the picture. The sum of these contributions is easily found to be an antisymmetric function of the labels associated with solid outgoing lines, of the labels associated with solid incoming lines, etc. As long as the over-all sign and the individual factors associated with a diagram are determined by the above rules, using in particular only the pair expectation values (31), it is formally possible to let labels of outgoing solid lines coincide, or to let labels of incoming solid lines coincide, etc. The sum over all diagrams associated with a picture containing identical labels on outgoing solid lines, or on incoming solid lines, etc., will give a vanishing result.

Therefore, it is now possible to let all the labels in a diagram run through all admissible values, independently of one another. The restriction to admissible values refers to the fact that only localized valence states are involved, but no conduction states. The overcounting resulting from this mutual independence makes it necessary to divide by

$$\mu_1!\mu_2!\cdots\nu_1!\nu_2!\cdots(1!)^{\nu_1+\mu_1}(2!)^{\nu_2+\mu_2}\cdots$$

where $\mu_1,\mu_2,\cdots$ is the number of $\vartheta_1,\vartheta_2,\cdots$, and $\nu_1,\nu_2,\cdots$ is the number of $\vartheta^*_1,\vartheta^*_2,\cdots$ in the diagram.

In summary, the expectation values of Ψ can be written as a sum over all different diagrams. A diagram consists of vertices, solid lines, dotted lines, and possibly external points. There are two kinds of vertices, with outgoing solid (incoming dotted) lines and with incoming solid (outgoing dotted) lines. There are two kinds of external points, with one incoming dotted line, and with one outgoing dotted line. Each line going out of one vertex (or external point) has to be tied to a line going into some vertex (or external point). A solid line is tied directly to another solid line; a solid line is tied to a dotted line, and vice versa, by inserting a short cross bar at the joining point; a dotted line can be tied either directly to another dotted line, or indirectly through the intermediary of a solid line segment, as shown in Fig. 3. Each vertex is labeled as a lattice site, and the lines going into and coming out of a vertex carry labels of band indices for localized valence states. Each external point carries the label of a lattice site with band index. The lattice site labels on the vertices and the external points are all different from one another. Similarly the band index labels on any particular vertex are different from one another. Two diagrams are different, if they cannot be brought to coincidence including the direction of lines and the labels on them by simply shifting the vertices on the paper without breaking any lines.

The contribution of a diagram is obtained as follows:

(1) To each vertex associate a factor ϑ_μ or ϑ^*_μ where μ is the number of incoming or outgoing solid lines;

(2) Attach a different lable βg to each short cross bar in the diagram;

(3) With each solid line from αf to γh associate a factor $W(\alpha f,\gamma h)$;

(4) With each dotted line from αf to γh associate a factor $S(\alpha f,\gamma h)$;

(5) Insert a factor (-1) for each solid line and each closed loop in the diagram;

(6) Insert a factor

$$1/\mu_1!\mu_2!\cdots\nu_1!\nu_2!\cdots(1!)^{\nu_1+\mu_2}(2!)^{\nu_2+\mu_2}\cdots,$$

where μ_1 is the number of ϑ_1,μ_2 the number of ϑ_2, etc., ν_1 the number of ϑ^*_1, etc. in the diagram;

(7) Sum independently over all labels excepting naturally the labels of external points, the labels associated with vertices run only over the band indices of localized valence states, whereas the labels associated with short cross bars run over all band indices (valence and conduction).

A special rule applies to the diagrams with more than one pair of external points, such as occur in the computation of Q_2 in (18) which involves the operators $b^\dagger_{\alpha_2 f_2}b^\dagger_{\alpha_1 f_1}b_{\gamma_1 h_1}b_{\gamma_2 h_2}$. If the open loops go from $\gamma_1 h_1$ to $\alpha_2 f_2$ (rather than $\alpha_1 f_1$) and from $\gamma_2 h_2$ to $\alpha_1 f_1$ (rather than $\alpha_2 f_2$) an extra factor (-1) has to be inserted.

In the following discussion of particular diagrams it is convenient to distinguish various types of labels which appear in the diagrams by the following rules: The double label consisting of a small Greek letter for the band index and a small Latin letter for the lattice site is replaced by one capital letter. An external point with outgoing dotted line is labeled Γ', and one with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

incoming dotted line is labeled Γ''. An outgoing dotted line on a vertex is labeled H', and an incoming dotted line on a vertex is labeled H''. A short cross bar is labeled G' when it joins an incoming solid line to an outgoing dotted line, and it is labeled G'' when it joins an outgoing solid line to an incoming dotted line. Finally, an incoming solid line on a vertex is labeled F' and an outgoing solid line on a vertex is labeled F''. Clearly, the labels Γ' and Γ'' are fixed, the labels F', F'', H', and H'' run through all localized valence states in the lattice, whereas the labels G' and G'' run through all localized states (valence and conduction) in the lattice. Also the labels Γ' and Γ'' may stand for valence as well as for conduction states.

8. LINKED DIAGRAMS

Any part of a diagram which can be completely separated from the remaining diagram without breaking any line, is called an unlinked part. Once a diagram is divided up completely into unlinked parts, its total contribution can easily be obtained from calculating the separate contributions for each unlinked part, the total being equal to the product of its parts.

Unlinked parts without external points are called closed linked diagrams, if they cannot be broken up further into unlinked parts. The contributions of all closed linked diagrams appear simply as a factor

$$\exp[\sum_{\text{closed linked}} \Lambda] \tag{33}$$

to the diagrams with external lines. Λ stands for the number calculated, according to the rules of the previous section, for a particular closed linked diagram.

Since (33) is just the normalization integral (Ψ,Ψ), this factor divides out if ρ_1 and ρ_2 are computed with a normalized correlated wave function Ψ. Therefore, we can write with the help of (16) and (18)

$$\rho_1(x,y)=\sum_{\Gamma'\Gamma''}\varphi_{\Gamma'}(x)\varphi^*_{\Gamma''}(y) \times \sum_{\substack{\text{open linked with}\\ 2\text{ external points}}} \Lambda(\Gamma'\Gamma''), \tag{34}$$

$$\rho_2(\xi,x;\eta,y)=\tfrac{1}{2}\rho_1(\xi,\eta)\rho_1(x,y)-\rho_1(\xi,y)\rho_1(x,\eta) +\tfrac{1}{2}\sum_{(\Gamma'_1\Gamma'_2)(\Gamma''_1\Gamma''_2)}\begin{vmatrix}\varphi_{\Gamma'_1}(\xi) & \varphi_{\Gamma'_1}(x)\\ \varphi_{\Gamma'_2}(\xi) & \varphi_{\Gamma'_2}(x)\end{vmatrix} \times\begin{vmatrix}\varphi^*_{\Gamma''_1}(\eta) & \varphi^*_{\Gamma_2''}(y)\\ \varphi^*_{\Gamma''_1}(\eta) & \varphi^*_{\Gamma_2''}(y)\end{vmatrix} \times \sum_{\substack{\text{open linked with}\\ 4\text{ external points}}} \Lambda(\Gamma'_1\Gamma'_2,\Gamma''_1\Gamma''_2). \tag{35}$$

The interest of the last formula lies in the net separation of the "properly correlated" part of ρ_2 by the diagram analysis, i.e., the part of ρ_2 which cannot be simply understood as the effect of many-particle statistics and the exclusion principle.

According to the last two formulas it is only necessary to obtain the contributions of all open linked diagrams with two or four external points. These diagrams can be obtained in a systematic fashion from the closed linked diagrams, of which there are fewer, of course.

A closed linked diagram can be associated to each open linked diagram by simply joining the end points of each open loop, i.e., joining Γ' and Γ'', Γ'_1 and Γ''_1, Γ'_2 and Γ''_2. In doing this, a diagram may arise which is not allowed under previously established rules. Indeed, the external points are always reached by a dotted line, but these dotted lines may not be attached at their other ends to a point H' of H''. Instead, they may both be attached to a point G' or G''. The closing of such an open loop would then lead to a sequence solid-dotted-solid line where neither end of the dotted line is attached to a point H' or H'', contrary to our rules. However, in view of (5) and (32), such an illegal sequence may be contracted into one solid line, and in this way a legitimate closed linked diagram is obtained.

Conversely, it is evident that we obtain all open linked diagrams if we open in turn every solid or dotted line, or every couple of solid and/or dotted lines in all closed linked diagrams, provided the diagram does not decay into two unlinked parts. The rule for opening solid or dotted lines is simple. First write the expression for the closed linked diagram. Second, in order to obtain the contribution to ρ_1 make in turn the following replacements.

$$W(HF)\rightarrow\sum_{G'_0G''_0}W(HG'_0)S(G'_0\Gamma'')S(\Gamma'G''_0)W(G''_0F),$$
$$S(HF)\rightarrow -S(H\Gamma'')S(\Gamma'F), \tag{36}$$

for every factor W and S. Third, in order to obtain the contribution to the properly correlated part of ρ_2 make the replacements (36) in turn on every couple of factors with the pairs of external points (Γ''_1,Γ'_1) and (Γ''_2,Γ'_2). The over-all sign remains the same as in the closed linked diagram.

9. THE FIRST-ORDER DENSITY FUNCTION

The original expression for ρ_1 contains two terms which cannot be associated with a closed linked diagram. Their diagrams are given in Fig. 3, and their contributions to ρ_1 follow directly from the last formula (31) together with (3) and (11)

$$\sum_{[\kappa k]}\psi_{\kappa k}(x)\psi^*_{\kappa k}(y), \tag{37}$$

where $[\kappa k]$ is the set of Bloch states which are occupied by electrons. The complementary set, occupied by holes, is designated by (κk). This is just the ρ_1 from the uncorrelated wave function Ψ_0 which forms the base for the itinerant electron model.

It is of interest to notice that the total number of electrons in the lattice

$$N=\int dx\rho_1(x,x) \tag{38}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

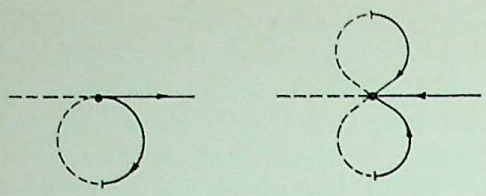

FIG. 4. Examples of bubbles.

is correctly given by (37). The correction terms which come from more complicated diagrams have to cancel one another in the integral (38). This fact is easily seen from (36) if we note that the integral (38) for any open linked diagram with two external points is equal to (± 1) times the contribution of the corresponding closed linked diagram; $+1$, if the open diagram resulted from opening a solid line; -1, if the open diagram resulted from opening a dotted line. A contribution to N from opening a solid line in a closed linked diagram is exactly canceled by the contribution to N from opening a dotted line in the same closed linked diagram.

This last property of the diagrams enables us to order the contributions to ρ_1 according to powers in the density m of holes in the valence band. m is defined as the ratio M/L where M is the average number of holes in localized valence states for the whole lattice. The order of some diagram is simply the power of m which occurs in the contribution of the associated closed linked diagram.

There are more terms of order one than (37). They arise from the closed linked diagrams which contain only ϑ_1, but no ϑ_2, ϑ_3, etc. Due to the simple structure of these diagrams they can all be evaluated. Their contribution together with (37) leads to substituting each occupied state $\psi_{\kappa k}(x)$ by a state $\bar{\psi}_{\kappa k}(x)$.

It is shown in Appendix B, how taking account of ϑ_1 throughout all possible diagrams is tantamount to redefining W in terms of $\bar{\psi}_{\kappa k}$ rather than $\psi_{\kappa k}$ and to a proper modification of the operators $\vartheta_2, \vartheta_3, \cdots$.

Another class of simple diagrams for ρ_1 is provided by the opening of the dotted and the solid lines in one of the two partial diagrams in Fig. 4. The vertices to which these "bubbles" are attached have other ingoing and outgoing lines, but the additions implied in all those other lines can be performed even before opening the bubbles. The result appears to the bubbles exactly as ϑ_1 would have appeared to them. Quite generally, any part of a diagram which can be reduced to ϑ_1 by taking loops off a vertex, appears to that diagram like a ϑ_1 insertion. Therefore, the effect of all such "dangling" parts in a diagram can be treated exactly as the effect of ϑ_1 contributions was treated in Appendix B.

The following result emerges: The treatment of ϑ_1 insertions is extended to include the "dangling" parts of a diagram. All that appears in the redefinition of Appendix B is the sum of ϑ_1 and all possible dangling parts. Since $\vartheta_1, \vartheta_2, \vartheta_3, \cdots$ are essentially determined by the assumptions concerning $O^{(1)}, O^{(2)}, O^{(3)} \cdots$ it seems that one is not free to choose ϑ_1 so as to cancel all the dangling parts. But the freedom to choose Ψ_0 still remains, and one might determine $\vartheta_1, \vartheta_2, \vartheta_3, \cdots$ variationally in order to determine $O^{(1)}, O^{(2)}, O^{(3)}, \cdots$ afterwards. In that case it is just as well to take $\vartheta_1 = 0$ and neglect all diagrams with dangling parts. We shall adopt this last viewpoint in the future development.

Up to the second order in the density of holes there is only one closed linked diagram out of which contributions to ρ_1 arise. This diagram is given in Fig. 5. It is of second order in ϑ_2. With assumed values for the constants determining the band structure, and for the overlap integrals, the band-structure term in the expectation value of the energy becomes, therefore, quadratic in ϑ_2. The Coulomb-repulsion term related to these second-order terms in ρ_1 is not only quartic in ϑ_2, but also in the density of holes, so that it can be neglected with respect to the band-structure term arising from ρ_1.

The explicit calculation of ρ_1 is done most easily and most usefully in terms of the Fourier transforms with respect to the lattice sites. Since ϑ_2 differs from zero only when all of its arguments are at the same lattice site, the Fourier transform does not affect ϑ_2 which simply becomes independent of the momenta exchanged between its in- and outgoing dotted and solid lines. Since the band indices are all carried along explicitly, the wave vectors k are always to be reduced to the first Brillouin zone. This implies conservation of wave vectors at each vertex up to a vector of the reciprocal lattice.

The terms in ρ_1 corresponding to the diagrams of Fig. 5 can easily be written down if the overlap $R(\alpha f, \gamma h)$ is simplified to $\delta_{\alpha\gamma}\delta_{fh}$. The localized orbits are then effectively Wannier states, and the two vertices of the diagrams in Fig. 5 have to be at the same lattice site. The particle propagator $W(F''F')$ has to be evaluated at the same lattice site $f' = f''$. It is shown in Appendix C that these assumptions have the following consequences. W differs from zero only if the orbits with band indices α' and α'' belong to the same irreducible representation of the crystal symmetry operations around the fixed lattice site $f' = f''$. For subsets $\{\alpha'\}$ and $\{\alpha''\}$ of the same irreducible representation, W is a multiple of the unit matrix.

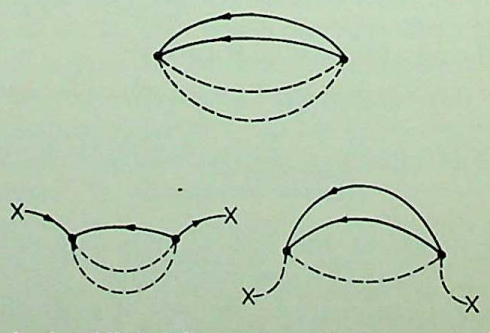

FIG. 5. Only closed linked diagram contributing to ρ_1 in the second order of density, and the two ρ_1 diagrams arising from it.

As long as the spin variable is specifically excluded from transformation under the crystal symmetry operations, W may have nonvanishing elements between orbits of the same irreducible representation, but different spin directions. Such a situation is typical of an uncorrelated wave function Ψ_0 which describes an antiferromagnetic metal or one with some kind of spiral structure. Although such cases are not hard to handle, we shall simplify matters by writing down our formulas in their absence. It follows then that

$$W(\alpha'' f,\alpha' f)=m_\alpha \delta_{\alpha'\alpha''}, \tag{39}$$

where m_α is the probability of finding the orbit $\alpha=\alpha'=\alpha''$ at f occupied by a hole.

The Fourier transforms are written in terms of

$$u_{\beta\kappa}(k)=e^{ikg}U_{\beta g,\kappa k}. \tag{40}$$

According to (4) this quantity indicates the contribution of $\psi_{\kappa k}(x)$ to the localized states of index β. There is no simple relationship between κ and β. In the most general case the index κ simply numbers the consecutive Bloch functions belonging to the wave vector k. However, if the picture of a conduction band as somehow distinguishable from the valence bands is at all significant, the following assumptions about $u_{\beta\kappa}(k)$ can be made. For given β and κ the quantity $u_{\beta\kappa}(k)$ varies with the wave vector k fairly abruptly in such a manner that in most regions of the Brillouin zone $\psi_{\kappa k}(x)$ can be called either valence-like or conduction-like. Since $u_{\beta\kappa}(k)$ is assumed to be a continuous function of k, the transition regions have a nonvanishing but small volume in the reciprocal space.

The propagation function $W(\alpha f,\gamma h)$ of (32) is now written as

$$W(\alpha f,\gamma h)=\frac{1}{L}\sum_{(\kappa k)} u^*{}_{\gamma\kappa}(k)u_{\alpha\kappa}(k)e^{ik(f-h)}. \tag{41}$$

According to the above assumptions concerning $u_{\beta\kappa}(k)$ the propagation of a hole from αf to γh is done mainly by those terms κk in the sum which have the same character as α and γ. In particular, if α and γ have different character $W(\alpha f,\gamma h)$ is small, and if α and γ refer both to valence states $W(\alpha,f,\gamma h)$ does not exceed the density m of holes in valence states. It is this last statement which allows us to classify diagrams according to the number of solid lines in them.

The contribution of the diagrams in Fig. 5 to ρ_1

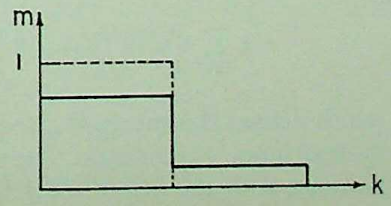

FIG. 6. Schematic distribution of holes in reciprocal space with (drawn out) and without (dotted) correlation.

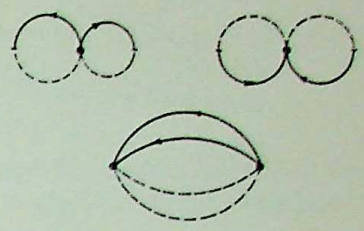

FIG. 7. Diagrams contributing to the properly correlated part of ρ_2 in the second order of density.

becomes

$$\frac{4}{L}\sum_{k(\kappa)(\lambda)}\sum_{\alpha\beta(\beta'\beta'')\gamma}\psi_{\kappa k}(x)u_{\alpha\kappa}(k)$$
$$\times\vartheta_2\begin{pmatrix}\alpha & \beta\\ \beta' & \beta''\end{pmatrix}m_\beta\vartheta_2^*\begin{pmatrix}\gamma & \beta\\ \beta' & \beta''\end{pmatrix}u_{\gamma\lambda}^*(k)\psi_{\lambda k}^*(y)$$
$$-\frac{4}{L}\sum_{k\kappa\lambda}\sum_{\alpha\beta(\beta'\beta'')\gamma}\psi_{\kappa k}(x)u_{\alpha\kappa}(k)$$
$$\times\vartheta_2^*\begin{pmatrix}\beta' & \beta''\\ \alpha & \beta\end{pmatrix}m_{\beta'}m_{\beta''}\vartheta_2\begin{pmatrix}\beta' & \beta''\\ \gamma & \beta\end{pmatrix}u_{\gamma\lambda}^*(k)\psi_{\lambda k}^*(y). \tag{42}$$

The summations (κ) and (λ) are restricted to the labels which are occupied by holes in Ψ_0, and the summation over $(\beta'\beta'')$ goes over all pairs of valence state indices. Since all indices α, β, β', β'', γ refer to valence states, only those indices κ and λ contribute to (42) which correspond to valence like states. The interpretation of (42) is therefore meant to apply only to valence states.

The first term in (42) describes a decrease in the occupation probability for those states which were originally fully occupied by valence holes. The second term spreads the holes which were freed by the first term over the whole available reciprocal space of valence character. The situation is schematically shown in Fig. 6. The kinetic energy and crystal-potential terms in the total energy can be obtained immediately.

10. THE SECOND-ORDER DENSITY FUNCTION

The closed linked diagrams which give contributions to the properly correlated part of ρ_2 have to have at least two solid and two dotted lines. On the other hand, as long as we are interested only in terms up to the second order in the density of holes, the only diagrams to be considered have not more than two solid lines. This shows that the only contributions of interest come from the diagrams in Fig. 7. Again these diagrams are at most of the second order in ϑ_2, so that the determination of ϑ_2 by minimizing the expectation value of the total energy for the correlated wave function Ψ is straightforward up to the second order in the density of holes.

The case of small overlap between valence states is of particular interest. The largest terms in the Hamiltonian are the Coulomb integrals with all orbits belonging to the same lattice site. The contribution of the diagrams above can then be evaluated quite easily,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

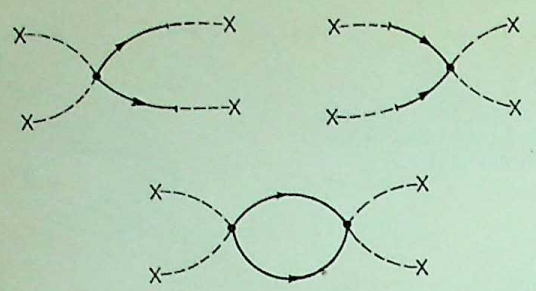

FIG. 8. The diagrams which contribute to the formula (43).

because in the lowest order of density and overlap only the diagrams in Fig. 8 with all external points at the same lattice site as that of ϑ_2 make a contribution.

The computation is straightforward for the same assumptions as were used in the derivation of (42). Together with the contribution of the valence hole term in (37) to the first term in (35) one finds for the terms in ρ_2 which are quadratic in the density

$$\bar{\rho}_2=\tfrac{1}{2}\sum_{(\alpha_1\alpha_2)(\gamma_1\gamma_2)}\begin{vmatrix}\varphi_{\alpha_1}(x) & \varphi_{\alpha_1}(\xi)\\ \varphi_{\alpha_2}(x) & \varphi_{\alpha_2}(\xi)\end{vmatrix}\begin{vmatrix}\varphi^*_{\gamma_1}(y) & \varphi^*_{\gamma_1}(\eta)\\ \varphi^*_{\gamma_2}(y) & \varphi^*_{\gamma_2}(\eta)\end{vmatrix}$$

$$\times\sum_{(\beta_1\beta_2)}\left[\delta\begin{pmatrix}\alpha_1 & \alpha_2\\ \beta_1 & \beta_2\end{pmatrix}+2\vartheta_2\begin{pmatrix}\alpha_1 & \alpha_2\\ \beta_1 & \beta_2\end{pmatrix}\right]m_{\beta_1}m_{\beta_2}$$

$$\times\left[\delta\begin{pmatrix}\gamma_1 & \gamma_2\\ \beta_1 & \beta_2\end{pmatrix}+2\vartheta^*_2\begin{pmatrix}\gamma_1 & \gamma_2\\ \beta_1 & \beta_2\end{pmatrix}\right] \quad (43)$$

at each lattice. The summations go over all different couples of valence states $(\alpha_1\alpha_2)$, $(\beta_1\beta_2)$, and $(\gamma_1\gamma_2)$. The function $\delta=1$ if the couples $(\alpha_1\alpha_2)$ and $(\beta_1\beta_2)$ are equal, otherwise $\delta=0$.

The function (41) is positive definite for $x=y$ and $\xi=\eta$. For given values of the densities m_β the ϑ_2 can be chosen such as to make $\bar{\rho}_2$ vanish. Such a requirement is reasonable if the one-center Coulomb and exchange integrals are much larger than the nearest neighbor overlaps divided by the atomic distance. This is just the assumption of narrow bands, and it leads immediately to a formula for ϑ_2, namely

$$2\vartheta_2\begin{pmatrix}\alpha_1 & \alpha_2\\ \gamma_1 & \gamma_2\end{pmatrix}=-\delta\begin{pmatrix}\alpha_1 & \alpha_2\\ \gamma_1 & \gamma_2\end{pmatrix}. \quad (44)$$

With this value for ϑ_2 one can compute the corrections to ρ_1 up to the second order in the densities m_β according to the preceding section. The redistribution of electrons in reciprocal space because of the strong correlation (44) is different according to the distribution of electrons in Ψ_0. Therefore, (44) already leads to a difference between ferromagnetic and nonferromagnetic arrangement of electrons in Ψ.

The advantage which correlation (44) gives to the ferromagnetic state, arises from having to overcome less accidental crowding of holes on the same site in Ψ_0. Correlation (44) forces fewer holes to be scattered outside of the Fermi surface if the holes all have the same spin direction. Correlation (44), however, prevents the electrons from taking advantage of the energy gain they experience when two of them crowd into the same lattice site with their spins parallel.

Quite generally some energy gain can be expected if the ϑ_2 as given in (44) is reduced by some small quantity ϵ,

$$2\vartheta_2\begin{pmatrix}\alpha_1 & \alpha_2\\ \gamma_1 & \gamma_2\end{pmatrix}=-\delta\begin{pmatrix}\alpha_1 & \alpha_2\\ \gamma_1 & \gamma_2\end{pmatrix}+\epsilon\begin{pmatrix}\alpha_1 & \alpha_2\\ \gamma_1 & \gamma_2\end{pmatrix}, \quad (45)$$

since the correlation energy connected with (43) increases with ϵ^2, whereas the single-particle energy due to the redistribution of electrons in reciprocal space decreases with ϵ. The coefficient of the former increase is of the order of the one-center Coulomb integral C, whereas the coefficient in the latter decrease is of the order of the valence bandwidth $\bar{E}$. Stabilization occurs at $\epsilon=\bar{E}/C$; the energy gain per lattice site is $\bar{E}^2/C$ times the density of holes squared.

The constant C to be inserted again depends on the spin arrangement in Ψ. The expression (44) has to be integrated over $x=y$ and $\xi=\eta$ with the kernel $e^2/|x-\xi|$. The resulting integral over the products of the 2 by 2 determinants is just equal to the Coulomb integral minus the exchange integral in the important case $(\alpha_1\alpha_2)=(\gamma_1\gamma_2)$. The exchange integral differs from zero only when α_1 and α_2 have the same spin, so that C is smaller in the ferromagnetic case, i.e., the energy gain from relaxing the correlation (42) is greater.

Among the off-diagonal elements $(\alpha_1\alpha_2)\neq(\gamma_1\gamma_2)$ some lead to exchange integrals (spin-flip transition). In the nonferromagnetic case, these off-diagonal elements may be expected to enforce Hund's rule locally to some extent.

11. TWOFOLD DEGENERATE VALENCE BAND

As the simplest possible application of the formulas (42) and (43), the case of a twofold degenerate band will be treated. This corresponds to the conditions in the Ni-Cu alloys, where the d states are in a cubic environment and there are some holes in the Bloch states made up of the x^2-y^2 and $2z^2-x^2-y^2$ states.

With the single particle Hamiltonian H_0 for the kinetic energy and the crystal potential one has $H_0\psi_{\kappa k}(x)=E_{\kappa k}\psi_{\kappa k}(x)$. In computing the expectation value of H_0 for the correlated wave function Ψ a quantity similar to the left-hand side of (39) arises. By the same group theoretical arguments as in Appendix C, it can be shown for valence states α and γ that

$$\frac{1}{L}\sum_{(k\kappa)}u^*_{\gamma\kappa}(k)E_{\kappa k}u_{\alpha\kappa}(k)=m_\alpha E_\alpha\delta_{\alpha\gamma}, \quad (46)$$

which defines the energy E_α, the average energy of the valence holes in the state α. The expectation value of H_0 becomes with the help of (42) for the correlated wave

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

function, omitting the contribution of the conduction-like states as being unaffected by the correlation,

$$\sum_{\alpha}(\bar{E}_\alpha - m_\alpha E_\alpha) + 4\sum_{\alpha\beta(\beta'\beta'')}\vartheta_2\begin{pmatrix}\alpha & \beta\\ \beta' & \beta''\end{pmatrix} \times[m_\alpha m_\beta E_\alpha - m_{\beta'}m_{\beta''}\bar{E}_\alpha]\vartheta_2^*\begin{pmatrix}\alpha & \beta\\ \beta' & \beta''\end{pmatrix}, \quad (47)$$

where $\bar{E}_\alpha$ is the average energy of all the states in the band α. $\bar{E}_\alpha$ arises formally if in (46) the index κk is summed over all values, and the factor m_α on the right hand side is dropped. The Hermitian character of ϑ_2, i.e.,

$$\vartheta_2^*(\beta'\beta'',\alpha\beta) = \vartheta_2(\alpha\beta,\beta'\beta''), \quad (48)$$

has been assumed in writing (47). The correlation term in (47) is positive, because $E_\alpha > \bar{E}_\alpha$, i.e., the holes in Ψ_0 have chosen to occupy the highest states available.

In treating the twofold degenerate band, the total density of valence holes is denoted by m, the two orbits by a and b, the spin directions by attaching an arrow to the orbital label. In the ferromagnetic case each band is occupied by $m/2$ holes per lattice site, which gives an average energy E_f according to (46). In the nonferromagnetic case the corresponding quantities are $m/4$ and E_n. In computing the Coulomb-interaction terms according to (43) we shall assume that only the ordinary Coulomb repulsion and exchange integrals are different from zero. Therefore, only the terms containing

$$\begin{aligned} A &= e^2\int\int\frac{dxdy}{|x-y|}|\varphi_a(x)|^2|\varphi_a(y)|^2,\\ B &= e^2\int\int\frac{dxdy}{|x-y|}|\varphi_b(x)|^2|\varphi_b(y)|^2,\\ C &= e^2\int\int\frac{dxdy}{|x-y|}|\varphi_a(x)|^2|\varphi_b(y)|^2,\\ J &= e^2\int\int\frac{dxdy}{|x-y|}\varphi_a(x)\varphi^*{}_b(x)\cdot\varphi_b(y)\varphi^*{}_a(y), \end{aligned} \quad (49)$$

are taken into account for the evaluation of (43). Correspondingly, among the ϑ_2 only those will be assumed to be different from zero which immediately relate to the above integrals. Therefore, the following abbreviations are introduced for the nonferromagnetic case

$$\begin{aligned} 2\vartheta_2\begin{pmatrix}a\uparrow & a\downarrow\\ a\uparrow & a\downarrow\end{pmatrix} &= 1-\epsilon_A,\\ 2\vartheta_2\begin{pmatrix}b\uparrow & b\downarrow\\ b\uparrow & b\downarrow\end{pmatrix} &= 1-\epsilon_B,\\ 2\vartheta_2\begin{pmatrix}a\uparrow & b\downarrow\\ a\uparrow & b\downarrow\end{pmatrix} &= 2\vartheta_2\begin{pmatrix}a\downarrow & b\uparrow\\ a\downarrow & b\uparrow\end{pmatrix} = 1-\epsilon_C,\\ 2\vartheta_2\begin{pmatrix}a\uparrow & b\uparrow\\ a\uparrow & b\uparrow\end{pmatrix} &= 2\vartheta_2\begin{pmatrix}a\downarrow & b\downarrow\\ a\downarrow & b\downarrow\end{pmatrix} = 1-\epsilon_D,\\ 2\vartheta_2\begin{pmatrix}a\uparrow & b\downarrow\\ a\downarrow & b\uparrow\end{pmatrix} &= 2\vartheta_2\begin{pmatrix}a\downarrow & b\uparrow\\ a\uparrow & b\downarrow\end{pmatrix} = \epsilon_J. \end{aligned} \quad (50)$$

In the ferromagnetic case only

$$2\vartheta_2\begin{pmatrix}a\uparrow & b\uparrow\\ a\uparrow & b\uparrow\end{pmatrix} = 1-\epsilon \text{ occurs.}$$

In this terminology the expectation value for the energy per lattice site is given in the ferromagnetic case by

$$4\bar{E} - mE_f + (m^2/2)(1-\epsilon)^2(E_f-\bar{E}) + (m^2/4)\epsilon^2(C-J), \quad (51)$$

and in the nonferromagnetic case by

$$\begin{aligned} 4\bar{E} - mE_n &+ (m^2/8)(E_n-\bar{E})\{(1-\epsilon_A)^2+(1-\epsilon_B)^2\\ &+2(1-\epsilon_C)^2+2(1-\epsilon_D)^2+2\epsilon_J^2\}\\ &+(m^2/16)\{A\epsilon_A^2+B\epsilon_B^2+2(C-J)\epsilon_D^2\\ &+2C(\epsilon_C^2+\epsilon_J^2)-4J\epsilon_C\epsilon_J\}. \end{aligned} \quad (52)$$

The remaining terms in the Coulomb repulsion are the same in the ferromagnetic and in the nonferromagnetic situations.

The minima are reached for

$$\epsilon = \frac{2(E_f-\bar{E})}{C-J+2(E_f-\bar{E})}, \quad (53)$$

with the energy (51) becoming

$$4\bar{E} - mE_f + \frac{m^2}{4}\frac{2(E_f-\bar{E})(C-J)}{C-J+2(E_f-\bar{E})}. \quad (54)$$

Since E_f is very near the top of the band structure if m is small, the quantity $2(E_f-\bar{E})$ can be interpreted as the width of the band. For the nonferromagnetic case one finds

$$\begin{aligned} \epsilon_A &= \frac{2(E_n-\bar{E})}{A+2(E_n-\bar{E})},\\ \epsilon_B &= \frac{2(E_n-\bar{E})}{B+2(E_n-\bar{E})},\\ \epsilon_C &= \frac{2(E_n-\bar{E})(C+2E_n-2\bar{E})}{(C+2E_n-2\bar{E})^2-J^2},\\ \epsilon_D &= \frac{2(E_n-\bar{E})}{C-J+2(E_n-\bar{E})},\\ \epsilon_J &= \frac{2(E_n-\bar{E})J}{(C+2E_n-\bar{E})^2-J^2} \end{aligned} \quad (55)$$

with the energy (52) equal to

$$\begin{aligned} 4\bar{E} - mE_n + \frac{m^2}{16}\Big\{&\frac{2(E_n-\bar{E})A}{A+2(E_n-\bar{E})}\\ &+\frac{2(E_n-\bar{E})B}{B+2(E_n-\bar{E})}+2\frac{2(E_n-\bar{E})(C-J)}{C-J+2(E_n-\bar{E})}\\ &+2\frac{C(C+2E_n-2\bar{E})-J^2}{(C+2E_n-2\bar{E})^2-J^2}2(E_n-\bar{E})\Big\}. \end{aligned} \quad (56)$$

The quantities ϵ are related by the equation $\epsilon_D-\epsilon_C=\epsilon_J$. By virtue of this relation the sum of all ϑ_2 operators commutes with every component of the total spin of the atom. A group of atomic states, e.g., the triplets made with the orbitals a and b which differ only in the direction of the total spin, occur with the same weight in Ψ, provided they had the same weight in Ψ_0. The expectation value for any component of the total spin vanishes at each lattice site, in Ψ as well as in Ψ_0. But the expectation value for the square of the total spin at any given lattice site may have changed.

The occurrence of ϵ_J can be viewed in the following way. $\bar{\rho}_2$ as given by (43) becomes diagonal in the two-particles wave functions $(a\uparrow a\downarrow)$, $(b\uparrow b\downarrow)$, $(a\uparrow b\uparrow)$, $(a\downarrow b\downarrow)$, $(a\uparrow b\downarrow)+(a\downarrow b\uparrow)$, $(a\uparrow b\downarrow)-(a\downarrow b\uparrow)$. The coefficients of the last two are $m^2(1-\epsilon_C+\epsilon_J)^2/16$ and $m^2(1-\epsilon_C-\epsilon_J)^2/16$. The correlated wave function Ψ prefers therefore the triplet over the singlet, even if there is no ferromagnetism present. Ψ is an example of how Hund's rule can be enforced even in unfilled bands.

In comparing (54) and (56) one notices that the last term in (54) is still smaller than the last two terms in (56) provided $(E_n-\bar{E})<(E_f-\bar{E})(1+J/C)$. This condition should be satisfied since one expects the d band to have a reasonable energy density at its top, so that $E_n-E_f\ll E_f-\bar{E}$ for small density of holes. If one assumes for simplicity's sake that the last term in (54) is equal to the last two terms in (56), and also that $A=B$, then the question is whether or not $m(E_n-E_f)$ is smaller than $m^2(E_n-\bar{E})A/4(A+2E_n-2\bar{E})$. If so, the ferromagnetic correlated state Ψ_f has a lower expectation value for the total energy than the nonferromagnetic Ψ_n.

If the band is parabolic at its top, $E_n-E_f\sim m^{2/3}$, and ferromagnetism is not possible in the present theory. If the density of states as a function of energy reaches a nonvanishing value ν_0 at the top of the band, $m(E_n-E_f)$, is quadratic in m, and ferromagnetism occurs, provided

$$2\nu_0(E_n-\bar{E})>[1+2(E_n-\bar{E})/A]. \tag{57}$$

The density ν_0 is meant to refer to only one of the four bands, arising from the spin and the orbital degeneracy.

One may consider $2(E_n-\bar{E})$ as the width of the d band; $2\nu_0(E_n-\bar{E})$ is then the density of states at the top measured against the density of states resulting from a uniform distribution of the states throughout the band. The inequality (57) requires ν_0 to be larger than the average of ν throughout the band by a factor $2[1+2(E_n-\bar{E})/A]$. In particular, this condition is satisfied if there is a peak in the density of states at its top, such as one may find in the fcc cubic structure.

It may be interesting to note the following: In a nondegenerate band with the Coulomb repulsion integral between localized states given by A, the condition for ferromagnetism is again (57). However, the ferromagnetic state in the nondegenerate band does not have the additional advantage which is due to the last term in (54) being smaller than the last two terms in (56). This advantage of the degenerate band over the nondegenerate band vanishes only in the case of very strong Coulomb repulsion between the two degenerate orbits. Therefore, the results of this section bring out the importance of degeneracy for achieving ferromagnetism.

ACKNOWLEDGMENTS

The author wishes to express his indebtedness to Professor R. Brout, Dr. S. Nettel, and Dr. H. Thomas for many very helpful discussions and suggestions.

APPENDIX A

Equation (29) has to be solved in the special case where $O^{(\nu)}$ differs from zero only if the set of band indices $(\gamma_1\cdots\gamma_\nu)$ coincides with the set $(\alpha_1\cdots\alpha_\nu)$, the factor associated with $O^{(\nu)}$ being independent of the set $(\gamma_1\cdots\gamma_\nu)=(\alpha_1\cdots\alpha_\nu)$. The ϑ_μ will be assumed to have these same properties. It is then not necessary to write down two sets of indices for every operator $O^{(\nu)}$ or ϑ_μ, and even the common set of band indices no longer has to be mentioned since the factors associated with $O^{(\nu)}$ depend only on the number ν for $O^{(\nu)}$ or μ for ϑ_μ. We shall, therefore, only discuss these factors. Since the indices $(\gamma_1\cdots\gamma_\mu)$ in ϑ_μ can still be permuted with respect to the indices $(\alpha_1\cdots\alpha_\mu)$ which are always supposed to be in some standard order; the quantity $\mu!$ ϑ_μ will always occur in the forthcoming argument.

The formulas (28) and (29) have now to be matched. We take a set of m indices $\beta_1,\cdots,\beta_m$ and collect the coefficients of $a^\dagger_{\beta_m}\cdots a^\dagger_{\beta_1}b_{\beta_1}\cdots b_{\beta_m}$ in (29) and in the sum over ν of (28), where we have to insert the definition (19) of the projection operator P_β. In this manner we find that

$$\frac{1}{\omega}\sum_{\substack{\mu_1+2\mu_2+\cdots=m,\\ \mu_1\geq 0,\mu_2\geq 0,\cdots}}\frac{m!}{\mu_1!\mu_2!\cdots}\vartheta_1^{\mu_1}\vartheta_2^{\mu_2}\cdots = \sum_{\nu=0}^{m}(-1)^{m-\nu}\binom{m}{\nu}O^{(\nu)}. \tag{A1}$$

In order to solve this system of equations we multiply each side with $z^m/m!$ where z is an arbitrary real number, and add over all values of m. This gives

$$\frac{1}{\omega}\exp(\vartheta_1 z+\vartheta_2 z^2+\cdots)=e^{-z}\sum_{\nu=0}^{\infty}\frac{z^\nu}{\nu!}O^{(\nu)}, \tag{A2}$$

after some elementary algebra. The terms with $m=0$ were put equal to one; ω can be fixed by the condition $O^{(0)}=1/\omega$.

The case $O^{(0)}=0$ presents difficulties in this formulation. Although they could have been avoided, it seems important to bring out quite clearly that equation (29) is useless as $O^{(0)}$ tends to zero. $O^{(0)}=0$ means that any

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

configuration with at least one lattice site completely empty is excluded in the correlated wave function. A requirement like $O^{(0)}=0$ is absolutely reasonable when there are at least as many particles as lattice sites. The present theory can, therefore, be expected to break down if it is physically necessary to discriminate against configurations with completely empty lattice sites. However, as long as such a condition does not have to be imposed, we can set $\omega=1$, since only the relative weights between the $O^{(\nu)}$ and between the ϑ_μ are physically significant.

The case of greatest interest is

$$O^{(0)}=O^{(1)}=1, \quad O^{(2)}=\epsilon, \tag{A3}$$

from which we obtain

$$\vartheta_1 z+\vartheta_2 z^2+\cdots=\ln\left(1+z+\epsilon\frac{z^2}{2}\right)-z$$

$$=\sum_{n=1}^{\infty}(-1)^{n-1}z^n\sum_{\nu=0}^{\nu=n-1}\frac{1}{n-\nu}\binom{n-\nu}{\nu}\left(\frac{\epsilon}{2}\right)^{\nu}-z. \tag{A4}$$

This gives for $\vartheta_1, \vartheta_2, \cdots$ the values

$$\vartheta_1=0, \qquad \vartheta_2=-\tfrac{1}{2}(1-\epsilon),$$
$$\vartheta_3=\tfrac{1}{3}-(\epsilon/2), \quad \vartheta_4=-\tfrac{1}{4}(1-6\epsilon+\epsilon^2), \quad \text{etc.} \tag{A5}$$

The chain of equations can be broken off at any point.

If ω is left explicitly in the relation between ϑ_μ and $O^{(\nu)}$ the conditions

$$O^{(0)}=\frac{1}{\omega}, \quad O^{(1)}=1, \quad O^{(2)}=\epsilon, \tag{A6}$$

lead to the equations

$$\ln\left(1+\omega z+\epsilon\omega\frac{z^2}{2}\right)-z=\vartheta_1 z+\vartheta_2 z^2+\cdots \tag{A7}$$

$$\vartheta_1=\omega-1, \qquad \vartheta_2=-\frac{\omega}{2}(\omega-\epsilon),$$

$$\vartheta_3=\omega^2\left(\frac{\omega}{3}-\frac{\epsilon}{2}\right), \quad \vartheta_4=-\frac{\omega^2}{4}(\omega^2-6\omega\epsilon+\epsilon^2), \quad \text{etc.} \tag{A8}$$

The case $\epsilon=1$, $\omega\to\infty$ is physically sound, but mathematically useless in terms of ϑ_1, ϑ_2, etc.

APPENDIX B

The two diagrams of Fig. 3 which contribute to (37) can be interpreted as follows. The first diagram gives ρ_1 for the wave function where all Bloch states κk are filled. The second diagram subtracts from the first the contribution

$$\sum_{(\kappa k)}\psi_{\kappa k}(x)\psi^*_{\kappa k}(y) \tag{B1}$$

which comes from the empty Bloch states of Ψ_0.

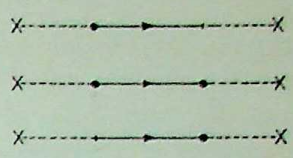

FIG. 9. Simple ρ_1 diagrams containing ϑ_1.

If we combine this last contribution to ρ_1 with the three contributions of Fig. 9, we can write the result as

$$\sum_{(\kappa k)}\bar{\psi}_{\kappa k}(x)\bar{\psi}^*_{\kappa k}(y), \tag{B2}$$

with the new Bloch state

$$\psi_{\lambda k}(x)=\psi_{\kappa k}(x)+\sum_{\alpha\beta\gamma\lambda}\psi_{\lambda k}(x)u_{\alpha\lambda}(k)S_{\alpha\beta k}\vartheta_1(\beta\gamma)u_{\gamma\kappa}(k). \tag{B3}$$

We have used the Fourier transform

$$S_{\alpha\beta k}=\sum_{g}S(\alpha 0,\beta g)e^{ikg}. \tag{B4}$$

The result of all the other diagrams with only ϑ_1 can be stated with the help of a matrix $T_{\kappa\lambda}(k)$ which has for every k as many rows and columns as there are holes with wave vector k in Ψ_0. We have

$$T_{\kappa\lambda}=\delta_{\kappa\lambda}+\sum_{\alpha\beta\gamma}\{u_{\alpha\kappa}S_{\alpha\beta}\vartheta_1(\beta\gamma)u^*_{\gamma\lambda}+u_{\alpha\kappa}\vartheta^*_1(\beta\alpha)S_{\beta\gamma}u^*_{\gamma\lambda}$$
$$+u_{\alpha\kappa}\vartheta^*_1(\beta'\alpha)S_{\beta'\beta''}\vartheta_1(\beta''\gamma)u^*_{\gamma\lambda}\}, \tag{B5}$$

where all the sums over band indices are taken at fixed wave vector k. Instead of subtracting (B1) or (B2) from the ρ_1 of a wave function with all Bloch states κk filled, one has now to subtract

$$\sum_{\kappa\lambda k}\bar{\psi}_{\kappa k}(x)T^{-1}_{\kappa\lambda}\bar{\psi}^*_{\lambda k}(y). \tag{B6}$$

The inverse of T which is inserted in (B6) as compared to (B2), simply normalizes the functions $\bar{\psi}_{\kappa k}(x)$. The term coming from the second diagram of Fig. 3 has, therefore, been replaced by a very similar term, namely one that arises from replacing the Bloch states $\psi_{\kappa k}(x)$ by the properly orthonormalized modification of $\bar{\psi}_{\kappa k}(x)$. Indeed, the states $\bar{\psi}_{\kappa k}(x)$ are not orthonormal, but one can find linear combinations which are orthonormal, say $\tilde{\psi}_{\kappa k}(x)$, and (B6) transforms then to

$$\sum_{(\kappa k)}\tilde{\psi}_{\kappa k}(x)\tilde{\psi}^*_{\kappa k}(y). \tag{B7}$$

Let us now examine an arbitrary diagram without any ϑ_1 in it. The particle lines connecting two vertices

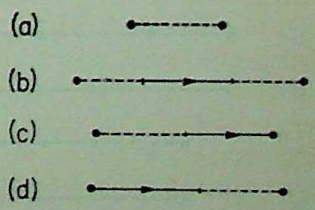

FIG. 10. The four possible particle lines between vertices if $\vartheta_1=0$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

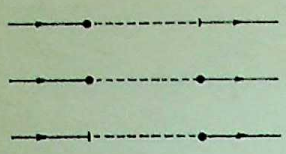

FIG. 11. The three possible insertions of ϑ_1 into a solid line.

or connecting a vertex to an external point are of the four different types shown in Fig. 10. (An external point is equivalent to a connection with a vertex.) The occurrences of ϑ_1 can arise in the following two ways.

First, the solid lines in Figs. 10(b), 10(c), and 10(d) are broken up an arbitrary number of times by inserting one of the three pieces shown in Fig. 11. The effect of these insertions is equivalent to the substitution

$$W(\alpha f,\gamma h)=\frac{1}{L}\sum_{(\kappa k)} U^*_{\alpha f,\kappa k}U_{\gamma h,\kappa k}\rightarrow \frac{1}{L}\sum_{(\kappa\lambda k)} U^*_{\alpha f,\kappa k}T^{-1}{}_{\kappa\lambda}U_{\gamma h,\lambda k}. \quad \text{(B8)}$$

Second, a ϑ_1 can be inserted at the ends of the solid lines in Figs. 10(b), 10(c), and 10(d) without breaking them. This gives the five diagrams listed in Fig. 12.

Combining Fig. 10(b) with Figs. 12(a), 12(b), and 12(c) is tantamount to substituting

$$W(G''G')\rightarrow \sum_{F''F'}[\delta_{F''G'}+\vartheta^*{}_1(F''G')]\times W(F''F')[\delta_{F'G'}+\vartheta_1(F'G')] \quad \text{(B9)}$$

in the diagram 10(b). The substitution (B9) in Fig. 10(c) or Fig. 10(d) can be justified only if the interpretation of the vertex to the right of Figs. 10(c), 10(d), 12(d), and 12(e) is changed by introducing a fictitious label G'' into Figs. 10(c) and 10(d), and G' into Figs. 12(d) and 12(e). This is done by the substitutions

$$\vartheta_2(H'_1H'_2,F'_1F'_2)\rightarrow \sum_{G'_1G'_2}\tilde{\vartheta}_2(H'_1H'_2,G'_1G'_2)\times[\delta_{G'_1F'_1}+\vartheta_1(G'_1F'_1)][\delta_{G'_2F'_2}+\vartheta_1(G'_2F'_2)],$$

$$\vartheta^*{}_2(H''_1H''_2,F''_1F''_2)\rightarrow \sum_{G''_1G''_2}[\delta_{F''_1G''_1}+\vartheta_1(F''_1G''_1)]\times[\delta_{F''_2G''_2}+\vartheta_1(F''_2G''_2)]\tilde{\vartheta}^*{}_2(H''_1H''_2,G''_1G''_2), \quad \text{(B10)}$$

and similar formulas for ϑ_3, etc. If the vertices in Figs. 10(c) and 10(d) are interpreted as $\tilde{\vartheta}_2$, $\tilde{\vartheta}_3$, etc., then the combined effect of Figs. 10(c) and 10(d) as well as 12(d) and 12(e) is again described by the substitution (B9). In all three diagrams 10(b), 10(c), and 10(d), the effect of ϑ_1 insertions is now described by the combined substitutions (B8) and (B9).

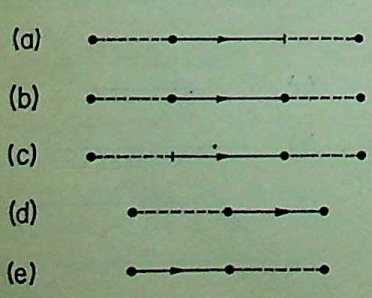

FIG. 12. The five possible ϑ_1 insertions without breaking a solid line.

Now, it follows immediately from (4) that

$$\sqrt{L}\int\psi^*{}_K(x)\psi_G(x)dx=U_{GK}, \quad \text{(B11)}$$

which shows with (32) that

$$W(F''F')=\int\psi^*{}_{F''}(x)dx\times\int\psi_{F'}(y)dy\sum_{(K)}\psi_K(x)\psi^*{}_K(y). \quad \text{(B12)}$$

K is used as abbreviation for the index pair κk. On the other hand, if we insert into this formula the sum over all K, rather than only the K of the holes, then we can write

$$\begin{aligned}\frac{1}{L}\sum_K U^*{}_{F''K}U_{F'K}&=\int\psi^*{}_{F''}(x)dx\int\psi_{F'}(y)dy\times\sum_{G'G''}\psi_{G'}(x)S(G'G'')\psi^*{}_{G''}(y)\\&=\sum_{G'G''}R(F''G')S(G'G'')R(G''G')\\&=R(F''F'). \quad \text{(B13)}\end{aligned}$$

If we take the Fourier transform as in (B4) and insert (40), it follows that

$$\sum_\kappa u^*{}_{\alpha\kappa}(k)u_{\gamma\kappa}(k)=R_{\alpha\gamma k}=\sum_g R(\alpha o,\gamma g)e^{ikg}. \quad \text{(B14)}$$

From this last relation, we find that

$$\sqrt{L}\int\bar{\psi}^*{}_K(x)\psi_G(x)dx=U_{GK}+\sum_F\vartheta_1(GF)U_{FK}. \quad \text{(B15)}$$

Therefore, the combination of (B8) and (B9), i.e., the elimination of all ϑ_1 from the diagrams, is effected by substituting

$$W(F''F')\rightarrow\int\psi^*{}_{F''}(x)dx\int\psi_{F'}(y)dy\times\sum_{(\kappa\lambda k)}\bar{\psi}_{\kappa k}(x)T^{-1}{}_{\kappa\lambda}\bar{\psi}^*{}_{\lambda k}(y) \quad \text{(B16)}$$

and replacing all $\vartheta_2, \vartheta_3, \cdots$ by $\tilde{\vartheta}_2, \tilde{\vartheta}_3, \cdots$.

APPENDIX C

The Bloch waves $\psi_{\kappa k}(x)$ are assumed to arise from some secular problem as a linear combination of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

functions $\psi_{\beta g}(x)$. Under a coordinate transformation $x=Tx'+t$ compatible with the lattice, one has

$$\psi_{\kappa k}(x)=e^{ikt}\psi_{\kappa k'}(x') \quad \text{with} \quad k=Tk'. \tag{C1}$$

Also one has for the localized orbits

$$\psi_{\beta g}(x)=\sum_{\alpha} T_{\beta\alpha}\psi_{\alpha f} \quad \text{with} \quad g=Tf+t, \tag{C2}$$

where the matrix $T_{\beta\alpha}$ gives the transformation of the orbits corresponding to the coordinate transformation T.

In view of the orthonormality of the functions $\psi_{\kappa k}(x)$ one finds for the coefficients U_{GK} of (4) the formula

$$\frac{1}{\sqrt{L}}U_{GK}=\int \psi^*{}_K(x)\psi_G(x)dx. \tag{C3}$$

If one inserts (C1) and (C2) it follows that

$$U_{GK}=e^{-ikt}\sum_{\alpha} T_{\beta\alpha}U_{FK'}, \tag{C4}$$

with $F=(\alpha f)$, $G=(\beta g)$, $K=(\kappa k)$, $K'=(\kappa k')$. Any expression depending on $U_{GK}, \psi_K, \psi_G, K, G$, etc., can be written in terms of $U_{FK'}, \psi_{K'}, \psi_F, K', F$, etc., with the help of (C1), (C2) and (C4). In the new expression in which only the latter quantities and the coefficients $T_{\beta\alpha}$ occur, it is possible to replace again $F\to G$, $K'\to K$, etc. If the resulting expression coincides with the original one, it is called invariant with respect to the transformation T.

Now one has for W as defined in (32) the transformation

$$W(G''G')=\sum_{\alpha'\alpha''} T^*{}_{\beta''\alpha''}T_{\beta'\alpha'}W(F)'F'' \tag{C5}$$

according to (C4). In order to obtain (39) we now put $t=0$, $g''=g'=f''=f'$. The arguments in W are then simply $\beta''\beta'$ and $\alpha''\alpha'$.

The formula (C5) is now averaged over all symmetry operations of the lattice which leave the lattice site $g=f$ fixed. This gives

$$W(\beta''\beta')=\sum_{\alpha'\alpha''}\left(\frac{1}{l}\sum_{T} T^*{}_{\beta''\alpha''}T_{\beta'\alpha'}\right)W(\alpha''\alpha'). \tag{C6}$$

If the orbits have been grouped according to the irreducible representation to which they belong, it is possible to apply one of the important results of group representation theory.[7]

$$\frac{1}{l}\sum_{T} D^{(j'')}{}_{\beta''\alpha''}(T)D^{(j')}{}_{\beta'\alpha'}(T)=\frac{1}{j}\delta_{j'j''}\delta_{\beta'\beta''}\delta_{\alpha'\alpha''}, \tag{C7}$$

where $D^{(j)}{}_{\beta\alpha}(T)$ is the matrix representing T in the representation j, the indices α', β', α'', β'' being restricted to the values relevant to j' and j''. j is the dimension of the representation j. l is the number of operations in the group. If (C7) is inserted into (C6) the formula (39) and the explanation preceding it follow immediately.

Mechanism of the Ferrimagnetic to Antiferromagnetic Transition in $Mn_{2-x}Cr_xSb$

H. S. JARRETT

E. I. du Pont de Nemours and Company, Central Research Department, Wilmington, Delaware*

(Received 16 December 1963)

The mechanism of the first-order ferrimagnetic to antiferromagnetic transition (exchange inversion) in $Mn_{2-x}Cr_xSb$, $x<0.41$, was investigated by exchange magnetostriction. A second-order term has been included in the strain energy which gives an effective elastic constant dependent on magnetization and magnetic ordering. It also introduces a discontinuous change in the magnetization at the transition and hence a contribution to the entropy change in addition to that caused by the change of lattice dimension. For $Mn_{2-x}Cr_xSb$, the effect of this term is small but necessary to obtain the qualitative behavior of the discontinuous change in lattice dimension and the shift in the Curie temperature with composition. The anisotropy behavior of $Mn_{2-x}Cr_xSb$ was investigated for various values of x, and it is shown that an anisotropy in the critical lattice dimension of only 4×10^{-4} Å accounts for the observed change in magnetic anisotropy with exchange inversion that occurs for transition temperatures between 200 and 350°K. For transition temperatures above 350°K, anisotropy is positive, and spin-flopping measurements can be made on the antiferromagnetic state. An expression for the critical field in the presence of exchange inversion is obtained and compared with experiment.

INTRODUCTION

THE basic features of exchange inversion have been investigated theoretically by Kittel.[1] In this paper Kittel's theory is extended to include Curie-point shifts, magnetization, entropy, and magnetic anisotropy and is applied to Cr-modified Mn_2Sb. Kittel proposes that a transformation from ferromagnetic (F) to antiferromagnetic (AF) spin ordering will take place by a first-order process when there is, during normal thermal contraction, a critical lattice dimension c_c at which the sign of the exchange interaction changes from F to AF. Accompanying the first-order transition is a discontinuous change in dimension of the crystalline unit cell. The magnitude of the discontinuous change, as Kittel has pointed out, is equal to the difference between the magnetoelastic expansion of the ferromagnetically ordered lattice and the contraction of the antiferromagnetically ordered lattice. Experimental data that have been obtained support qualitatively the essential features of this theory.

The ternary composition $Mn_{2-x}Cr_xSb$ is an ideal magnetic material on which to check semiquantitatively the features of an exchange-inversion theory. Mn_2Sb forms sets of 3-layer sheets[2] of strongly coupled spins ($J/k\sim450$°K); the spins between sets are only weakly coupled by exchange forces ($J/k\sim80$°K at the Curie temperature). The net saturation moment of this 3-layer set is approximately 0.9 Bohr magneton.[3] We shall assume that detailed knowledge of the interatomic exchange forces is not needed and that this 3-layer set may be replaced with a single plane of spins strongly coupled ferromagnetically. Effects of magnetoelastic energy within this plane will also be neglected.

Thus, the model representing Mn_2Sb is a stack of weakly coupled ferromagnetic planes, the interplanar exchange changing sign at some accessible lattice dimension. A main function of the Cr modifier is to provide an initial lattice contraction so that, depending on the amount present, the critical lattice dimension for exchange inversion occurs at some temperature below the Curie temperature.

FREE ENERGY

In order to account for the exchange energy dependence on lattice dimension, the exchange energy is expanded in a Taylor series to quadratic terms about the critical lattice dimension c_c at which the exchange energy vanishes:

$$J(c)=\rho(c-c_c)+(\rho'/2)(c-c_c)^2. \quad (1)$$

Here ρ and ρ' are the first and second derivatives of the exchange interaction evaluated at c_c. This expansion for the exchange energy is identical to that used by Kittel except that he considered only the linear dependence of J on lattice parameter.

When the elastic energy $\frac{1}{2}R(c-c_T)^2$ is included, the interplanar free energy per unit volume becomes

$$F/V=\tfrac{1}{2}R(c-c_T)^2 -[\rho(c-c_c)+(\rho'/2)(c-c_c)^2]m_1m_2\cos\phi. \quad (2)$$

Here, R represents the elastic constant divided by the square of the average lattice dimension, and c_T is the lattice dimension in the absence of magnetic forces. The parameter m_i is the reduced sublattice magnetization obtained by normalizing the magnetization to the saturation value M_0 at absolute zero.

The equilibrium value of c is given by $\partial F/\partial c=0$, which yields

$$c=c_T+\left[1-\frac{\rho' m_1m_2}{R}\cos\phi\right]^{-1} \times\left[\frac{\rho m_1m_2}{R}\cos\phi+(c_T-c_c)\frac{\rho' m_1m_2}{R}\cos\phi\right] \quad (3)$$

and, upon substitution into the free energy, Eq. (2), we obtain

$$\frac{F}{VR}=\left\{-\frac{1}{2}\left(\frac{\rho m_1 m_2}{R}\right)^2\cos^2\phi-\frac{\rho}{R}m_1m_2(c_T-c_c)\right.$$
$$\left.\times\left[1+\frac{\rho'}{2\rho}(c_T-c_c)\right]\cos\phi\right\}\left[1-\frac{\rho' m_1 m_2}{R}\cos\phi\right]^{-1}. \quad (4)$$

Both the elastic energy and the second term in the exchange energy appear quadratically. A quadratic term in the exchange produces an effective elastic constant that is dependent on the spin orientation.

The condition for a transition to occur between F and AF spin configurations is no longer $c_T=c_c$ of the Kittel theory but is readily obtained by equating the free energy for F ordering to the free energy for AF ordering to give

$$c_T-c_c=\frac{\rho}{\rho'}\left\{-1+\left[1-\left(\frac{\rho' m_1 m_2}{R}\right)^2\right]^{1/2}\right\}. \quad (5)$$

This expression reduces to the Kittel condition when $\rho'=0$, and approaches the Kittel condition as the exchange-inversion temperature approaches the Curie point, where the sublattice magnetization is small. We now obtain from Eq. (3) the difference in interplanar spacing Δc between the F and AF states,

$$\Delta c=c^{\mathrm{F}}-c^{\mathrm{AF}}=\frac{2\rho m_1 m_2}{R[1-(\rho' m_1 m_2/R)^2]}\left[1+\frac{\rho'}{\rho}(c_T-c_c)\right]. \quad (6)$$

Substitution of Eq. (5) for the transition condition gives the discontinuous change in lattice dimension at the transition

$$\Delta c_s=\frac{2\rho m_1 m_2}{R}\left[1-\left(\frac{\rho' m_1 m_2}{R}\right)^2\right]^{-1/2}, \quad (7)$$

which is similar to the Kittel theory but is modified by the quadratic exchange term.

So far, this development has paralleled that of Kittel, but the results given demonstrate how the quadratic exchange term alters related conditions of the linear exchange theory. These expressions will also be necessary when attempting a fit to the experimental data using ρ/R and ρ'/R as adjustable parameters.

The free-energy expression, Eq. (4), is not complete, since the intraplanar exchange energy Jm^2 and magnetic ordering entropy S have not been taken into account. Therefore, the following terms must be added to Eq. (4):

$$-(J_1/2)m_1^2-(J_2/2)m_2^2-kTS_1-kTS_2, \quad (8)$$

where the classical entropy for N spins[4] with reduced moment m is given by

$$\sigma=-\frac{N}{2}\left[\left(\frac{1+m}{2}\right)\ln\left(\frac{1+m}{2}\right)+\left(\frac{1-m}{2}\right)\ln\left(\frac{1-m}{2}\right)\right]$$

for each sublattice.

ENTROPY CHANGE

Addition of the terms (7) to Eq. (4) gives the total free-energy expression of the system including, in a rather disguised form, the lattice entropy. This fact may be demonstrated by differentiating the free energy with respect to temperature and taking the difference between the total entropy for F ordering and AF ordering. At the transition, given by the condition of Eq. (5), we obtain

$$\Delta S=-R\Delta c\left[\frac{\rho'}{R}\frac{1}{m}\frac{\partial m}{\partial T}\frac{\Delta c}{2}+\frac{\partial c_T}{\partial T}\right]. \quad (9)$$

Thus, the change in entropy of the lattice at the transition is included in the dimension c_T. The first term in the bracket of Eq. (9) is of interest as it represents the magnetic contribution of the effective elastic energy to the change in entropy. Magnetization terms do not enter otherwise in Eq. (9) because the sublattice magnetization is assumed to be unchanged at the transition.[5] The magnitude of the first term of Eq. (9) at room temperature is of the order

$$\frac{1}{2}\frac{\rho'}{R}\frac{1}{m}\frac{\partial m}{\partial T}\frac{\Delta c}{c}\approx\frac{0.3}{2}(0.0015)\left(\frac{0.03}{6.5}\right)\approx 10^{-6}/^{\circ}\mathrm{K}$$

for Mn_2Sb, while

$$\frac{1}{c}\frac{\partial c_T}{\partial T}\approx 20\times 10^{-6}/^{\circ}\mathrm{K},$$

and hence the first term is negligible. Therefore, the change in entropy at the F/AF phase transition arises largely from the lattice distortion and becomes

$$\Delta S\simeq -C\left(\frac{\Delta c}{c}\right)\left(\frac{1}{c}\frac{\partial c_T}{\partial T}\right), \quad (10)$$

where C is the appropriate elastic constant in the direction of the strain $\Delta c/c$.

MAGNETIZATION

Minimization of the free energy, Eq. (4) plus (8), with respect to the sublattice magnetization and rearrangement of terms gives

$$m=\tanh\left\{\frac{mM_0}{kT}H_w\right\}, \quad (11)$$

[4] J. S. Smart, Phys. Rev. 90, 55 (1953).

[5] A. E. Austin, E. Adelson, and W. H. Cloud, Phys. Rev. 131, 1511 (1963).

where

$$H_w=\frac{2R}{NM_0}\left(\frac{J}{R}+\left\{\left(\frac{\rho m}{R}\right)^2\left(1-\frac{\rho' m^2}{2R}\cos\phi\right)+(c_T-c_c)\left[\rho+\frac{\rho'}{2}(c_T-c_c)\right]\cos\phi\right\}\times\left[1-\frac{\rho' m^2}{R}\cos\phi\right]^{-2}\right). \quad (12)$$

It has been assumed in Eq. (12) that the two sublattices are equivalent and that $J_1=J_2$. The magnetization given by Eq. (11) is actually the Brillouin function for spin $\frac{1}{2}$. This form arises because the entropy expression assumes only two spin orientations. The first term of Eq. (12) represents the Weiss field due to intraplanar exchange, while the second term is due to interplanar exchange and, it is important to note, is dependent on the spin configuration through the $\cos\phi$ term. If the ρ' term were not included, the $\cos\phi$ dependence disappears, and there is no difference in the Weiss fields for F and AF ordering at the transition.

Thus, the magnetization is discontinuous at the transition because of the second-order ρ' term. However, even for fairly large values of $\rho'/R\sim\frac{1}{2}$, the discontinuous change of sublattice magnetization is of the order of a few percent and would be difficult to detect by neutron diffraction, for example. A large change in sublattice magnetization would alter all previously derived expressions, but for practical purposes we may ignore the small change in magnetization as long as $\rho'/R<\frac{1}{2}$. This restriction is no stronger than the initial assumption that the exchange energy dependence on lattice dimension can be represented by Eq. (1).

CURIE TEMPERATURE

Also contained in Eq. (11) is the unusual effect of a temperature-dependent Weiss field. In most molecular field treatments it is assumed that exchange interactions are constant over the entire temperature range below the Curie temperature. In exchange inversion, however, the exchange interaction is dependent on temperature through lattice contraction. Such effects should, therefore, influence the Curie temperature.

The Curie temperature for the magnetization expressed by Eq. (11) is

$$T_c=\frac{R}{Nk}\left\{(c_{T_c}-c_c)\left[\frac{\rho}{R}+\frac{\rho'}{2R}(c_{T_c}-c_c)\right]\cos\phi\right\}+\frac{J}{Nk}, \quad (13)$$

where $(c_{T_c}-c_c)$ indicates that (c_T-c_c) is to be evaluated at T_c. We thus have a self-consistent equation in which T_c is contained explicitly on the left-hand side and implicitly on the right-hand side of Eq. (13). The second term J/Nk in Eq. (13) represents the Curie temperature of the ferrimagnetically ordered 3-layer set of planes, while the first term is the interplanar Curie temperature. The Curie temperature is dependent on $\cos\phi$. For positive ρ the Curie temperature for F ordering is higher than the Curie temperature for AF ordering by twice the interplanar exchange energy. Thus, as temperature is decreased, ferromagnetic ordering first occurs and is the most stable configuration.

APPLICATION TO Mn_2Sb

In this section, the foregoing model is applied to Cr-modified Mn_2Sb.[6] It should be emphasized that the foregoing expressions represent a single composition whose F/AF transition occurs at a temperature T_s. In applying such a model to $Mn_{2-x}Cr_xSb$ for various values of x, in which T_s varies with chromium content, one must investigate whether the behavior of all compositions can be represented by a model whose parameters are independent of composition, and yet whose thermodynamic quantities exhibit the observed functional dependence on composition.

Compositional changes are introduced into the function (c_T-c_c) by assuming that the temperature dependence of c_T remains the same as that of Mn_2Sb, but that the modifying element (chromium) reduces the absolute value of c_T. Thus, the requirement on the modifying element is that the lattice contraction introduced by it is just the amount required to satisfy Eq. (5) at the transition temperature T_s.

There are probably some deviations from this assumption at high chromium content, but the theory is not quantitative enough to warrant consideration of such deviations. At this point, we must mention a metallurgical property of this material. An increase in the value of x does not represent a proportional decrease in the value of c_T. It has been found that the chromium tends to segregate into an ever-present MnSb Widmanstätten precipitate,[7] and there is not a corresponding increase of chromium content in the Mn_2Sb phase proportional to the amount introduced into the melt. It must therefore be assumed that the transition temperature T_s occurs when Eq. (5) is satisfied and that the chromium in $Mn_{2-x}Cr_xSb$ has introduced just the reduction in c_T required to satisfy Eq. (5) at T_s.

We shall also assume that c_c is constant throughout the entire range of transition temperatures. The value of c_c is critical only when calculating the F and AF lattice parameters for a given transition temperature. Otherwise c_c always appears in the expression (c_T-c_c) and, if this difference can be obtained, c_c needs to be known only approximately. A third assumption is that the magnetization of the sublattice of our model is given by the measured magnetization rather than by Eq. (11). As has already been discussed,[5] the spins of the 3-layer

sets of atomic planes remain ordered antiparallel and appear to be strongly coupled by exchange forces. We assume, therefore, that the details of the magnetization behavior of Mn I and Mn II ions within this plane do not contribute to exchange inversion except through the temperature dependence of the magnetization of the entire 3-layer set. One would not expect that Eq. (11) should represent the magnetization of Mn_2Sb. On the other hand, the conclusions drawn from Eq. (11) by use of the Weiss field is semiquantitatively correct even though the functional form is not. This functional dependence arose because we have used classical statistics in the magnetic entropy and assumed only a single sublattice.

To obtain the parameters ρ/R and ρ'/R, consider the discontinuous change in the c lattice parameter given by Eq. (7). The elastic constant R does not need to be known until absolute energy comparisons are made. The best fit to Δc_s is given by $\rho/R=0.02$ Å and $\rho'/R=0.4$.

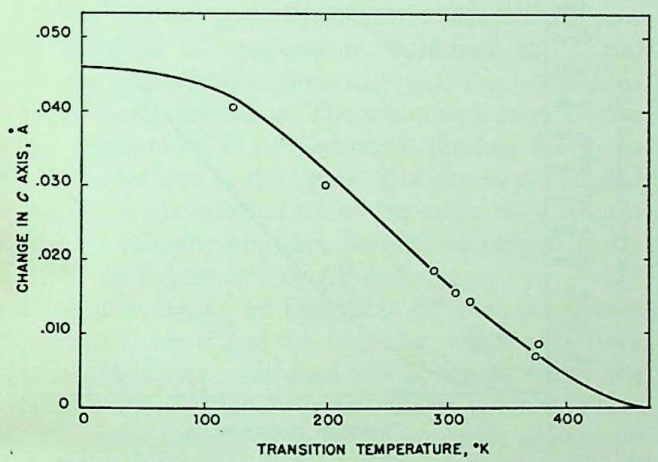

FIG. 1. Discontinuity in c axis as a function of transition temperature T_s. Experimental results (Ref. 6) are shown by the open circles.

Within the limits of experimental error, the value of ρ'/R is not too critical. For example, a 0.1 variation in ρ'/R can be tolerated and still obtain a fit with the experimental data. The value of ρ/R is more critical for only 0.001 Å variation can be tolerated here. This fit of experimental data to the theoretical equation is shown in Fig. 1. Since the introduction of chromium reduces both T_c and the saturation moment, the magnetization of Mn_2Sb cannot be used in Eq. (7). Instead, the magnetization measured at $T=T_s$ of that composition whose F/AF transition temperature is T_s is used. This magnetization is lower than the magnetization of Mn_2Sb at the corresponding temperature.

We may now obtain the temperature dependence of (c_T-c_c) for unmodified Mn_2Sb. From Eq. (3) we obtain c_F, the dimension of the unit cell for ferromagnetic ordering at $\phi=0$. Rearrangement of terms gives

$$(c_T-c_c)=(c_F-c_c)[1-(\rho'/R)m^2]-(\rho/R)m^2, \quad (14)$$

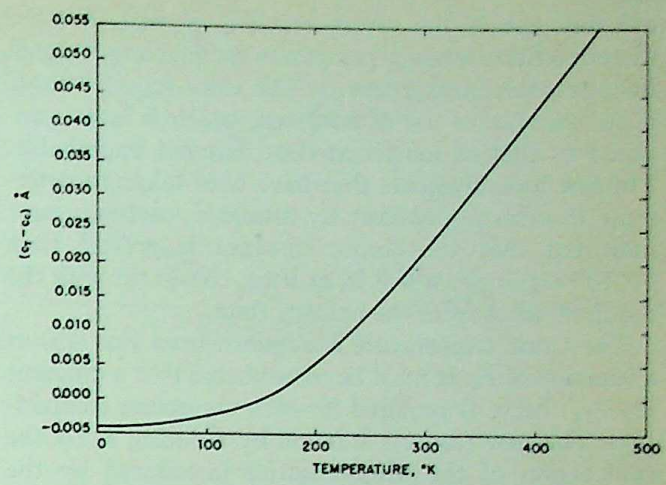

FIG. 2. Dimension (c_T-c_c) as a function of temperature calculated from the thermal contraction of Mn_2Sb.

where the values of the magnetization to be used in Eq. (15) are those of Mn_2Sb. It is seen in Eq. (14) that c_c must be known. The experimentally measured lattice dimension of Mn_2Sb is c_F. The value of c_c within reasonable limits does not affect appreciably the empirically determined temperature dependence of (c_T-c_c). Selection of the value of $c_c=6.506$ Å is discussed later in the paper. Figure 2 shows the temperature dependence of (c_T-c_c) obtained from Eq. (14).

The change in entropy may now be calculated by use of Fig. 2 and Eq. (10). The value of the entropy is dependent only on the rate of change of c_T with temperature. The calculated change in entropy is shown in Fig. 3 in units of the elastic constant. Agreement with the experimentally measured ΔS given by the open circles is good, if it is assumed that the elastic constant C is 4.7×10^{12} ergs/cm³. Some experimental values[8] of ΔS in units of the elastic constant are shown for comparison. Such agreement is also indicative of the validity of the assumption that the temperature dependence of c_T is nearly independent of chromium content. We have been unable to measure an elastic constant along the c

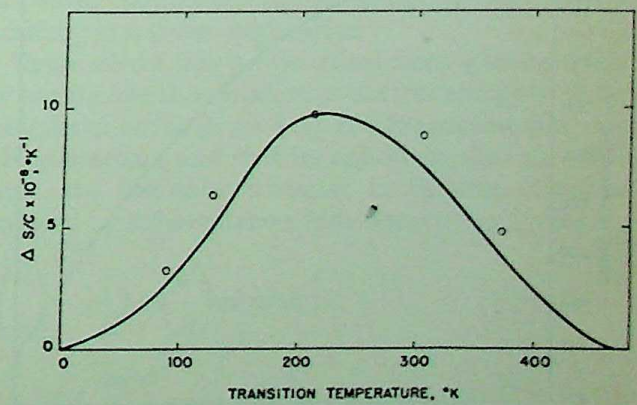

FIG. 3. Entropy change versus transition temperature. The data of Flippen (Ref. 9) are shown for comparison.

axis because of the severe cracking normal to the c direction that always accompanies samples large enough for ultrasonic measurements. The value required for C is comparable to C_{11} of tungsten, which is large compared to that of most materials, but not improbable. The few measurements that have been taken to determine the elastic constant by ultrasonic methods have indicated that the elastic constant is greater than 3×10^{12} ergs/cm^3, which is, at least, consistent with the required value from the entropy data.

The Curie temperature is obtained from Eq. (13) as a function of T_s. It must be remembered that a different (c_T-c_c) curve is required for each chromium composition. The new (c_T-c_c) is found by reducing c_T by the contraction of the Mn_2Sb lattice introduced by the chromium. The temperature which satisfies the equality in Eq. (13) is the Curie temperature for the composition. The Curie temperatures for various ternary compositions were thus calculated from the experimentally determined lattice contractions and the results are shown in Fig. 4 plotted against the associated F/AF transition temperature T_s. The measured Curie temperatures are included for comparison.

For the foregoing calculation the intraplanar exchange energy must be known. From the measured Mn_2Sb Curie temperature J/Nk is found to be 470°K by subtracting the value of the first term for Mn_2Sb on the right-hand side of Eq. (13). Actually an unknown parameter is introduced by the scale factor R/Nk, which converts elastic energy to temperature units. Our model compresses the 3-layer set of planes into a single layer. Therefore, the effective density N of the magnetic ions is not known, and the value we select for N influences the value of the intraplanar Curie temperature. However, N cannot be varied widely because the T_c calculated for the modified Mn_2Sb materials would deviate widely from the experimentally measured values. There is no real advantage gained in making a least-squares fit, so the density of magnetic ions in the 3-layer set, 6.2×10^{22}/cm^3, is selected as the density N of ions for the model. The effective value of R is obtained from the change in entropy, Eq. (9), and the scale factor is $R/Nk=1.5\times10^4$ °K/Å^2.

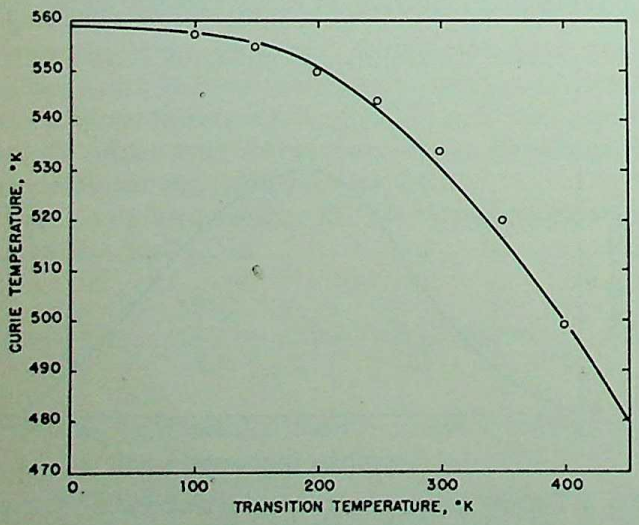

FIG. 4. Dependence of Curie temperature on F/AF transition temperature. Experimental results (Doerner and Flippen, to be submitted) are shown for comparison.

The parameters which have been evaluated allow calculation of the sublattice magnetization from Eq. (11). The sublattice magnetization for (c_T-c_c) given in Fig. 2, which would correspond to unmodified Mn_2Sb, is essentially a Brillouin function with $J=\frac{1}{2}$. For (c_T-c_c) modified to give $T_s>0$°K, the sublattice magnetization differs slightly from the unmodified (c_T-c_c) because of the reduction of Curie temperature, but the shape is still essentially a Brillouin function. The calculated discontinuity in M for $T_s=300$°K is only 0.8%. There is little agreement between the experimental and the theoretical magnetization compared to the rather remarkable agreement in the foregoing calculations. This result is to be expected, of course, since the functional form of the magnetic entropy is based on a molecular field model of a single sublattice.

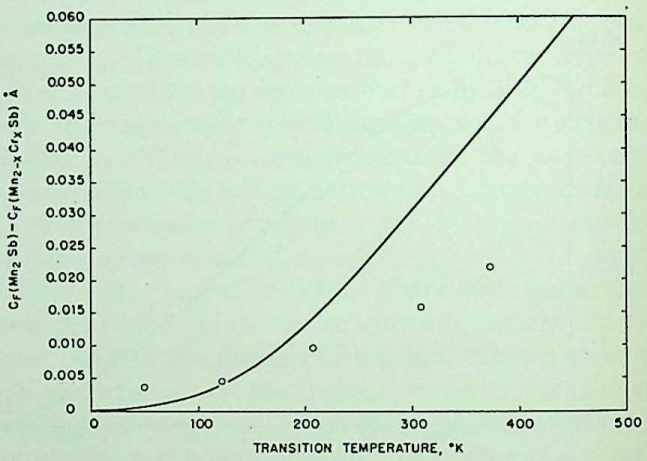

FIG. 5. Reduction of the ferromagnetic lattice dimension with increasing T_s.

A value for c_c has been used in the foregoing calculations, but its derivation has not been established. The expression for c_F is obtained from Eq. (3) for $\phi=0$ and $m=m_s$, the measured value of the magnetization at T_s. The lattice contraction in the F state due to the introduction of chromium is then given by

$$\Delta c_F=\frac{c_T-c_c+(\rho/R)m_s^2}{1-(\rho'/R)m_s^2}+c_c-c_F(Mn_2Sb)$$

and is shown in Fig. 5 with the experimental points obtained from Fig. 1 of Darnell *et al.*[6]

The value of c_c was selected to fit the low T_s materials. It is seen that deviations by a factor of 2 occur for high T_s materials, which indicates that our initial assumptions about the passive role of the chromium may not be entirely valid. Either c_c is not constant over

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the range of transition temperatures or the temperature dependence of c_T changes at high chromium content. However, in view of the success of the theory which assumes the functional form of c_T is not changed with the addition of chromium, it seems more probable that c_c is not constant.

ANISOTROPY

The anisotropy energy has not been taken into account in the foregoing treatment. On the whole, the anisotropy energy is 1 to 2 orders of magnitude smaller than the smallest exchange interaction, and its inclusion has not been necessary. There is however, an effect of anisotropy which is quite apparent. Consider Fig. 10 of Darnell *et al.*[6] It is seen that the temperature T_A at which the anisotropy changes sign for F ordering is not continuous across the T_s boundary into the AF region, but lies on this boundary from 200 to 350°K before entering the AF region. This effect is ascribed to an anisotropy in the interplanar exchange energy. In Fig. 6 the free energy is represented schematically as a linear function of temperature. Although the actual functional dependence is more complex, this representation serves this discussion. The anisotropy contribution is also exaggerated in proportion to the free energy so that it can be seen in the figure. The curves are labeled according to the orientation of the spins with respect to the crystallographic axis, parallel or perpendicular to c, and according to F or AF ordering.

It has been shown by Darnell *et al.*[6] that the anisotropy energies for F and AF ordering, which arise from dipole-dipole and crystal-field effects, are so nearly the same that the small differences can be ignored. Thus, the first-order contribution to the magnetic anisotropy energy to be added to the free energy is the same for F and AF ordering, and anisotropy is continuous across the F/AF transition. However, in second order, the anisotropy mixes with the exchange energy producing an anisotropic exchange. The effect of an anisotropic exchange is shown in Fig. 6 by the difference in the temperature at which $F_{AF}{}^{\perp}$ and $F_F{}^{\perp}$ intersect and $F_{AF}{}^{\parallel}$ and $F_F{}^{\parallel}$ intersect. The free energy at the intersection for parallel ordering is lower than that for perpendicular ordering by the anisotropy energy. For transition temperatures between the $F_{AF}{}^{\perp}$ and $F_F{}^{\perp}$ intersection and the $F_{AF}{}^{\parallel}$ and $F_F{}^{\parallel}$ intersection, Fig. 6(a) results. Since the magnetic system follows the lowest free energy, the F/AF transition takes place with a concomitant transition from positive to negative anisotropy. This situation is the condition for a transition between 200 and 350°K.

Figure 6(b) represents the free-energy relations for F/AF transition temperatures $T_s>350$°K. Here the $F_{AF}{}^{\parallel}$ and $F_F{}^{\perp}$ intersection is at a temperature lower than the F/AF transition temperature T_s, and the anisotropy remains positive at T_s. Figure 6(c) shows the situation for a low F/AF transition temperature,

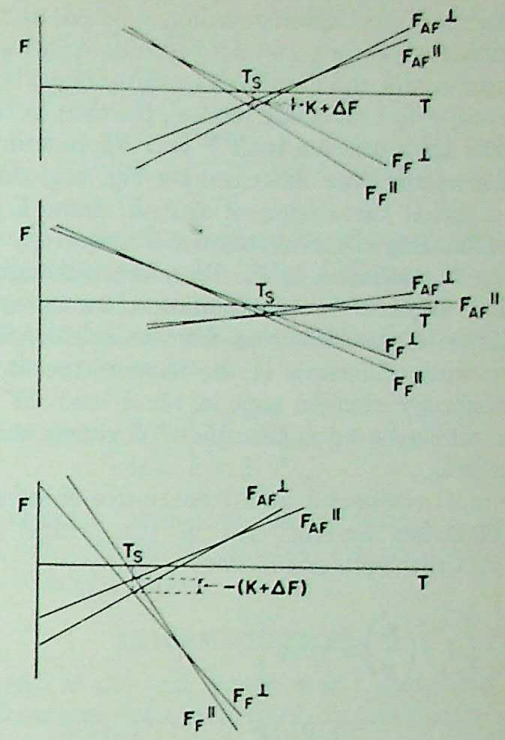

FIG. 6. Schematic representation of the effect of anisotropic exchange on magnetocrystalline anisotropy: (a) 200°K$<T_s<$350°K, (b) $T_s>$350°K, (c) $T_s<$200°K.

$T_s<200$°K. Here the $F_F{}^{\parallel}$ and $F_F{}^{\perp}$ intersection is at a temperature higher than T_s and the anisotropy changes from positive to negative before the F/AF transition occurs.

Relative to the free energy for parallel orientation of spins, the free energy for perpendicular orientation is

$$F_{AF,F}{}^{\perp}=F_{AF,F}{}^{\parallel}+\Delta F_{AF,F}+K^0.$$

The differences between the $F^{\perp}$ and $F^{\parallel}$ curves of Fig. 6 are due to the temperature dependence of the $(\Delta F+K)$ terms. Thus, the anisotropy of Mn_2Sb must contain not only terms of the type described by Darnell *et al.* and designated here by K^0 but also an anisotropic exchange ΔF whose contribution cannot be distinguished experimentally in a given composition.

These effects may be described more quantitatively by considering the variation of the free energy with the interplanar exchange $\rho(c-c_c)$. If it is assumed that only ρ is anisotropic, and that its anisotropy $\Delta\rho=\rho_{\parallel}-\rho_{\perp}$ is small, the first-order deviation in the free energy is obtained by differentiation with respect to ρ, giving

$$\Delta\left(\frac{F}{R}\right)=-\left[1-\left(\frac{\rho'}{R}\right)m^2\cos\phi\right]^{-1}$$
$$\times\left[\left(\frac{\rho m^2}{R}\right)^2\cos^2\phi+\left(\frac{\rho}{R}\right)m^2(c_T-c_c)\cos\phi\right]\frac{\Delta\rho}{\rho}. \quad (15)$$

From Eq. (15), the magnitude of the anisotropy in the free energy ΔF depends on the spin ordering through

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$\cos\phi$. In the Kittel approximation, $\rho'=0$. At the F/AF transition $(c_T-c_c)=0$, and ΔF becomes independent of spin ordering for the F and AF configurations. Without the second-order exchange term ρ', the shift in the free energy is the same for both F and AF ordering, and behavior of the type described by Fig. 6(a) does not arise. Explicit calculation of $\Delta(F/R)$ from Eq. (15) shows that this contribution to the anisotropy of the AF state is smallest near T_s. Therefore, although there may be a second-order contribution to the temperature dependence of the anisotropy from an anisotropic ρ/R, no significant difference in the temperature at which the anisotropy changes sign in the F and AF states occurs. Similarly, an anisotropic ρ'/R suffers the same deficiencies.

The most reasonable additional source of anisotropy is a variation $\Delta c_c=c_c^{\perp}-c_c^{\parallel}$ of the critical lattice dimension with spin orientation,

$$\Delta\left(\frac{F}{R}\right)=\left[1-\left(\frac{\rho'}{R}\right)m^2\cos\phi\right]^{-1}\times\left[\frac{\rho}{R}+\frac{\rho'}{R}(c_T-c_c)\right]m^2\cos\phi\Delta c_c. \quad (16)$$

Here, in the Kittel approximation $\rho'=0$, the incremental changes in the free energy are in opposite direction for the F and AF states, i.e., this contribution to the anisotropy from Eq. (16) changes sign at T_s. Such behavior is just that which is necessary to account for the qualitative arguments summarized by Fig. 6. Thus, the first-order anisotropy constant may be expressed as

$$K=K^0+\rho m^2\Delta c_c\cos\phi, \quad (17)$$

where K^0 contains all other contributions to the anisotropy that are predominately independent of spin ordering, e.g., crystal-field anisotropy and contributions such as expressed by Eq. (15).

In order to show that the additional contribution to the anisotropy in Eq. (17) is plausible, we compare the temperatures at which the anisotropy changes sign for the F and AF states. For the situation described by Fig. 6(a), anisotropy changes sign when exchange inversion occurs for a range in T_s of 150°. By use of the value of ρ/R found previously, Δc_c must be 4×10^{-4} Å. Such a value for Δc_c is reasonable, unfortunately however, it is difficult to detect directly. It is significant, however, that such a small anisotropy in the exchange can play a dominant role in the magnetic anisotropy whenever magnetoelastic effects are present.

SPIN FLOPPING

The appearance of positive anisotropy in the antiferromagnetic state suggests that spin-flopping experiments can be performed on the high-chromium Mn_2Sb compositions. Such experiments have been reported by Flippen.[9] Spin flopping has not been treated in an exchange-inversion material, and we outline briefly here the derivation of the spin-flopping conditions. Exchange inversion and spin flopping are quite different phenomena and should not be confused. Besides the obvious fact that exchange inversion can take place in the absence of an externally applied field, the most important feature is that the F/AF transition can be induced by an external field applied along any crystallographic direction. Spin flopping, however, can occur only when the anisotropy of the antiferromagnetic state is positive and when the external field is applied parallel to the anisotropy field. The spin configuration in the "spin flopped" state is canted, and this state is stable only in the presence of the applied magnetic field. The state is not stabilized when the external field is applied perpendicular to the anisotropy field or when the anisotropy is negative.

The condition for an exchange-inversion transition has been treated thus far in the absence of external fields. However, an F/AF transition can be induced at temperatures below T_s by application of a sufficiently strong magnetic field. The condition for an F/AF transition in the presence of an applied field is given by equating the free energies for F and AF ordering, including the magnetic energy of the applied field,

$$F(\pi)=F(0)+2\mathbf{H}\cdot\mathbf{M} \quad (18)$$

from which is obtained the critical field for the F/AF transition

$$H_c^{\mathrm{AF/F}}=\frac{m}{M_0}\left\{\left(\frac{\rho m^2}{R}\right)^2\rho'+(c_T-c_c)\times\left[\rho+\frac{\rho'}{2}(c_T-c_c)\right]\right\}\left[1-\left(\frac{\rho' m^2}{R}\right)^2\right]^{-1}. \quad (19)$$

It can be verified that the derivative of Eq. (19) with respect to temperature and application of the magnetic form of the Clausius–Clapeyron equation gives Eq. (8). Also, it can be seen by direct substitution that the critical field vanishes when Eq. (5) is satisfied.

The anisotropy has been ignored in Eq. (18). Anisotropic exchange introduces anisotropy in the critical field for the F/AF transition. If this were the only contribution to the anisotropy, the calculated value of Δc_c gives a critical field perpendicular to the c axis about 2000 G larger than the field applied parallel for a given temperature. When all sources of anisotropy are included, one would expect the anisotropy of the critical field to be proportional to the magnetocrystalline anisotropy field. Such anisotropy in the critical field is mentioned by Bierstedt[10] in connection with his resis-

tivity measurements. More detailed unpublished data of Bierstedt show that the lower critical field is parallel to the easy direction of the anisotropy. Thus, the lower critical field changes from parallel to perpendicular to the c axis for compositions with $T_s<200°$K, the temperature below which the anisotropy changes sign before the exchange inversion occurs.

The second-order quantity ρ'/R is small, and its inclusion contributes only additional complications. We shall neglect it in the succeeding calculation of spin flopping. Eq. (19) becomes

$$H_c^{\mathrm{AF/F}}=\frac{m}{M_0}\rho(c_T-c_c). \tag{20}$$

To obtain the spin-flopping conditions we again equate the free energies

$$F(\pi)=F(\theta)+2\mathbf{H}\cdot\mathbf{M}+2K\sin^2\theta. \tag{21}$$

Here the solution of Eq. (21) is anticipated by assuming that H is directed along the anisotropy field of the antiferromagnetic state and that the "spin-flopped" state is canted with the moments of the two sublattices making the same angle θ with respect to the applied field. Equation (21) may be rearranged to give

$$\cos\theta\left[\cos^3\theta+\left(\frac{m^2\rho(c_T-c_c)+K}{\rho^2m^4}R-1\right)\times\cos\theta+R\frac{H_c^{\mathrm{AF/C}}M}{\rho^2m^4}\right]-\frac{KR}{\rho^2m^4}=0, \tag{22}$$

where K is the anisotropy energy of the canted state. In order to obtain the critical field $H_c^{\mathrm{AF/C}}$ for spin flopping, the equilibrium value of θ must be determined by setting the torque equal to zero, $\partial F/\partial\theta=0$, where F is understood to contain the anisotropy and magnetic energies. Thus, the equilibrium condition

$$\cos^3\theta-\frac{1}{2}\left[1-\frac{K+2\rho(c_T-c_c)m^2}{2\rho^2m}R\right]\times\cos\theta+\frac{H_c^{\mathrm{AF/C}}M}{\rho^2m^4}-\frac{KR}{\rho^2m^4}R=0 \tag{23}$$

must be satisfied simultaneously with Eq. (22).

General solution of Eqs. (22) and (23) are complex, however, the essential features may be obtained by an approximate solution applicable to the experimental conditions of Flippen. Substitution of the field dependence of the F/AF transition and the observed critical field for spin flopping in Eq. (23) indicate that $\theta\cong90°$, and $\cos^3\theta$ can be neglected. Therefore, by solving Eq. (23) for $\cos\theta$ and substituting into Eq. (22), the spin-flopping condition is obtained

$$H_c^{\mathrm{AF/C}}=\frac{1}{M}\left(2\left\{K\left[\frac{\rho^2m^4}{R}-\rho(c_T-c_c)m^2\right]\right\}^{1/2}-K\left\{K\Big/\left[\frac{\rho^2m^4}{R}-\rho(c_T-c_c)m^2\right]\right\}^{1/2}\right). \tag{24}$$

When K is small compared to the magnetic strain ρ^2m^4/R, the second term of Eq. (24) may be neglected for any value of (c_T-c_c). Substitution of Eq. (20) gives the relation between the spin-flopping field and the field for exchange inversion

$$H_c^{\mathrm{AF/C}}=\frac{2}{M}\left\{K\left[\left(\frac{\rho^2m^4}{R}\right)+H_c^{\mathrm{F/AF}}M\right]\right\}^{1/2}. \tag{25}$$

The anisotropy field of the canted state is found to be of the order of 1000 Oe or 2×10^5 erg/cm^3 from analysis of the data of Flippen.

INTERMEDIATE STATE

Darnell *et al.*[6] and Austin *et al.*[5] show that at low transition temperatures a third magnetic state appears as an interruption in the F/AF transition. The foregoing model does not account for such behavior principally for two reasons: First, effectively only nearest-neighbor interactions are contained in the model, and there is no competition between exchange interactions for spin direction that might give rise to a helical structure. Second, the model assumes a Bravais lattice and even if the details of the exchange interactions were included, only proper helical structures would result. The spin configuration of the intermediate state must be represented by a mixture of two configurations,

$$\mathbf{S}_n=\mathbf{D}+\mathbf{U}\cos(\mathbf{k}\cdot\mathbf{r}_n)+\mathbf{V}\sin(\mathbf{k}\cdot\mathbf{r}_n), \tag{26}$$

a $k=0$ ferromagnetic component and a helical component commensurate with the lattice periodicity given by $k_z=2\pi/3c$. For $x<0.022$ in the composition $Mn_{2-x}Cr_xSb$ the intermediate state is stable at absolute zero. In order to account for such a spin configuration, one must treat the actual crystal structure of Mn_2Sb by the generalized Luttinger-Tisza method proposed by Lyons and Kaplan[11] and Lyons *et al.*[12] Preliminary calculations indicate that the spin eigenfunction given in Eq. (26) can lower the energy eigenvalues below the ferromagnetic and antiferromagnetic states. Details of this calculation will be published in a forthcoming paper.

DISCUSSION

The foregoing theory based on a highly simplified model of Mn_2Sb demonstrates considerable success in accounting for the behavior of the F/AF transition in

$Mn_{2-x}Cr_xSb$. As pointed out by Bierstedt,[10] this transition is accompanied by hysteresis. For transitions near room temperature, the hysteresis is less than 1 deg of temperature. However, below about 200°K, hysteresis begins increasing sharply and reaches a value of about 20° for a transition occurring near the temperature of liquid nitrogen. First-order transitions to the ferromagnetic state in MnAs and the associated hysteresis have been investigated by Bean and Rodbell.[13] They point out that the maximum hysteresis arises when the spin system remains at the initial minimum of the free energy, even though it is not the lowest minimum, until the free energy is "down-hill-all-the-way." The measured hysteresis in MnAs is about 2/3 of this maximum value.

[13] C. P. Bean and D. S. Rodbell, Phys. Rev. 126, 104 (1962).

This situation does not hold for the F/AF transition in $Mn_{2-x}Cr_xSb$. Kittel has shown that the maximum hysteresis in a_T is $\Delta a_T = 2\rho m^2/R$. The free energy used in this treatment does not alter appreciably this expression. At room temperature, therefore, the expected hysteresis in Δa_T using ρ/R obtained previously is of the order of 10^{-2} Å, which may be transformed to a thermal hysteresis of about 50° by use of Fig. 2. This large discrepancy with the observed hysteresis indicates some very efficient mechanism nucleates the new state so that for transitions near room temperature the most stable state is nearly the equilibrium state. At low temperatures this nucleation mechanism must become less efficient, since the thermal hysteresis increases rapidly. A satisfactory model has not been obtained.

Magnetic Susceptibilities of Transition Elements in Host Crystals. II. Ni^{2+} in ZnO and CdS†

WILLIAM H. BRUMAGE AND CHUN C. LIN*
Department of Physics, University of Oklahoma, Norman, Oklahoma
(Received 10 December 1963)

The magnetic susceptibilities of Ni^{2+}-doped ZnO and CdS crystals have been measured along and perpendicular to the trigonal crystalline axes over the temperature range of 28–500°K. The magnetic susceptibilities of both crystals approach constant values at low temperature and decrease more rapidly with increasing temperature at $T>60$°K. An unusually large magnetic anisotropy is observed for Ni^{2+}:ZnO. The non-Curie behavior can be explained on the basis that the ground state of Ni^{2+} is nonmagnetic (A_1) and the temperature-dependent susceptibility arises mainly from the ions in the first two excited states (A_2 and E). By fitting the theoretical susceptibilities to the experimental values, the spin-orbit coupling constant of Ni^{2+}:ZnO is obtained as -175 ± 25 cm^{-1} and the trigonal field splitting of the $T_1[^3T(F)]$ state (the lowest T_1 state) as 100 ± 10 cm^{-1}. The corresponding quantities for Ni^{2+}:CdS are -170 ± 10 cm^{-1} and 10 ± 4 cm^{-1}. In both crystals the A_2 component of the $T_1[^3T(F)]$ state lies below the E level. The large reduction of the spin-orbit coupling constant from the free-ion value indicates a rather strong covalency between the Ni^{2+} ion and the ligands. Combination of the trigonal splittings of the $T_1[^3T_1(F)]$ state with those of $T_2[^3T_1(P)]$ observed in the optical spectra leads to a determination of the trigonal field parameters. The experimental values of the trigonal parameters are consistent with those calculated by using the point-charge model and assuming a local contraction of the lattice with a slightly larger contraction for the three anions off the trigonal axis than for the one on the axis.

I. INTRODUCTION

In a previous paper we have pointed out that the magnetic susceptibilities of V^{3+}-doped corundum may be used quite effectively for determining certain structural parameters of the crystals.[1] For example, the trigonal field splitting of the lowest $^3T_1$ level of V^{3+}:Al_2O_3 was determined from the Van Vleck temperature-independent susceptibility which was evaluated from the magnetic data in the temperature interval of 77–295°K, and the zero-field splitting of the ground state was obtained from the susceptibilities at low temperatures. By combining these results with those of electron spin resonance experiments and optical spectra,[2] the two trigonal field parameters and the spin-orbit coupling constant were estimated. The trigonal field parameters were found to be in reasonable agreement with the ones calculated from the empirical point-charge model. In this paper we shall report some magnetic measurements of Ni^{2+}:CdS and Ni^{2+}:ZnO. The susceptibility data make it possible to locate the first two excited states which hitherto have not been determined accurately.[3]

Values of the spin-orbit coupling constant and the trigonal field parameters can then be obtained, and the latter are compared with the calculations of the point-charge model.

In both CdS and ZnO host crystals, a Ni^{2+} ion is situated in a tetrahedral site.[4,5] Since Ni^{2+} has an electron configuration of $(3d)^8$ and since the pattern of the energy level splitting due to a tetrahedral field is just the inverted form of that of an octahedral field, the ordering of the crystalline Stark levels of Ni^{2+}:CdS and V^{3+}:Al_2O_3 are identical if one ignores the effect of the trigonal distortion. However, the spin-orbit coupling constant of Ni^{2+} is considerably larger than that of V^{3+}. Thus, in Ni^{2+}:CdS the spin-orbit splittings are much greater than the trigonal terms, while these two effects are of comparable magnitude for Ni^{2+}:ZnO. It is convenient to consider the spin-orbit interaction as the major perturbation to Ni^{2+} in a cubic field and then introduce the trigonal terms as the second perturbation. Figure 1 shows the energy level diagram of a Ni^{2+} ion in tetrahedral site.

The ground state A_1 is nonmagnetic, i.e., the average magnetic moment for this state is zero. At very low temperature the susceptibility should approach a constant value which is equal to the sum of the diamagnetism of the host crystal and the Van Vleck temperature-independent susceptibility. If we choose the trigonal axis as the z axis, it is easily shown that the matrix elements of μ_x and μ_y connect an A_1 state with only the E states, while μ_z has elements between A_1 and A_2 only. It follows that for an external magnetic field along the z axis, the Van Vleck term is dictated primarily by the first A_2 level (in the trigonal field) while in the case of a perpendicular field, the lowest E state gives the major contribution to the temperature-independent paramagnetic susceptibility. As the temperature is increased, the excited states begin to receive appreciable population and the susceptibilities then depart from the low-temperature asymptotic values. Because of this strong dependence of χ_z and χ_x on temperature, the positions of the first A_2 and the first E states can be determined quite accurately. In the case of Ni^{2+}:CdS, we are able to obtain from the magnetic data a trigonal splitting of the lowest A_2–E pair as small as 10 cm^{-1}. Furthermore, since both the first excited A_2 and E levels are a few hundred cm^{-1} above the ground state, direct determination of the location of these levels is difficult by other means and the magnetic measurements are particularly effective for this purpose.

II. EXPERIMENT

The crystals of Ni^{2+}:CdS were furnished by Dr. T. L. Estle of Texas Instrument Inc., and Ni^{2+}:ZnO by Dr. H. A. Weakleim of the RCA Laboratories. The measurements of the magnetic susceptibility were made by means of the Faraday balance used in our previous work.[1] In Tables I and II are shown the magnetic susceptibilities of Ni^{2+}:CdS and Ni^{2+}:ZnO crystals along and perpendicular to the trigonal axis over the temperature range of 28–500°K. The concentrations of the nickel ions in ZnO and CdS are 0.076 and 0.84%, respectively, as determined from the analysis of the magnetic data. The accuracy of the measured susceptibility in ZnO (±4%) is somewhat lower than in CdS (±2%) because of the smaller concentration of Ni^{2+} in the former.

III. THEORY AND ANALYSIS OF DATA

The theoretical analysis of the magnetic susceptibility of a (d^2) or (d^8) atomic system in a trigonal field has been treated in detail for the $V^{3+}:Al_2O_3$ crystals.[1] As pointed out in Sec. I, for the case of Ni^{2+} in a slightly distorted tetrahedral site, it is advantageous to consider the spin-orbit coupling as the major perturbation on the perfect tetrahedral field and the trigonal distortion as a minor one. Thus, a slight modification will be made to the theory presented in Ref. 1.

The Hamiltonian for a Ni^{2+} ion is written as

$$H=H_0+V_c+\lambda\mathbf{L}\cdot\mathbf{S}+V_t+\mu_0(\mathbf{L}+g_s\mathbf{S})\cdot\mathcal{H}. \quad (1)$$

The various members in the right-hand side of Eq. (1) represent the Hamiltonian of a free Ni^{2+} ion, the cubic (tetrahedral) crystalline field, the spin-orbit interaction term, the trigonal field, and the interaction with the external field $\mathcal{H}$. As was done before, the two crystal potential terms are taken as[6]

$$V_c=\sum_{i=1,2} r_i^4 A_4^0\{Y_{4,0}(\theta_i\phi_i)+(10/7)^{1/2}\times[Y_{4,3}(\theta_i\phi_i)-Y_{4,-3}(\theta_i\phi_i)]\}, \quad (2)$$

$$V_t=\sum_{i=1,2}\{r_i^2 B_2^0 Y_{2,0}(\theta_i\phi_i)+r_i^4 B_4^0 Y_{4,0}(\theta_i\phi_i)\}. \quad (3)$$

Here the summation is to be extended over the two $(3d)$ holes rather than electrons. The crystal-field parameters are defined as

$$\beta=-A_4^0\langle r^4\rangle/14\sqrt{\pi},$$
$$\gamma=-B_4^0\langle r^4\rangle/42\sqrt{\pi},$$
$$\tau=-(\sqrt{5})B_2^0\langle r^2\rangle/140\sqrt{\pi},$$

and, in the case of a pure cubic field β is equal to $\frac{2}{3}Dq$.

Let us first consider the part of the Hamiltonian

$$H'=H_0+V_c+\lambda\mathbf{L}\cdot\mathbf{S}. \quad (4)$$

[6] See, for example, D. S. McClure, Solid State Phys. 9, 399 (1959).

The lowest configuration $(3d)^8$ of a Ni^{2+} ion gives rise to the terms ^3F, ^1D, ^3P, ^1G, and ^1S which are split by the cubic field, e.g.,

$$^3F\rightarrow{}^3T_1+{}^3T_2+{}^3A_2, \quad ^3P\rightarrow{}^3T_1. \quad (5)$$

The spin-orbit coupling causes further splitting of the levels as

$$^3T_1\rightarrow A_1+E+T_1+T_2,$$
$$^3T_2\rightarrow A_2+E+T_1+T_2, \quad (6)$$
$$^3A_2\rightarrow T_2.$$

The eigenfunctions of H_0 corresponding to the various terms of the $(3d)^8$ configuration are taken as the usual Clebsch-Gordan type combinations[7] of one-electron orbitals, and the multiplet separations are treated as parameters to be determined from the optical spectra. From the eigenfunctions of H_0 we can construct the cubic-field functions according to Table IV of Ref. 1. These functions are characterized by the irreducible representations of the cubic group to which they belong. Since V_c has matrix elements connecting $^3T_1(^3F)$ and $^3T_1(^3P)$, a transformation

$$\begin{matrix}{}^3F\\{}^3P\end{matrix}\begin{pmatrix} a_1 & a_2\\ -a_2 & a_1\end{pmatrix} \quad (7)$$

must be applied to these two states in order to diago-

nalize H_0+V_c. This results in a mixing between the F and P states. When the spin-orbit coupling is taken into consideration, the nine functions associated with the $^3T_1$ (also $^3T_2$) must be regrouped in such a way as to exhibit the decomposition shown in (6). The symbol $\phi(T_2,{}^3T_1,+)$ is used to denote a new function obtained in this manner corresponding to the T_2 representation and originating from the $^3T_1$ state. The last symbol inside the parenthesis specifies a particular component of the degenerate state. The functions ϕ are listed in Table III. In the representation with ϕ as the basis, H' is not completely diagonal since $\mathbf{L}\cdot\mathbf{S}$ does connect members of the $^3T_1$ manifold with those of $^3T_2$.

When the trigonal field is introduced, the T_1 and T_2 split into A_2+E and A_1+E, respectively. The energy matrix (in the absence of external field) then factorizes into blocks corresponding to A_1, A_2, and E. For magnetic susceptibilities below 500°K, the highly excited states are insignificant, so we will consider only the manifold associated with the ^3F state (with F-P mixing included). The energy matrix is shown in Table IV. Any mixing of these states with higher excited states can arise only from the spin-orbit coupling or from V_t and are too small to affect the susceptibilities.

A. Ni^{2+}:CdS

The optical studies reported by Weakliem[5] suggest that the environment of the Ni^{2+} in CdS is very nearly cubic because of the apparent isotropy of the spectrum. The same conclusion can also be reached from the small observed magnetic anisotropy (Table I). It is therefore convenient to diagonalize first the Hamiltonian H', defined by Eq. (3), and subsequently treat V_t by first-order perturbation. To diagonalize H' we shall take the values of β and $\triangle_P$ (the spacing between ^3F and ^3P for the limiting free ion) as 257 and 8550 cm^{-1}, respectively, according to the results of Weakliem.[5] This gives the F-P mixing coefficients as

$$a_1=0.991\,,\quad a_2=0.138.$$

The wave functions which diagonalize H' are now labeled by the irreducible representations of the cubic group. Thus, a wave function of a particular symmetry species can be expressed as linear combinations of the functions listed in Table III, e.g.,

$$\psi(T_2,+)=a\phi(T_2,{}^3T_1,+)+b\phi(T_2,{}^3T_2,+). \qquad (8)$$

When the trigonal potential is introduced, these functions may still be used as the approximate wave function of $H'+V_t$, and the effect of V_t is to produce splittings or shifts of the energy levels. The wave functions and energies of the lowest nine states which are associated with the $^3T_1(F)$ group are determined in this manner.

With the wave functions for these nine states, the magnetic susceptibilities have been calculated by means of the standard procedure[8] and are expressed in terms of the energy levels of the low-lying states and the matrix elements of $\mathbf{L}$ and $\mathbf{S}$ between these states. The formulas for $\chi_{\|}$ and $\chi_{\perp}$ are

$$\chi_{\|}=2NB\Big[\frac{|(0|\mu_z|1)|^2}{\Delta_1}+\exp(-\Delta_1/kT)\times\Big\{-\frac{|(0|\mu_z|1)|^2}{\Delta_1}+\frac{|(1|\mu_z|4)|^2}{\Delta_4-\Delta_1}\Big\}+2\exp(-\Delta_2/kT)\times\Big\{\frac{|(2|\mu_z|2)|^2}{2kT}+\sum_{i\neq 2}\frac{|(2|\mu_z|i)|^2}{\Delta_i-\Delta_2}\Big\}+2\exp(-\Delta_3/kT)\times\Big\{\frac{|(3|\mu_z|3)|^2}{2kT}+\sum_{i\neq 3}\frac{|(3|\mu_z|i)|^2}{\Delta_i-\Delta_3}\Big\}+\exp(-\Delta_4/kT)\times\Big\{\frac{|(1|\mu_z|4)|^2}{\Delta_1-\Delta_4}\Big\}+2\exp(-\Delta_5/kT)\times\Big\{\frac{|(5|\mu_z|5)|^2}{2kT}+\sum_{i\neq 5}\frac{|(5|\mu_z|i)|^2}{\Delta_i-\Delta_5}\Big\}\Big], \qquad (9)$$

$$\chi_{\perp}=4NB\sum_i\Big[\frac{|(0|\mu_x|i)|^2}{\Delta_i}+\exp(-\Delta_1/kT)\times\Big\{\sum_i\frac{|(1|\mu_x|i)|^2}{\Delta_i-\Delta_1}\Big\}+\exp(-\Delta_2/kT)\times\Big\{\frac{|(2|\mu_x|2)|^2}{2kT}+\sum_{j\neq 2}\frac{|(2|\mu_x|j)|^2}{\Delta_j-\Delta_2}\Big\}+\exp(-\Delta_3/kT)\times\Big\{\frac{|(3|\mu_x|3)|^2}{2kT}+\sum_{j\neq 3}\frac{|(3|\mu_x|j)|^2}{\Delta_j-\Delta_2}\Big\}+\exp(-\Delta_4/kT)\times\Big\{\sum_i\frac{|(4|\mu_x|i)|^2}{\Delta_i-\Delta_4}\Big\}+\exp(-\Delta_5/kT)\times\Big\{\frac{|(5|\mu_x|5)|^2}{2kT}+\sum_{j\neq 5}\frac{|(5|\mu_x|j)|^2}{\Delta_j-\Delta_5}\Big\}\Big],$$

where

$$B^{-1}=1+\exp(-\Delta_1/kT)+2\exp(-\Delta_2/kT)+2\exp(-\Delta_3/kT)+\exp(-\Delta_4/kT)+2\exp(-\Delta_5/kT),$$

and

$$i=2,\,3,\,5;$$
$$j=0,\,1,\,2,\,3,\,4,\,5.$$

In the above equations the energy spacing between the kth level and the ground level is represented by Δ_k and the numbers 0, 1, 2, 3, 4, 5 represent the A_1, T_1A_2,

here and the readers are referred to Ref. 9 for the mathematical details.

The excited states beyond the $^3T_1(F)$ manifold are at least about 3000 cm^{-1} above the ground state, so they can be ignored as far as the magnetic susceptibility is concerned. It was found that the theoretical susceptibilities at temperatures below 500°K depend on λ and a parameter K which is defined as

$$K=-30\gamma-3\tau, \tag{10}$$

but is practically independent of the individual values of γ and τ. The calculated susceptibilities can be fitted to the experimental data by choosing $\lambda=-170$ cm^{-1}, and $K=-20$ cm^{-1} (see Fig. 2). These give the positions of the first two excited states (A_2 and E) as 230 and 240 cm^{-1}, respectively. It is rather remarkable to note that one is able to determine a splitting as small as 10 cm^{-1} from the magnetic measurements. This occurs because the magnetic anisotropy depends quite sensitively on this A_2-E splitting. When the uncertainty of the experimental data is taken into consideration, the trigonal splitting is determined as 10 ± 4 cm^{-1}. Likewise, the accuracy of λ and K is estimated to be

$$\lambda=-170\pm10 \text{ cm}^{-1},$$
$$K=-20\pm8 \text{ cm}^{-1}. \tag{11}$$

The determination of the individual values of γ and τ will be discussed in Sec. IV.

B. Ni^{2+}:ZnO

The rather large magnetic anisotropy of Ni^{2+}:ZnO (Fig. 3) indicates that the trigonal field here is considerably greater than that in Ni^{2+}:CdS. In fact, from the susceptibility data we find that the spin-orbit coupling constant and the trigonal field parameters are of comparable magnitude. The approximate method for determining the energy levels and wave functions used in the previous section is no longer applicable here; rather one must solve the entire 21×21 secular equation as given in Table III. The amount of F-P mixing in this case is, however, quite small and can be neglected. With a given set of values of λ, γ, and τ, one can solve the secular equation numerically and calculate $\chi_{\parallel}$ and $\chi_{\perp}$ according to Eq. (9). The wave functions for the lowest nine states are given in Ref. 9. Again the calculated susceptibilities are governed chiefly by λ and K, and by fitting the theoretical values to the experimental data, we found

$$\lambda=-175\pm25 \text{ cm}^{-1},$$
$$K=-225\pm25 \text{ cm}^{-1}. \tag{12}$$

Figure 3 shows the comparison between the theoretical and observed susceptibilities. The energies of the first two excited states (A_2 and E) are 160 and 260 cm^{-1}.

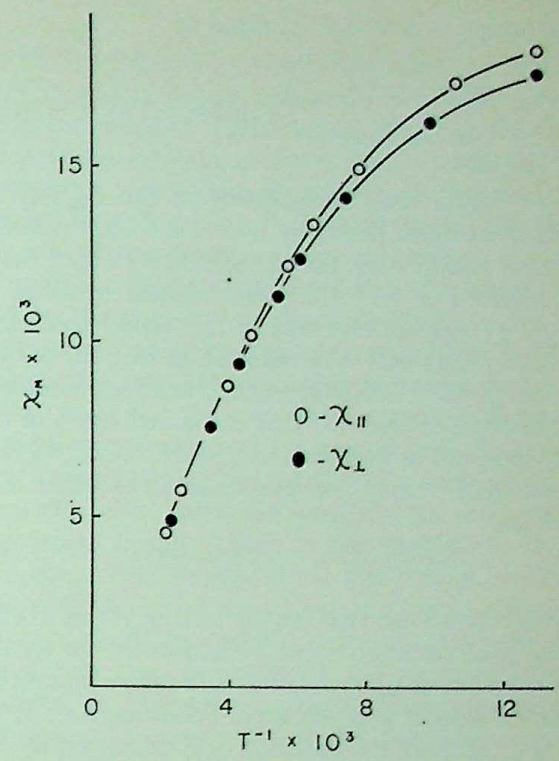

FIG. 2. Magnetic susceptibilities (per gm-ion) of Ni^{2+}:CdS from 77–500°K.

IV. DISCUSSION

From the optical spectrum, Weakliem[5] has determined the trigonal splitting of the level $T_2[^3T_1(P)]$ of Ni^{2+}:ZnO as 41 cm^{-1}. By combining this splitting with the parameter K given in Eq. (10), the two trigonal

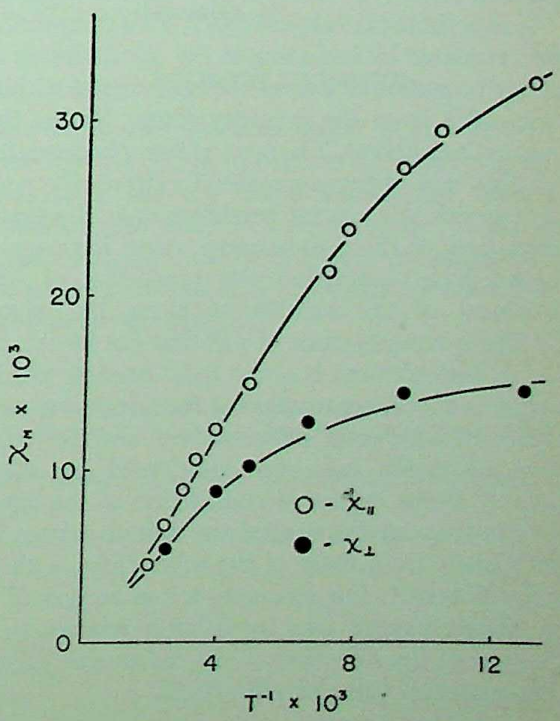

FIG. 3. Magnetic susceptibilities (per gm-ion) of Ni^{2+}:ZnO from 77–500°K.

field parameters can be determined as

$$\left.\begin{aligned}\gamma &= 7.5\ \text{cm}^{-1}\\ \tau &= -1.4\ \text{cm}^{-1}\end{aligned}\right\},\quad \text{for } Ni^{2+}:ZnO. \tag{13}$$

Here we found that the splitting of the $T_2[^3T_1(P)]$ state is determined primarily by τ. On the other hand, K depends mainly on γ, the contribution of τ on K being quite small. For Ni^{2+}:CdS, the trigonal splitting of $T_2[^3T_1(P)]$ was not observed in the optical spectrum, presumably too small to be resolved. In fact, the optical spectrum of Ni^{2+}:CdS shows nearly complete isotropy. If, however, it is assumed that the contribution of the τ term in K can be neglected also for Ni^{2+}:CdS, as is in the case of Ni^{2+}:ZnO, one can make an estimate of γ from K as

$$\gamma \cong 0.67\ \text{cm}^{-1},\quad \text{for } Ni^{2+}:CdS. \tag{14}$$

It has been shown that for the case of $V^{3+}:Al_2O_3$ the trigonal field parameters can be accounted for by the empirical point-charge model.[1] It is therefore interesting to make a similar analysis here. Following Ref. 1, we shall first compare the values of γ/β calculated by the point-charge model with the experimental results. The use of γ/β, rather than γ, gives a better test of the point-charge model, since the former is independent of $\langle r^4\rangle$ as well as the effective charge assigned to the ions of the host crystals to account for the departure from purely ionic bonding. Let us first assume that the impurity ion is situated exactly at the site of Zn^{2+}. From the crystal structure data[4] and using only the four nearest-neighbor oxygen ions, we obtain from the point-charge calculation $\gamma/\beta=0.04$ for Ni^{2+}:ZnO as compared with the experimental value of 0.027. This computation has been repeated by including in the calculation of the crystalline potential all ions of the host crystal within a radius of 20 Å from the impurity center (rather than four nearest neighbors). The ratio γ/β now becomes 0.05 which does not differ substantially from the value calculated with the nearest neighbors only. To explain the deviation of the point-charge value from experiment, we have considered the possibility of small displacement of the substituent along the trigonal axis.[1,2] The minimum value of γ/β that can be obtained by such a displacement is about 0.04. Another possible distortion is a local contraction of the lattice due to the difference in ionic radii between Ni^{2+} and Zn^{2+}. This type of distortion has been considered by several authors.[5,10] If the degree of contraction of the oxygen ion on the trigonal axis (called the unique oxygen ion) differs slightly from those of the other three, a change of γ/β will result. For example, a contraction of the three off-axis oxygen ions by 0.028 Å relative to the unique ion in the direction of the cation site will give the experimental value of $\gamma/\beta=0.027$.

The calculation of τ from the point-charge model is considerably more difficult, as it is necessary to introduce an additional assumption of using the self-consistent field atomic wave function of Ni^{2+} to evaluate $\langle r^2\rangle$ which is not always valid.[11] Also, the convergence of this parameter in summing over the lattice is rather poor. We have carried out the summation to 30 A and the results still fluctuate considerably. However, we are able to obtain a rough estimate of τ as 1 cm^{-1} for the case of zero displacement of the Ni^{2+} from the cation site and no distortion of the lattice. With the distorted lattice as used in the previous paragraph (and no displacement of the impurity ions), the value of τ becomes -7 cm^{-1} which is of the same sign as the experimental value. In view of the assumptions involved in the calculation of τ, it is not reasonable to expect anything more than a qualitative agreement with experiment, and thus the point-charge calculation of this parameter will not be pursued further at this stage.

In the case of Ni^{2+}:CdS, the point-charge model gives, for zero displacement and no distortion, $\gamma/\beta=0.018$ which is much larger than the experimental value. We have used only the nearest-neighbor anions for this calculation since the inclusion of ions at lattice sites further away, as we have seen earlier, will not change this parameter greatly. From the apparent isotropy of the optical spectrum[5] as well as the smallness of γ/β, we note that the crystalline field around the Ni^{2+} in CdS has considerably smaller trigonal components than is inferred from the crystal structure of CdS. Like the case of Ni^{2+}:ZnO, the experimental value of γ/β cannot be explained by the displacement of the substituent alone. On the other hand, the picture of local distortion where the lattice relaxes toward the impurity ion in such a manner as to restore back to a nearly perfect tetrahedral configuration, does account for the small apparent anisotropy. Indeed, the experimental value of γ/β corresponds to a contraction of the three off-axis anions through 0.02 Å relative to the fourth one. The idea of local lattice contraction in Ni^{2+}:CdS was suggested by Weakliem in his optical studies.[5]

Thus, in both Ni^{2+}:ZnO and Ni^{2+}:CdS, the experimental values of the trigonal field parameters are consistent with those calculated from the empirical point-charge model[1] with a local distortion of the lattice such that the three anions of the trigonal axis relax toward the Ni^{2+} slightly more than does the one on the axis. Of course, the point-charge model is a highly idealized picture. When it is applied to crystals with an appreciable amount of covalency, a "displacement" of the anion may result from an actual movement of the lattice site as well as a shift of the electron cloud due to a change of the degree of covalency. In our application here no sharp distinction can be made between these two effects and the term "lattice distortion" really

refers to a movement of the effective center of charge of the anion.

The spin-orbit coupling constants of Ni^{2+} in both CdS and ZnO are about one-half of the free-ion value (-340 cm^{-1}). They are also substantially smaller than the spin-orbit constants of Ni^{2+} in octahedral field, e.g., -245 cm^{-1} for Ni^{2+}:MgO,[12] and -250 cm^{-1} (or -270) for Ni Tutton salt.[12] Similar reduction from the free-ion values was also found for the Slater-Condon parameters for Ni^{2+} in CdS and ZnO from the analysis of the optical spectra.[5] These results point toward the idea of strong bonding between the impurity ion and the ligands. One also notices the fact that the Slater-Condon parameters are appreciably smaller for Ni^{2+} in CdS than in ZnO which is suggestive of a stronger covalency in the former. However, the same sort of difference in λ (-170 ± 10 cm^{-1} versus -175 ± 25 cm^{-1}) is not so obvious from the magnetic measurements, although a larger covalency in Ni^{2+}:CdS is compatible with our results within their limits of accuracy. It is interesting to note that a substantially larger reduction of the spin-orbit constant has been reported in Cu^{2+}:ZnO.[13]

Our analysis leads to the conclusion that the magnetic susceptibilities of Ni^{2+} in CdS and ZnO can be explained quantitatively by using the ligand field theory. The considerable reduction of the spin-orbit coupling constant indicates delocalization of the valence electrons of the Ni^{2+}. It has been pointed out that even in the case of Cu^{2+}:ZnO where an unusually strong bonding between the impurity ions and the ligands is found, the delocalized electrons in Cu^{2+}:ZnO extend only over the Cu^{2+} ion and its nearest neighbors.[13] Thus the use of the ligand field theory in our case should be justifiable. The effect of the covalent bonding is taken into account by making the spin-orbit constant an adjustable parameter. In fact, if one assumes different degrees of covalency between the one-electron orbitals t_2 and e as was done for Cu^{2+}:ZnO, the spin-orbit interaction is then described by two parameters, i.e., $(t_2|H_{s\text{-}0}|t_2)$ and $(t_2|H_{s\text{-}0}|e)$. However, since at $T<500$°K the magnetic susceptibility is governed primarily by the ground state and the two trigonal components of $T_1[^3T_1(F)]$, and since all these two states belong to the $(t_2)^2$ configuration (in the notation of the strong-field scheme), the susceptibility should be rather insensitive to $(t_2|H_{s\text{-}0}|e)$ and hence the value of λ determined here corresponds to the coupling constant of the t_2 state. It has also been customary to introduce an additional parameter, the "orbital reduction factor" k, which relates the matrix elements of the orbital angular momentum evaluated by using the ligand field LCAO MO with those evaluated by the pure atomic functions.[13,14] Generally, this factor is not much less than one even when there is a considerable reduction in λ. For instance, in the case of Fe^{2+} in ZnF_2,[15] the spin-orbit constant is about 60% of the free-ion value and k is around 0.95. Even in the very strong bonding case of Cu^{2+}:ZnO where λ is less than 10% of the value of a free Cu^{2+}, the orbital reduction factor is only 0.46.[13] In our theoretical analysis here, this reduction ratio is not used, i.e., it is taken as unity. When the orbital reduction ratio is included in the theory, all the matrix elements of $\mathfrak{u}$ which are relevant in the calculation of the susceptibility, are modified by the same multiplicative constant. The inclusion of k merely alters the theoretical χ by a constant factor and has the same effect as changing the concentration of the nickel ion. Thus the orbital reduction ratio cannot be obtained from our susceptibility data as the precise concentrations of Ni^{2+} in both ZnO and CdS are not known. On the other hand, the crystal field parameters λ and K affect the shape of the curve of χ versus T rather than the absolute magnitude of the susceptibility, hence the values of these parameters which we gave in the preceding paragraphs still stand correct even when the orbital reduction factor is taken into consideration.

Electronic Specific Heats of Dilute Solid Solutions

H. JONES*
Department of Physics, Oklahoma State University, Stillwater, Oklahoma
(Received 2 January 1964)

The partition function of an electron gas in the presence of scattering centers, such as exist in a dilute solution, is obtained by using the method first introduced by Matsubara. It is shown that the electronic specific heat at low temperatures, in such a case, contains a term arising from virtual electron scattering. If the Fermi limit in the pure metal lies just beyond a sharp peak in the density-of-states curve, this term increases the specific heat. Comparison with the observations by Rayne on the dilute solid solutions of zinc and germanium in copper indicate that the effect discussed is probably the explanation of the observed initial increase in the low-temperature specific heat at small concentrations.

1. INTRODUCTION

THE electronic properties of disordered alloys are difficult to analyze because there are no simple quantum numbers in terms of which the single-electron wave functions can be described. Equilibrium properties, however, are fully determined when the partition function is known, and this can be obtained as the trace of an operator with respect to any complete orthonormal set of total wave functions. For dilute solid solutions the Slater determinants of the Bloch functions of the pure metal form an obvious choice for such a set. In this representation, the wave function of the ground state of the alloy is not a single Slater determinant, as in the Hartree-Fock approximation for a pure metal, but an infinite series of such determinants. The first member of the series corresponds to the ground state of the pure metal, and the other members to various excited states. In wave-vector k space the alloy has not therefore a sharply defined Fermi surface in its ground state but one which is broadened by the effect of virtual electron scattering. There must, of course, always be a precisely defined Fermi limit in terms of the true one-electron states of the alloy but these are not representable in k space. When the solute concentration is a few percent, the broadening of the Fermi surface of the ground state will be large compared to the thermal broadening in the pure metal at low temperatures.

If the density of states in the pure metal has special features lying just below the Fermi limit, these will not affect the low-temperature electronic specific heat of the pure metal, but they will affect that of the dilute alloy if the ground-state broadening, just referred to, is large enough to include these features. This appears to be exactly the situation which exists in copper and its solid solutions. In pure copper it is believed that the Fermi limit lies just beyond the peak of the density-of-states curve. Hence, in dilute solid solutions, the influence of this peak may be felt on the equilibrium properties and, in particular, on the low-temperature electronic specific heat. It will be shown that in such a case it leads to a slight increase in the specific heat even when the electron concentration remains constant. This increase is closely related to the residual electrical resistance and is determined by the matrix elements of the scattering potential.

2. PERTURBATION EXPANSION OF THE PARTITION FUNCTION

The partition function is obtained as a particularly simple example of the method introduced by Matsubara[1] and developed by Thouless.[2] Let H denote the complete Hamiltonian, N the number of electrons in a volume v, $\beta=1/kT$, and $\alpha=\mu\beta$. If μ denotes the partial potential α is the activity. The grand partition function Z is given by the trace of ψ, where

$$\psi=e^{\alpha N-\beta H}, \tag{1}$$

and

$$Z=\mathrm{Tr}\psi=\sum_n\langle n|e^{\alpha N-\beta H}|n\rangle. \tag{2}$$

The wave functions $|n\rangle$, which are used for the evaluation of the trace are Slater determinants of Bloch functions including the spin factor and relating to the pure metal.

To simplify the notation let

$$H-\mu N=H_0+V(\mathbf{r}), \tag{3}$$

where H_0 is the Hamiltonian of the pure metal minus μN, and $V(\mathbf{r})$ is the potential energy of an electron due to the randomly distributed impurity atoms. $V(\mathbf{r})$ is therefore the difference between the potential in the solid solution and that in the pure metal.

The interaction representation is defined by

$$\psi_I=e^{H_0\beta}\psi, \tag{4}$$

and if we write

$$H_1(u)=e^{H_0u}V(\mathbf{r})e^{-H_0u}, \tag{5}$$

or in terms of the creation and annihilation operators, $\tilde{C}_k(u)$, $C_k(u)$,

$$H_1(u)=\sum_{k,l}\langle k|V|l\rangle\tilde{C}_k(u)C_l(u), \tag{6}$$

then

$$\partial\psi_I/\partial\beta=-H_1(\beta)\psi_I, \tag{7}$$

which may be solved by iteration as follows:

$$\psi_I=1-\int_0^\beta du_1 H_1(u_1)+\int_0^\beta du_1\int_0^{u_1} du_2 H_1(u_1)H_1(u_2)$$
$$-\int_0^\beta du_1\int_0^{u_2} du_2\int_0^{u_2} du_3 H_1(u_1)H_1(u_2)H_1(u_3)+\text{etc.}, \tag{8}$$

where

$$\beta>u_1>u_2>u_3\cdots.$$

The above solution not only satisfies (7) but also the boundary condition, $\psi_I=1$, when $\beta=0$.

From (4) and (2) it follows that, with ψ_I as given by (8),

$$\frac{Z}{Z_0}=\frac{\sum_n\langle n|e^{-H_0\beta}\psi_I|n\rangle}{\sum_n\langle n|e^{-H_0\beta}|n\rangle}, \tag{9}$$

where Z_0 is the partition function relating to the pure metal. The terms of the sum (8) can be evaluated in a manner exactly analogous to that used for the determination of the energy of the ground state in the many-body problem.

Writing

$$H_0=\sum_k(\epsilon_k-\mu)C_k^+C_k,$$

it follows from relations similar to (5), and applicable to any operator, that

$$C_k(u)=C_ke^{-(\epsilon_k-\mu)u},$$
$$\tilde{C}_k(u)=C_k^+e^{(\epsilon_k-\mu)u}. \tag{10}$$

An essential feature of Matsubara's method (cf. Ref. 2) lies in the following definition of the normal product which ensures that its trace in (9) vanishes:

$$N[C_k^+C_k]=(1-f_k)C_k^+C_k-f_kC_kC_k^+. \tag{11}$$

For example, the contribution to Z/Z_0 of any normal product occurring in (8) is given by

$$(1/Z_0)\sum\langle n|e^{-H_0\beta}N[C_k^+C_k]|n\rangle$$
$$=(1/Z_0)\sum\langle n|e^{-H_0\beta}\{(1-f_k)C_k^+C_k-f_kC_kC_k^+\}|n\rangle, \tag{12}$$

which is zero, if

$$(1/Z_0)\sum\langle n|e^{-H_0\beta}C_k^+C_k|n\rangle=f_k,$$
and
$$(1/Z_0)\sum\langle n|e^{-H_0\beta}C_kC_k^+|n\rangle=1-f_k. \tag{13}$$

The number f_k, defined by (13), is just the occupation number for the state k, i.e.,

$$f_k=\{1+e^{\beta(\epsilon_k-\mu)}\}^{-1}. \tag{14}$$

The contractions then introduce factors f_k or $1-f_k$ as indicated below. Using the linked-graph theorem, the result to second order can be given in the following form.

$$\ln(Z/Z_0)=\ln(\sum\text{ all graphs})=\sum(\text{linked graphs})$$
$$=-\beta\sum_k V_{kk}f_k+\beta\sum_{k,l}|\langle k|V|l\rangle|^2$$
$$\times[f_k(1-f_l)/(\epsilon_l-\epsilon_k)]+\text{etc.} \tag{15}$$

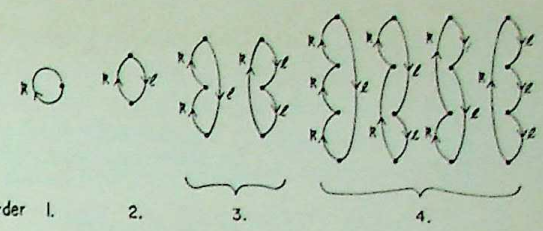

FIG. 1. Diagrams for the perturbation series of the partition function involving only two wave vectors.

The second-order term in (15) diverges logarithmically near the Fermi limit, and it is therefore necessary to make a partial summation over all orders of (8) in which only two wave vectors, k and l, are involved. If we represent the vertices by points with the values of u increasing upwards, the graphs of the terms to be summed are as shown in Fig. 1.

When the operators are u ordered as in (8), it follows from (13) that an upward line corresponds to $C_kC_k^+$ and gives a factor $1-f_k$ and a downward line to $C_l^+C_l$ which gives a factor f_l. The energy denominators for all these particular graphs are powers of $\epsilon_l-\epsilon_k$ and the matrix elements at the vertices either V_{kl}, V_{lk}, V_{kk}, or V_{ll}. [Henceforth we use this abreviated notation rather than that of (15).] It is now easy to see that the above sequence of graphs gives the following contribution to $\ln(Z/Z_0)$.

$$-\beta\sum_k V_{kk}f_k+\beta\sum_{k,l}\frac{|V_{kl}|^2f_k(1-f_l)}{\epsilon_l-\epsilon_k}$$
$$\times\left\{1-\left[\frac{V_{kk}f_k+V_{ll}(1-f_l)}{\epsilon_l-\epsilon_k}\right]+[\ ]^2-[\ ]^3+\cdots\right\}$$
$$=-\beta\sum_k V_{kk}f_k+\beta\sum_{k,l}\frac{|V_{kl}|^2f_k(1-f_l)}{\epsilon_l-\epsilon_k+\{V_{kk}f_k+V_{ll}(1-f_l)\}}, \tag{16}$$

which remains finite at the Fermi limit. It may be noted that the lower limits of the integrals in (8) (i.e., the zeros) give no contribution because factors like $e^{(\epsilon_k-\epsilon_l)\beta}$, etc., combine with f_k and f_l in such a way as to lead to exact cancellation. There are, of course, many other terms in the expansion of ψ_I, but all will involve higher powers of the nondiagonal matrix elements V_{kl}, and will therefore be neglected in the present approximate considerations.

The range of ϵ_k and ϵ_l (now written for convenience as ϵ and η, respectively) over which the summand of the second sum of (16) differs appreciably from zero is shown in Fig. 2.

Since all quantities in (16) apart from V_{kl} depend only on the energies of the states k and l, the first step in the summation is to average $|V_{kl}|^2$ over all relative directions θ of the vectors k and l, and to assume that the result depends only on ϵ and η. This assumption is correct if the matrix elements are calculated with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

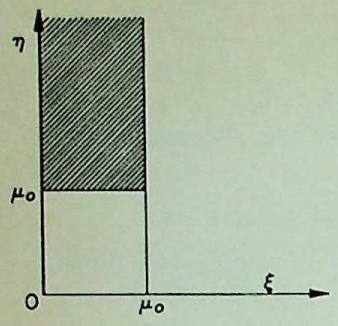

FIG. 2. Range of integration for the second-order correction to the partition function.

respect to free-electron wave functions. It will be assumed, therefore, that

$$\frac{1}{2}\int_0^{\pi} |V_{kl}|^2 \sin\theta d\theta = K(\epsilon,\eta) = K(\eta,\epsilon). \tag{17}$$

To simplify the calculations the following assumptions and approximations are also made: (i) that in the demoninator of (16) f_k and f_l may be replaced by their values at absolute zero, (ii) V_{kk} is independent of k and equal to a constant V. Hence, if $N(\epsilon)$ denotes the density of states, the sum (16) may be written as an integral as follows:

$$\begin{aligned}\int\int \frac{N(\epsilon)N(\eta)K(\epsilon,\eta)}{\eta-\epsilon+2V} f(\epsilon)[1-f(\eta)]d\epsilon d\eta \\ = \int_0^{\mu_0} d\epsilon \int_{\mu_0}^{\infty} d\eta \frac{N(\epsilon)N(\eta)K(\epsilon,\eta)}{\eta-\epsilon+2V} \\ + \int_{\mu_0}^{\infty} d\eta \int_0^{\infty} d\epsilon \frac{N(\epsilon)N(\eta)K(\epsilon,\eta)}{\eta-\epsilon+2V}\phi(\epsilon) \\ - \int_0^{\mu_0} d\epsilon \int_0^{\infty} d\eta \frac{N(\epsilon)N(\eta)K(\epsilon,\eta)}{\eta-\epsilon+2V}\phi(\eta),\end{aligned} \tag{18}$$

where

$$\phi(\epsilon) = \begin{cases} \{1+e^{\beta(\epsilon-\mu)}\}^{-1}, & \epsilon > \mu_0 \\ -\{1+e^{-\beta(\epsilon-\mu)}\}^{-1}, & \epsilon < \mu_0, \end{cases} \tag{19}$$

and the second and third integrals are taken along the boundary of the shaded region of Fig. 2. The term arising from the immediate neighborhood of (μ_0,μ_0) has been omitted as negligible compared with the others. In the last integral the symbols ϵ and η may be interchanged; and therefore, if

$$g(\epsilon) = \int_0^{\mu_0} \frac{N(\eta)K(\epsilon,\eta)}{\epsilon-\eta+2V} d\eta + \int_{\mu_0}^{\infty} \frac{N(\eta)K(\epsilon,\eta)}{\epsilon-\eta-2V} d\eta, \tag{20}$$

the whole of the second sum of (16) may be written

$$-\beta E_2 - \beta \int_0^{\infty} N(\epsilon)g(\epsilon)\phi(\epsilon)d\epsilon, \tag{21}$$

where E_2 is the second-order energy due to the perturbation and is independent of temperature. If E_1 denotes the energy correction in the first order, then

$$\ln Z = \ln Z_0 - \beta(E_1+E_2) - \beta \int_0^{\infty} N(\epsilon)g(\epsilon)\phi(\epsilon)d\epsilon. \tag{22}$$

The last term of (22) can be written

$$\begin{aligned}-\beta \int_0^{\infty} N(\epsilon)g(\epsilon)\phi(\epsilon)d\epsilon \\ = \beta \int_0^{\mu} \frac{N(\epsilon)g(\epsilon)d\epsilon}{1+e^{-\beta(\epsilon-\mu)}} - \beta \int_{\mu}^{\infty} \frac{N(\epsilon)g(\epsilon)d\epsilon}{1+e^{\beta(\epsilon-\mu)}}.\end{aligned} \tag{23}$$

Let $x=\beta(\epsilon-\mu)$, then

$$\begin{aligned}\beta \int_0^{\infty} N(\epsilon)g(\epsilon)\phi(\epsilon)d\epsilon = \int_0^{\infty} \frac{dx}{1+e^x}\left[N\left(\mu+\frac{x}{\beta}\right)g\left(\mu+\frac{x}{\beta}\right)\right. \\ \left. - N\left(\mu-\frac{x}{\beta}\right)g\left(\mu-\frac{x}{\beta}\right)\right],\end{aligned} \tag{24}$$

in which the usual approximation has been made of replacing the lower limit $-\beta\mu$ by $-\infty$ in one integral.

The partition function for the pure metal is well known and may be expressed

$$\begin{aligned}\ln Z_0 = \beta\{\mu n(\mu) - E(\mu)\} + \frac{1}{\beta}\int_0^{\infty} \ln(1+e^{-x}) \\ \times\left[N\left(\mu+\frac{x}{\beta}\right)+N\left(\mu-\frac{x}{\beta}\right)\right]dx,\end{aligned} \tag{25}$$

where

$$n(\mu) = \int_0^{\mu} N(\epsilon)d\epsilon, \quad \text{and} \quad E(\mu) = \int_0^{\mu} N(\epsilon)\epsilon d\epsilon, \tag{26}$$

are both functions of temperature through their dependence on μ. On substituting (24) and (25) into (22) it follows that for low temperatures,

$$\begin{aligned}\ln Z = \alpha n(\mu) - \beta[E(\mu)+E_1+E_2] \\ + \frac{\pi^2}{6\beta}\left\{N(\mu) - \left[\frac{d}{d\epsilon}N(\epsilon)g(\epsilon)\right]_{\mu}\right\}.\end{aligned} \tag{27}$$

It may be noted that $N(\mu)$ is the density of states including the factor 2 which arises as a consequence of each state being doubly occupied by electrons of opposite spins.

The properties of an assembly consisting of a fixed number of electrons are obtained by using the relation,

$$(\partial \ln Z/\partial\alpha)_{\beta} = \bar{n}, \tag{28}$$

to determine μ when $\bar{n}$ is constant. The energy is then given by

$$-(\partial \ln Z/\partial\beta)_{\alpha} = \bar{E}. \tag{29}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The specific heat of the system C_v (it has been assumed throughout that the volume is constant) is given by

$$C_v=-\frac{\beta^2}{k}\left(\frac{\partial\bar{E}}{\partial\beta}\right)_{\bar{n}}=\gamma T. \tag{30}$$

Although γ may readily be evaluated, it is sufficient for the present purpose to note that

$$\gamma=\gamma_0\left\{1-\frac{1}{N(\mu)}\left[\frac{d}{d\epsilon}N(\epsilon)g(\epsilon)\right]_\mu\right\}, \tag{31}$$

where γ_0 refers to the pure metal.

3. EVALUATION OF MATRIX ELEMENTS

It will be assumed that the potential $V(\mathbf{r})$ arises from ν screened unit positive charges randomly distributed through the volume v which contains N electrons and the same number of lattice sites. The solute concentration is therefore given by $c=\nu/N$. Hence

$$V(\mathbf{r})=-e^2\textstyle\sum_i \exp\{-\alpha|\mathbf{r}-\mathbf{R}_i|\}/|\mathbf{r}-\mathbf{R}_i|, \tag{32}$$

where $\mathbf{R}_i$ denotes the position of the solute atoms, and α is the reciprocal of the screening length.

If in order to estimate the magnitude of V_{kl} we use free-electron wave functions defined by

$$\psi_{\mathbf{k}}=\frac{1}{\sqrt{v}}e^{i\mathbf{k}\cdot\mathbf{r}}, \tag{33}$$

the following well-known result is readily obtained.

$$V_{kl}=-\frac{4\pi e^2}{v}\frac{1}{|\mathbf{k}-\mathbf{l}|^2+\alpha^2}\textstyle\sum_i e^{i(\mathbf{k}-\mathbf{l})\cdot\mathbf{R}_i}. \tag{34}$$

As a result of the random nature of the distribution of solute atoms,

$$|V_{kl}|^2=\left(\frac{4\pi e^2}{v}\right)^2\frac{\nu}{(|\mathbf{k}-\mathbf{l}|^2+\alpha^2)^2}. \tag{35}$$

The average of this expression over all directions of $\mathbf{l}$ relative to $\mathbf{k}$ depends only on k^2 and l^2 and therefore is in accordance with assumption (17).

In order to simulate the effect of the peak in the density of states of copper just below the Fermi limit and at the same time enable the integrals to be evaluated without too much difficulty we adopt the following model.

$$N(\eta)=N_0+Np\delta(\eta-\epsilon_1), \quad \epsilon_1<\mu_0, \tag{36}$$

where N_0 is a constant. Here p is a fraction of order 10^{-1}. It is further assumed that $K(\mu,\eta)\to 0$ for large values of η as would be the case with (35). Substituting (36) into (20) gives

$$g(\epsilon)=\int_0^{\mu_0}\frac{N_0K(\epsilon,\eta)}{\epsilon-\eta+2V}d\eta+\int_{\mu_0}^{\infty}\frac{N_0K(\epsilon,\eta)}{\epsilon-\eta-2V}d\eta+\frac{NpK(\epsilon,\epsilon_1)}{\epsilon-\epsilon_1+2V}. \tag{37}$$

When $\epsilon\simeq\mu_0$ it will be seen that the first two integrals are of opposite sign and tend to cancel each other, and their contribution to $g'(\mu)$ will not be considered further. The third term represents the effect of the peak in $N(\epsilon)$ and its variation with ϵ results mainly from the denominator. Hence a reasonable approximation is

$$g'(\mu)=-NpK(\mu,\epsilon_1)/(\mu-\epsilon_1+2V)^2, \text{ and } N'(\mu)=0. \tag{38}$$

Thus

$$\gamma=\gamma_0\left\{1+\frac{K(\mu,\epsilon_1)Np}{(\mu-\epsilon_1+2V)^2}\right\}. \tag{39}$$

To estimate the additional term in γ we use (35) and (17) and find

$$\frac{K(\mu,\mu)Np}{\mu^2}=\frac{(4\pi e^2)^2}{\Omega^2}\left(\frac{\hbar}{2m}\right)^2\frac{p}{\mu^2(w^2+4w\mu)}\left(\frac{\nu}{N}\right), \tag{40}$$

where Ω is the atomic volume which may be written $\Omega=\frac{4}{3}\pi r_s^3$, and $w=(\hbar^2/2m)\alpha^2$. Hence using the free-electron approximation to determine μ_0 and writing for simplicity, $w=\mu$,

$$\frac{K(\mu,\mu)Np}{\mu^2}=\frac{p}{5}\left(\frac{256}{4\pi^4}\right)^{1/3}\frac{(e^2/r_s)^2}{\mu^2}c, \tag{41}$$

which gives finally, neglecting $2V$ compared with $\mu-\epsilon_1$,

$$\gamma=\gamma_0\left\{1+\frac{0.13p}{(1-\epsilon_1/\mu)^2}\cdot\frac{(e^2/r_s)^2}{\mu^2}c\right\}. \tag{42}$$

Suppose the ratio of the two energies is unity, that ϵ_1 lies $\frac{1}{10}$ of μ_0 below the Fermi limit, and that $p\simeq 10^{-1}$, i.e., one-tenth of the electrons lie under the effective part of the peak. These rough estimates which seem reasonable enough then give $\gamma=\gamma_0(1+c)$, where c is the concentration expressed as a fraction.

4. RELATION TO RESIDUAL RESISTIVITY

Imagine a hole to exist in the Fermi distribution at absolute zero in the neighborhood of ϵ_1. Elastic scattering due to impurities will result in a finite lifetime τ of any particular state k of this hole. This lifetime will be approximately equal to the relaxation time for impurity resistivity. Each level therefore will have a width of order $\hbar/\tau$. The delta function of (36) is therefore effectively replaced by a function of width $\hbar/\tau$, and if $\mu-\epsilon$, is small part of the tail will overlap the Fermi limit and give a contribution to the linear electronic specific heat. This argument can be made semiquantitative as follows. The linewidth at ϵ may be written

$$\frac{\hbar/\tau}{\pi\{(\epsilon-\eta)^2+(\hbar/\tau)^2\}}, \tag{43}$$

and hence if the density of states in the pure metal is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$N_0(\eta)$ in the solid solution it is

$$N(\epsilon)=\int_0^\infty \frac{N_0(\eta)\hbar/\tau}{\pi\{(\epsilon-\eta)^2+(\hbar/\tau)^2\}}d\eta. \tag{44}$$

For the model in which the density-of-states $N_0(\eta)$ is as given by (36) it follows that

$$N(\mu)=N_0+\frac{(\hbar/\tau)Np}{\pi\{(\mu-\epsilon_1)^2+(\hbar/\tau)^2\}}. \tag{45}$$

Hence when $\hbar/\tau \ll \mu-\epsilon_1$, which implies that the correction is small and corresponds to a second-order effect,

$$N(\mu)=N_0+\frac{Np(\hbar/\tau)}{\pi\mu^2(1-\epsilon_1/\mu)^2} \tag{46}$$

and

$$\gamma=\gamma_0\left\{1+\frac{p(\hbar/\tau)}{\pi\mu(1-\epsilon_1/\mu)^2}\right\}, \tag{47}$$

where the approximation $N_0\mu \simeq N$ has been used. The relaxation time is given by the well-known formula,

$$\frac{\hbar}{\tau}=\frac{mkv}{2\pi\hbar^2}\int_0^\pi |V_{kl}|^2(1-\cos\theta)\sin\theta d\theta, \tag{48}$$

where $v=\Omega N$ is the volume which contains ν impurities and with respect to which the electronic wave functions are normalized. If we define half of the integral as $K'(\mu,\mu)$, then a simple calculation shows that

$$\hbar/\tau=3\pi NK'/2\mu, \tag{49}$$

and

$$\gamma=\gamma_0\{1+[3K'Np/2(\mu-\epsilon_1)^2]\}, \tag{50}$$

which is similar to (39) apart from the numerical factor 3/2, the neglect of $2V$ in the denominator and the different definitions of K and K'. Both derivations show that the addition to the electronic specific heat is proportional to the residual resistivity.

5. COMPARISON WITH EXPERIMENTAL RESULTS

The electronic specific heats of dilute solid solutions of Zn and Ge in Cu have been measured by Rayne[3] and by Veal and Rayne.[4] It is found that initially for small concentrations of the solute γ increases in both cases. Since the Fermi limit lies beyond the peak of the density of states a simple theory would suggest a decrease of γ due to the increase of the electron concentration. This decrease is easily calculated and is indicated by Veal and Rayne. If we attribute the difference between the observed increase and the expected decrease to virtual electron scattering and express the results for the initial slopes by giving the values of b in $\gamma/\gamma_0=1+bc$, where c is the fractional concentration, then for Zn we find $b=1.4$ and for Ge, $b=5.8$. Equation (42) appears therefore to give values of b of roughly the right magnitude. Moreover, as might be expected, Ge with the greater scattering power has the higher value.

There are other examples where the observed electronic specific heat is larger than would be anticipated from a simple band model. For example, Keesom and Kurrelmeyer[5] find for a copper-nickel alloy containing approximately 20 at.% Ni, a γ value which is 1.56 times as great as the γ value for pure Cu. Conventional theory visualizes the d band as just filled in $Cu_{60}Ni_{40}$. At 80% Cu the Fermi limit will be beyond the point where $N(\epsilon)$ rises steeply due to the d levels. A similar situation to that discussed in the preceding theory therefore exists and may perhaps be explained in the same way. The measurements of Hoare and his collaborators[6,7] on Ag-Pd and Au-Pt point in the same direction.

Motional Narrowing of Nuclear Magnetic-Resonance Lines in Manganese-Doped Lithium Fluoride*

T. G. Stoebe, T. O. Ogurtani, and R. A. Huggins
Department of Materials Science, Stanford University, Stanford, California
(Received 6 January 1964)

Nuclear magnetic-resonance experiments have been performed between 25 and 550°C in LiF powder doped with manganese. Motional narrowing of the Li^7 resonance line occurred somewhat below 400°C. Resonance absorption lines were not observable in the temperature range 200–390°C, probably because an effective loss of paramagnetic relaxation centers increased the spin-lattice relaxation time. Electron spin-resonance experiments verified that the paramagnetic manganese does cluster upon heating above 200°C. A method of analysis is developed which eliminates errors due to constant linewidth contributions in the analysis of motional narrowing data in terms of diffusion activation energies. The activation energy for motion of Li ion vacancies in LiF is found to be 0.74 eV.

I. INTRODUCTION

MOTIONAL narrowing of nuclear magnetic-resonance lines has been used to investigate extrinsic diffusion in several doped ionic crystals. Examples include[1] LiBr where vacancies present on Li sites gave rise to extrinsic Li-ion diffusion, and[2,3] CaF_2 where F ions were seen to diffuse. In the present study, motional narrowing is observed in manganese-doped LiF powder. The substitution of Mn^{2+} ions for Li^+ ions in LiF gives rise to an equal number of Li-ion vacancies to maintain charge neutrality. For this reason, it is possible to interpret motional narrowing in this system in terms of the diffusion of Li-ion vacancies.

II. EXPERIMENTAL TECHNIQUES

Powdered LiF samples were prepared by precipitation with NH_4F from an aqueous solution of LiCl containing 0.1% $MnCl_2$. They were subsequently filtered, washed, and then dried at 100°C for a short time. The Li^7 nuclear magnetic-resonance absorption line was observed at 7.5 Mc/sec using a modified Varian wide-line spectrometer. Experiments were performed between 25 and 550°C by inserting an air-cooled high-temperature Dewar in the Varian probe.

III. METHOD OF DATA ANALYSIS

To date, the analysis of motional narrowing curves to give diffusion coefficients has been only moderately successful. In metallic aluminum[4] and lithium,[5,6] experimental activation energies for diffusion have varied from values obtained by other techniques[7–9] by up to 30%. This is due both to changes in lineshape and constant contributions to the linewidth, which make data analysis uncertain.

A method has been developed which enables analysis of motional narrowing data to produce accurate values of diffusion activation energies. It eliminates errors due to any constant contributions to the linewidth, including magnetic-field inhomogeneities, and is applicable in temperature regions where the lineshape is nearly constant.

Since narrowed lines are nearly Lorentzian,[10] the actual dipolar linewidth δH_d can be related to the diffusion coefficient D by the relation

$$\delta H_d = C\delta H_0 D^{-1} = A\exp(E/kT), \tag{1}$$

where E is the activation energy for motion of Li-ion vacancies. The constant A contains the concentration of vacancies in the system and the factor relating the linewidth to $(1/T_2)$. The relation between the measured line width δH_m and the actual dipolar linewidth can be written

$$\delta H_m = a\delta H_d + b\delta H_1, \tag{2}$$

where δH_1 is a constant.

One of the methods of data analysis that has been used by others consists of plotting $\ln\delta H_m$ versus $1/T$ and equating the slope of the curve to E/k. If, however, a constant addition to the line width is present such as given in (2), the slope S obtained in this manner is not E/k but rather

$$S = \frac{d\ln\delta H_m}{d(1/T)} = \frac{E}{k}\frac{1}{[1+(b\delta H_1/aA)e^{-E/kT}]}. \tag{3}$$

Equation (3) shows that S becomes smaller than E/k at higher temperatures, which is the region of interest in the present case.

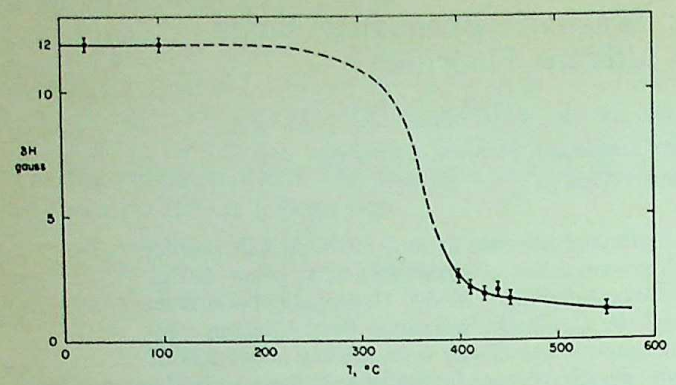

FIG. 1. Linewidth of Li^7 resonance line in Mn-doped LiF as a function of temperature.

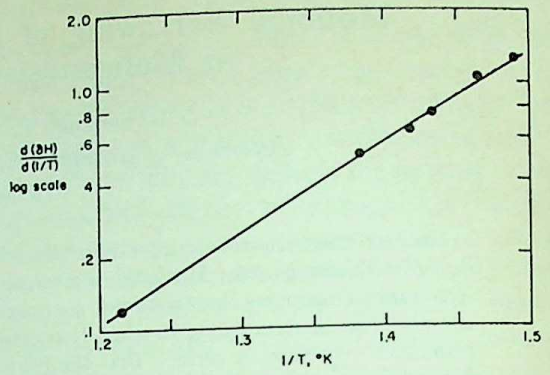

FIG. 2. Plot of $\ln[d\delta H/d(1/T)]$ versus $1/T$ for the data of Fig. 1, which yields activation energy of 0.74 eV. (*Note added in proof.* The scale on abscissa and ordinate should contain a factor of 10^3.)

If, however, δH_m is first differentiated with respect to $1/T$, followed by taking the logarithm of this derivative, we have

$$\ln\Delta \equiv \ln\frac{d\delta H_m}{d(1/T)} = \text{const} + \frac{E}{kT}. \qquad (4)$$

The slope S of a plot of $\ln\Delta$ versus $1/T$ will now yield the true value of E/k, independent[11] of δH_1. This analysis is easily performed, since Δ can be evaluated at several temperatures on a plot of the experimental data for δH_m versus $1/T$.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

The temperature variation of the observed linewidth, defined as the width in gauss between the points of maximum and minimum slope, is given in Fig. 1. The limits of error shown were determined from estimates of the experimental accuracy in determining the linewidth and from the variations between values obtained from several experimental measurements at the same temperature. The room-temperature values of linewidth may be compared with the half max-min linewidth of about 6 G given by Chang *et al.*[12,13] in similar samples at 77°K. Nuclear-resonance lines of F^{19} in this material narrowed by about 25% in the same temperature range in which the Li^7 narrowed.

Absorption lines could not be obtained in the temperature interval 200–390°C because of a long spin-lattice relaxation time. This was probably caused by an effective loss of paramagnetic-relaxation centers from the system. Electron spin-resonance experiments were performed, indicating that the manganese ions are uniformly distributed in the lattice at room temperature. After heating the samples for short times above 200°C, the electron spin-resonance line observed at room temperature loses its hyperfine structure due to a strong exchange interaction. This is probably due to clustering of Mn in the Li sublattice, similar to the clustering observed by Jennings[14] in Mn-doped LiCl single crystals. The electron spin-resonance spectra before heating are very similar to those observed by Chang *et al.*[12,13]

The analysis described in Sec. III has been performed on the high-temperature data of Fig. 1. The resulting straight line, shown in Fig. 2, yields an activation energy of 0.74 eV, with a precision of about 10%. This is in good agreement with the activation energies obtained in the extrinsic region by investigators using other techniques; electrical-conductivity results[15] have given $E=0.65$ eV and spin-echo experiments in single crystals[16] have given 0.71 eV. By comparison of the present data with the results of electrical conductivity experiments,[15] it can be determined that the vacancy concentration in the present work is about 5×10^{-5}.

[11] It should be noted that if we include the bilinear term in the expansion of Eq. (2), $(c\delta H_d\delta H_1)$, nothing is changed in the result except the constant a.

PHYSICAL REVIEW VOLUME 134, NUMBER 4A 18 MAY 1964

Localized Mode in an Anharmonic Crystal*†

WILLIAM M. VISSCHER
University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico
(Received 8 April 1963, revised manuscript received 17 January 1964)

We consider a harmonic crystal with a single isotopic impurity whose coupling to its neighbors includes a cubic anharmonic term. The impurity is chosen to be light enough that a localized mode exists. The Hamiltonian for this system is truncated, in a physically reasonable way, so as to yield an exactly solvable Schrödinger equation. The solutions give a new insight into the nature of the localized mode, which in this approximation is exactly analogous to an unstable particle in the Lee model of field theory. The wave functions are exhibited and the lifetime is calculated for a light impurity in a simple cubic lattice at $T=0$.

I. INTRODUCTION

AN isolated impurity in a harmonic crystal gives rise to certain changes in the vibration spectrum[1–5] of the system. In particular, if the impurity is lighter than the host-crystal atoms and the impurity-mass to host-mass ratio is less than a certain critical number dependent on the atomic arrangement, then a so-called localized mode appears above the quasicontinuum of phonons. The characteristics of this mode are that when it is excited only the atoms near the impurity participate in the motion (the attenuation length decreases as the frequency increases); and that its frequency is higher than the maximum phonon frequency. The latter may be looked upon as the reason why the mode *is* localized; its frequency is too high to propagate in the lattice. The localized mode is a single normal mode of the system, with a sharp frequency.

It is the purpose of this note to investigate what happens to the localized mode when the interatomic force is allowed to contain certain anharmonic terms.[6] The "single-particle" description of independent oscillators (harmonic forces only) then goes over into the analog of an interacting many-body system, and the physics and mathematics encountered is similar to that which occurs in a wide variety of problems. The localized mode state of the harmonic approximation becomes mixed with the multiphonon states whose energies lie nearby. The strength of the anharmonic interaction determines the width of the energy interval in which the mixing occurs; the energy width in turn governs the coherence of the localized mode (now only an approximate eigenstate) and therefore its lifetime.

Lowest order perturbation theory involves the calculation of the diagram shown in Fig. 1, with time increasing from left to right. The single localized mode which is present in the initial state (dashed line) decays into two phonons in the final state (wavy lines) through a cubic anharmonic interaction. The matrix element of the interaction operator

$$h=\sum_{lm} B_{klm}a_m^\dagger a_l^\dagger a_k \tag{1}$$

between a localized mode state (k) and a state in which two phonons (l and m) are present is all that is involved in the perturbation calculation. Such a calculation has been performed by Klemens,[6] who used the phonon operators of the perfect crystal, and the localized mode operator[7] of Montroll and Potts.[2]

The interaction Eq. (1) is one of the terms which arise from the expansion of a cubic anharmonic term in the lattice potential energy

$$H'=\sum_{ij} C_{ij}(\mathbf{x}_i-\mathbf{x}_j)^3 \tag{2}$$

in terms of the phonon and localized mode creation and annihilation operators. The cubic anharmonic term has no lower bound for large relative displacements; hence one would not expect any solutions of a problem in which it is the only perturbation. For our anharmonic interaction, however, we choose only a part of Eq. (2),

[6] This question has been studied before by different methods. See P. G. Klemens, Phys. Rev. 122, 443 (1961) and A. A. Maradudin, *1962 Brandeis Lectures in Theoretical Physics* (W. A. Benjamin and Company, Inc., New York, 1963), Vol. 2.

[7] The localized mode displacements assumed by Klemens were those given by Montroll and Potts as asymptotic forms, except that he inadvertently omitted the alternation of sign with each successive lattice distance from the impurity. This omission tends to make Klemens' result for the width too large, as does the fact that he used phonon operators for the perfect harmonic crystal rather than those for the harmonic crystal with a single isolated impurity.

such that the resulting systems may easily be solved exactly. Our method exhibits the solutions for the wave function explicitly, hence has an esthetic advantage over a perturbation calculation, although the quantitative results should be taken only to lowest order in the anharmonicity parameters.

We shall keep only Eq. (1) and its Hermitian conjugate and consider their sum to be the anharmonic interaction and drop the rest of the terms in Eq. (2). The principal justification for this is that it allows an exact solution to be easily obtained, but it is possible to argue as follows that at least some of the dropped terms are unimportant. The anharmonic interaction is large only when the displacements are large, and the displacement of any atom in the crystal due to the excitation of a single phonon is proportional to $N^{-1/2}$, where N is the total number of atoms. On the other hand, the localized mode displacements do not vanish as one lets $N\to\infty$, but approach a finite limit which decreases more or less exponentially with distance from the impurity atom. It might therefore be reasonable to expect that the most important terms in the expansion of Eq. (2) are those which involve the creation or annihilation of one or more localized modes. Most of the terms in the expansion of Eq. (2) do not satisfy this criterion.

We therefore take

$$H'=h+h^\dagger \tag{3}$$

as our anharmonic interaction. The basic Feynman diagram is Fig. 1 and the time-reverse of it, and we have essentially defined a Lee model[8,9] of the anharmonic crystal.

The total Hamiltonian for this model is

$$H=H_0+H', \tag{4}$$

where H_0 is the harmonic Hamiltonian

$$H_0=\sum_s \hbar\omega_s(n_s+\tfrac{1}{2}),$$

$$n_s=a_s^\dagger a_s.$$

II. EIGENSTATES AND EIGENVALUES

The ground state of H is the same as that of H_0, and the one-phonon states are identical too. It is only when we get to the one localized mode state and the states containing two phonons that the effects of H' begin to be felt.

We therefore consider the localized mode state, which is mixed by H' with two phonon states, and let

$$\Psi=C_k\Phi_k+\sum C_{lm}\Phi_{lm}, \tag{5}$$

where the C's are constants subject to a normalization condition

$$|C_k|^2+\sum_{lm}|C_{lm}|^2=1, \tag{6}$$

and

$$\Phi_k=a_k^\dagger\Phi_0,$$
$$\Phi_{lm}=2^{-1/2}a_l^\dagger a_m^\dagger\Phi_0, \tag{7}$$

with Φ_0 the ground state, and k always referring to the localized mode, l, m to phonons in the quasicontinuum.

By requiring that Eq. (5) be an eigenstate of H with eigenvalue E one immediately obtains

$$(E-\epsilon_k)C_k=2^{1/2}\sum_{lm}B_{klm}^\dagger C_{lm},$$
$$(E-\epsilon_{lm})C_{lm}=2^{1/2}B_{klm}C_k, \tag{8}$$

where ϵ_k and ϵ_{lm} are eigenvalues of H_0 with Φ_k and Φ_{lm}, respectively. Therefore unless E happens to coincide with one of the ϵ_{lm}'s or C_k vanishes we must have

$$E-\epsilon_k=2\sum_{lm}\frac{|B_{klm}|^2}{E-\epsilon_{lm}}, \tag{9}$$

which has as many solutions $E=E_\lambda$ as there are terms in the sum, plus one. Equation (9) is very similar to that obtained by Glaser and Källen[9] in their investigation of a Lee model[8] for an unstable particle. A graph of the right- and left-hand sides of Eq. (9) appears in Fig. 2. The intersections define the set of eigenvalues E_λ.

Certain features of Fig. 2 deserve comment. One is that for a given size crystal it is always possible to have a single negative eigenvalue E_λ for the anharmonic coefficients B_{klm} large enough. However, because as it is defined in Eq. (1) B_{klm} should decrease as $N^{-1/2}$ in order to correspond with Eq. (2) with C_{ij} independent of N; the point of appearance of the negative eigenvalue as a function of anharmonic-force strength will be independent of crystal size for large crystals. The negative eigenvalue appears only for very large B_{klm}. Its existence is due to the fact that our Hamiltonian is not positive definite. Another feature is that an eigenvalue pops up out of the quasicontinuum, reminiscent of the appearance of the localized mode in the harmonic case.

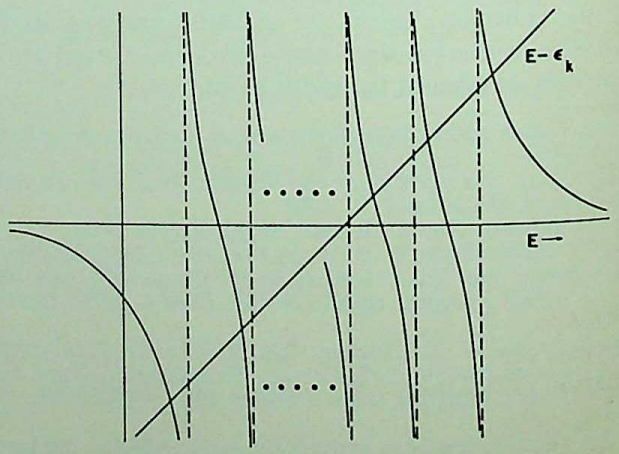

FIG. 2. Graphical solution of Eq. (9). The lowest asymptote will generally be at an energy of order $\hbar\omega_L/N$, the highest slightly below $2\hbar\omega_L$, where ω_L is the maximum phonon frequency.

This state appears at a smaller, but still unphysically large, value of the anharmonic coupling. Like the negative eigenvalue, the critical-coupling parameter at which the positive energy state appears becomes independent of crystal size for large crystals.

III. COMPLETENESS

Since it is our purpose to study the evolution of the localized mode state as anharmonic forces are introduced, it behooves us to be sure that the set of states given by Eqs. (5) and (8) really spans that part of the Hilbert space which can be reached by operating repeatedly with the anharmonic Hamiltonian on the harmonic localized mode state Φ_k. To do this it is sufficient to show that

$$\sum_\lambda \Psi_\lambda \Psi_\lambda^\dagger = \Phi_k \Phi_k^\dagger + \sum_{lm} \Phi_{lm} \Phi_{lm}^\dagger , \tag{10}$$

where Ψ_λ is an eigenfunction of the Hamiltonian [Eq. (4)] with eigenvalue E_λ [a root of Eq. (9)], and which has the form of Eq. (5). The calculation is straightforward and proceeds as follows. Upon substitution of Eq. (5) into (10), we obtain

$$\begin{aligned}\sum_\lambda \Psi_\lambda \Psi_\lambda^\dagger = &\sum_\lambda C_k(\lambda) C_k^\dagger(\lambda) \Phi_k \Phi_k^\dagger \\ &+ \sum_{lm} C_{lm}(\lambda) C_{lm}^\dagger(\lambda) \Phi_{lm} \Phi_{lm}^\dagger \\ &+ \sum_{l'm' \neq lm} C_{l'm'}(\lambda) C_{lm}^\dagger(\lambda) \Phi_{l'm'} \Phi_{lm}^\dagger \\ &+ \sum_{lm} C_k(\lambda) C_{lm}^\dagger(\lambda) \Phi_k \Phi_{lm}^\dagger \\ &+ \sum_{lm} C_{lm}(\lambda) C_k^\dagger(\lambda) \Phi_{lm} \Phi_k^\dagger , \end{aligned} \tag{11}$$

and illustrate by calculating the coefficient of $\Phi_k \Phi_k^\dagger$.

We introduce a function $C_k(E)$ of the complex variable E, which has the property that it coincides with $C_k(\lambda)$ at $E=E_\lambda$, and is analytic in a small region surrounding each E_λ. Then

$$\sum_\lambda C_k(\lambda) C_k^\dagger(\lambda) = \frac{1}{2\pi i} \int_C C_k(E) C_k^\dagger(E) d \ln D(E) , \tag{12}$$

where

$$D(E) = E - \epsilon_k - F(E) , \tag{13}$$

and

$$F(E) = 2 \sum_{lm} \frac{|B_{klm}|^2}{E - \epsilon_{lm}} , \tag{14}$$

The contour C encircles the roots of $D(E)$ in a counterclockwise sense, and excludes any singularities of $C_k(E)$. Equation (12) follows from the fact that the eigenvalues E_λ are the roots of $D(E)$. Now, from Eqs. (6) and (8) we see that to within a phase factor

$$C_k(E) = [1 - F'(E)]^{-1/2} \tag{15}$$

has the properties we require for $C_k(E)$, and therefore

$$\sum_\lambda C_k(\lambda) C_k^\dagger(\lambda) = \frac{1}{2\pi i} \int_C \frac{dE}{E - \epsilon_k - F(E)} = 1 , \tag{16}$$

which follows by expanding the contour to an infinite circle. Using some care in excluding the singularities of the C's, the other coefficients in Eq. (11) can be similarly shown to be unity or to vanish, and Eq. (10) follows.

IV. LIFETIME OF LOCALIZED MODE

If we imagine that in the anharmonic crystal we can somehow excite the *harmonic* localized mode, its lifetime may easily be calculated. To do this it suffices to calculate

$$(\Psi(0), \Psi(t)) = (\Phi_k, \Psi(t)) , \tag{17}$$

with

$$\Psi(t) = \sum_\lambda C(\lambda) \Psi_\lambda e^{-iE_\lambda t} , \tag{18}$$

and the C's chosen so that

$$\Psi(0) = \Phi_k . \tag{19}$$

Equation (19) implies that

$$C(\lambda) = C_k^\dagger(\lambda) , \tag{20}$$

and the scalar product of Eq. (17) is easily seen to be

$$(\Psi(0), \Psi(t)) = \frac{1}{2\pi i} \int_C e^{-iEt} \frac{1}{E - \epsilon_k - F(E)} dE . \tag{21}$$

Because of the presence of the exponential we can't evaluate the integral as easily as before, and must carefully study the denominator in the integrand.

If we are interested in times short compared to the longest periods of vibration of the crystal, then we may as well consider the infinite crystal. Therefore, we study the behavior of $F(E)$ in the limit $N \to \infty$. It will become an integral

$$F(E) = \int_0^{2\hbar\omega_L} \frac{\rho(k,\epsilon) d\epsilon}{E - \epsilon} \tag{22}$$

with $\rho(k,\epsilon)$ real and positive, of form similar to that encountered in many fields, but in particular in the theory of lattice-vibration spectra. $F(E)$ has acquired a cut in the locus of the poles it had before $N \to \infty$; the poles, in other words, have become dense along the real axis from 0 to $2\hbar\omega_L$. By analogy with similar integrals which have been calculated in other connections, we can sketch (Fig. 3) the real and imaginary parts of $F(E-i\delta)$, where δ is an infinitesimal positive number. The qualitative features of Fig. 3 which are certainly independent of the crystal model used are the general behavior of the real part for $E<0$ and $E>2\hbar\omega_L$; the fact that the imaginary part is positive for $0<E<2\hbar\omega_L$ and vanishes outside this range, and the rapid increase

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

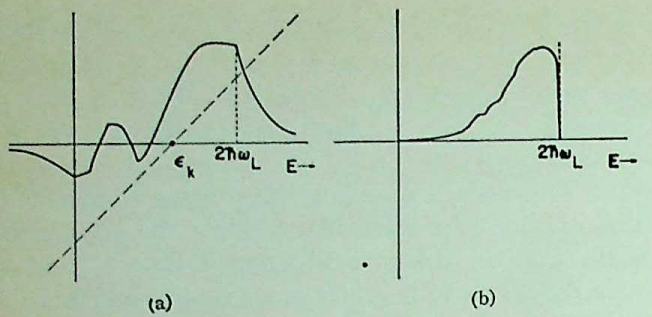

FIG. 3. Real (a) and imaginary (b) parts of $F(E-i\delta)$ for $N\to\infty$. The dashed line in (a) is $E-\epsilon_k$. Notice that, in this model, for a very large anharmonic term, the localized mode (defined now by the intersection) is an eigenstate, since then the imaginary part of F vanishes. For a realistically small anharmonic force, however, the intersection will not be far removed from ϵ_k.

in general of the absolute values of the real and imaginary parts of $F(E)$ as E increases from 0 to $2\hbar\omega_L$. This latter follows from the rapid increase of the density of states of two phonons which is a factor in $\rho(k,\epsilon)$.

$D(E)$ and hence the denominator of the integrand of Eq. (21) can never have any roots but real ones, because of the Hermiticity of the Hamiltonian. We can therefore contract the contour around the cut and obtain

$$(\Psi(0),\Psi(t))=\frac{1}{\pi}\int^{2\hbar\omega_L} e^{-iEt}\frac{h(E)dE}{[E-\epsilon_k-g(E)]^2+h^2(E)}, \quad (23)$$

where we have set

$$F(E-i\delta)=g(E)+ih(E). \quad (24)$$

The form of Eq. (23) is such that if $h(E)$ is small and $g(E)$ is slowly varying in the neighborhood of E_0 where E_0 is chosen such that

$$E_0-\epsilon_k-g(E_0)=0, \quad (25)$$

then it becomes approximately

$$(\Psi(0),\Psi(t))=e^{-iE_0t}e^{-\Gamma t/2} \quad (26)$$

with

$$\Gamma/2=h(E_0)=\pi\rho(k,E_0). \quad (27)$$

This is the same result which would be obtained from first-order perturbation theory, except there E_0 would be replaced by ϵ_k. To obtain a numerical answer from Eq. (27) one needs first to find out what B_{klm} is implied by a reasonable form of C_{ij} in Eq. (2); this is not a trivial task because it involves finding the eigenvectors of the secular matrix of the imperfect harmonic crystal.

V. CALCULATION OF $F(E)$

We shall now take a simple model for the harmonic crystal with a single impurity, for which we already know the eigenvectors,[10] and calculate $F(E)$ as expressed in Eq. (14).

[10] W. M. Visscher, Phys. Rev. 129, 28 (1963).

A simple and perhaps fairly reasonable form for the anharmonic energy is

$$H'=b(x_{000}-x_{100})^3-b(x_{000}-x_{-100})^3, \quad (28)$$

where x_{ijk} is the displacement in the x direction of the atom in the (ijk) simple cubic lattice site from its equilibrium position. In the model that we are using motions in the 3 Cartesian direction are independent and separable, so Eq. (28) represents a general central cubic anharmonic interaction between the impurity at (000) and its nearest neighbors. For positive b, H' gives rise to an extra repulsion for small interatomic distances, an extra attraction for large ones. It can be thought of as representing a physical situation where the impurity is a misfit in an otherwise perfect harmonic crystal.

If we now expand x_{ijk} in terms of the creation-annihilation operators $a_s^\dagger$, a_s according to

$$x_{ijk}=\sum_s (C_{s,ijk}{}^\dagger a_s{}^\dagger+C_{s,ijk}a_s)=\sum_s x_{ijk}{}^s, \quad (29)$$

(where the sum is over the normal modes of the imperfect harmonic crystal) and substitute into Eq. (28), we can pick out the terms having the form of those contained in h [Eq. (1)].

$$h=3b\sum_{l,m}[(C_{l,000}-C_{l,100})(C_{m,000}-C_{m,100})-(C_{l,000}-C_{l,-100})(C_{m,000}-C_{m,-100})]\times(C_{k,000}{}^\dagger-C_{k,100}{}^\dagger)a_l{}^\dagger a_m{}^\dagger a_k. \quad (30)$$

Here, as before, l and m refer to normal modes in the quasicontinuum of the imperfect harmonic crystal (phonons), and k refers to the localized mode.

In arriving at Eq. (30) we have made use of the fact that the localized mode is always an even excitation of the lattice about the impurity position, i.e., $C_{k,100}=C_{k,-100}$. If we were to use boundary conditions such that the phonons, too, are either even or odd with respect to the impurity position, then the contributions to the sum in Eq. (30) will have (l even, m odd) or (l odd, m even). Thus

$$B_{klm}=6b(C_{l,000}-C_{l,100})(C_{m,-100}-C_{m,100})\cdot(C_{k,000}{}^\dagger-C_{k,100}{}^\dagger)a_l{}^\dagger a_m{}^\dagger a_k \quad (31)$$

for l corresponding to an even mode; B_{klm} vanishes otherwise.

Specializing now to the case of a mass impurity (no change in the harmonic forces connecting the impurity to its neighbors) we can calculate the C's.

Equation (5′) of Ref. 10 may be written

$$x_{ijk}{}^s=g_{ijk,000}{}^s\delta\mu\omega_s{}^2x_{000}{}^s, \quad (32)$$

where $g^s=g(\omega_s{}^2)$ is given there in Eq. (23′), and $\delta\mu$ is the difference between the impurity and host mass. Equation (32) implies that the frequencies of the normal modes for which the displacement of the impurity atom

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

does not vanish are given by the roots of

$$g_{000,000^s}\delta\mu\omega_s^2=1\,, \tag{33}$$

and that the C's of Eq. (31) satisfy

$$C_{s,\alpha}=(g_{\alpha 0^s}/g_{00^s})C_{s,0} \tag{34}$$

for the even modes, and for the odd modes the C's are the same as for the perfect crystal. In Eq. (34) we have denoted the triplet (ijk) by α. For the even modes, then, a complete specification of the C's awaits only a normalization condition, which, upon requiring that

$$[p_\alpha,x_{\alpha'}]=-i\hbar\delta_{\alpha\alpha'} \tag{35}$$

and

$$[a_s,a_{s'}{}^\dagger]=\delta_{s's}\,, \tag{36}$$

can be straightforwardly shown to be

$$|C_{s,0}|^2=\frac{\hbar}{2\omega_s\mu}(g_{00^s})^2\Big/\left[\sum_\gamma(g_{\gamma 0^s})^2+\frac{\delta\mu}{\mu}(g_{00^s})^2\right]. \tag{37}$$

Then, if we use the fact that

$$g_{00^s}-g_{10^s}=2(\omega_s/\omega_L)^2g_{00^s}+(2/\mu\omega_L{}^2)\,, \tag{38}$$

which can be verified from the forms of the g's given in Eq. (25′) of Ref. 10, Eq. (31) can be rewritten

$$|B_{klm}|^2=(24b)^2(\mu'/\mu)^4k^4l^4|C_{k,0}|^2|C_{l,0}|^2 \times|C_{m,1}-C_{m,-1}|^2, \tag{39}$$

where $\mu'=\mu+\delta\mu$ and $l=\omega_l/\omega_L$, $k=\omega_k/\omega_L$, and where m refers to an odd mode in which the impurity is located at a node. It then follows that $C_{m,\alpha}$ is not different from that for the perfect lattice, and therefore

$$|C_{m,1}-C_{m,-1}|^2=(\hbar/2\mu N\omega_m)4\sin^2\varphi_x{}^m, \tag{40}$$

where N is the number of atoms in the crystal and $\varphi_x{}^m$ is the x component of the wave vector of the mth phonon.

We are now in a position to write down an integral form for the sum in $F(E)$, Eq. (14). The sum over l can be replaced by an integral as follows:

$$\sum_l|C_{l,0}|^2\rightarrow\frac{1}{2\pi i}\int_C\frac{\hbar}{2\omega_l}\frac{d\omega_l{}^2}{(g_{00}{}^l)^{-1}-\delta\mu\omega_l{}^2}\rightarrow \frac{\hbar}{2\pi\gamma}\int_0^{\omega_L}d\omega_lG(l)\,, \tag{41}$$

where the contour encircles the zeroes of the denominator in the range $0<\omega_l<\omega_L$, and the second step is achieved upon taking the limit $N\rightarrow\infty$ and contracting the contour about the cut which then appears from 0 to ω_L.

$$G(l)=2\gamma\frac{\mathrm{Im}g_{00}{}^l(\omega_l{}^2-i\epsilon)}{(1-\delta\mu\omega_l{}^2\,\mathrm{Re}g_{00}{}^l)^2+(\delta\mu\omega_l{}^2\,\mathrm{Im}g_{00}{}^l)^2}\,, \tag{42}$$

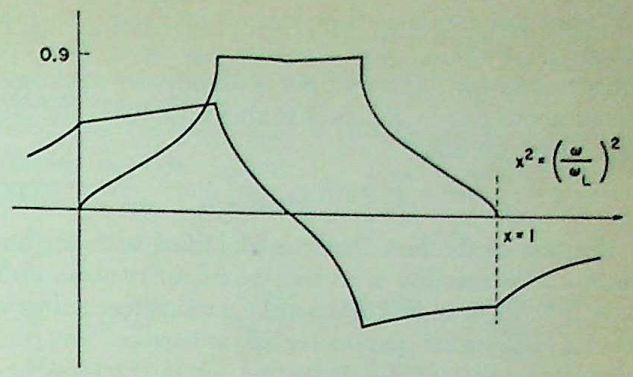

FIG. 4. Real and imaginary parts of $2\gamma g_{00}(\omega)$.

and γ is the harmonic force constant. The sum over m can be similarly expressed:

$$\sum_m\frac{\hbar}{2\mu N\omega_m}\rightarrow\frac{\hbar}{2\pi\gamma}\int_0^{\omega_L}d\omega_mG_0(m)\,, \tag{43}$$

where

$$G_0(m)=2\gamma\,\mathrm{Im}g_{00}(\omega_m{}^2-i\epsilon)\,. \tag{44}$$

Now, if we take E to be removed from the real axis, we can write

$$F(E)=2\left(\frac{24b\hbar\omega_L}{\pi\gamma}\right)^2\left(\frac{\mu'}{\mu}\right)^4k^4|C_{k,0}|^2 \cdot\int_0^1\frac{dldml^4G(l)G_0(m)\langle\sin^2\varphi_x{}^m\rangle}{E-\epsilon_l-\epsilon_m}\,, \tag{45}$$

where the bracket denotes an average over all modes with energy ϵ_m. The dimensionless function $G(l)$ has been calculated numerically in Ref. 10; its shape for various impurity masses is exhibited in Fig. 9 of that paper and Fig. 4 of the present paper shows the real and imaginary parts of g_{00}. $|C_{k,0}|^2$ is, as can be seen from Eq. (29), just the contribution of the localized mode to the mean-square displacement of the impurity; this has also been calculated in Ref. 10. We can, semiquantitatively, identify

$$bC_{k,0}/\gamma=r \tag{46}$$

as the ratio of the anharmonic potential energy of the impurity atom to its harmonic energy when the localized mode is excited.

The imaginary part of $F(E)$, according to Eq. (27), is equal to the half-width of the localized mode line.

$$\Gamma/2=h(E)=\frac{2\hbar\omega_L}{\pi}(24r)^2\left(\frac{\mu'}{\mu}\right)^4k^4 \cdot\int_0^1dll^4G(l)G_0\left(\frac{E}{\hbar\omega_L}-l\right)\left\langle\sin^2\varphi_x\left(\frac{E}{\hbar\omega_L}-l\right)\right\rangle. \tag{47}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

An approximate numerical integration[11] for the case where $E=1.12\hbar\omega_L$, which is the harmonic localized mode energy for this model if $\mu'=0.5\,\mu$, yields the result that the integral in Eq. (47) is about 5×10^{-3}. For this case, then, we find

$$\Gamma/2\approx0.2\hbar\omega_L r^2. \tag{48}$$

Because of the fact that r is identified with the anharmonic interaction of an isolated impurity atom with its neighbors, it is difficult to make a numerical estimate for it. The usual parameter of anharmonicity, the Grüneisen constant,[12] is measured for interactions between atoms of the host crystal. But if we associate these quantities with each other, we find that a reasonable Grüneisen constant (of the order of unity) for a crystal implies that r for the force between each atom and its nearest neighbors is of the order of 10^{-2}. Therefore, from Eq. (48) we see that the order of magnitude of the ratio of the half-width to energy of the anharmonic localized mode is 10^{-4}. Within the limitation of the calculations, this result is not in disagreement with the widths obtained in the references cited above.[6] No careful quantitative work will be done here, because we do not believe the model we use to be realistic enough to warrant it. The significance of the present work lies more in the form than in the magnitude of the answers.

The real part of $F(E)$ is just Eq. (45) with the integral replaced by a principal value integral. It will be of the same order-of-magnitude as the imaginary part; hence the shift of the localized mode (downward in energy for frequencies close to the phonon cutoff) is comparable to its width.

[11] An analytic approximation can be made in the limit of small impurity mass.

Energy Bands for the Iron Transition Series*

L. F. Mattheiss†
Solid-State and Molecular Theory Group, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received 16 December 1963)

Preliminary energy-band calculations for elements of the iron transition series have been completed using the augmented plane-wave method. The results include plots of energy as a function of wave vector along a line of symmetry for elements crystallizing in the face-centered cubic (Ar, Co, Ni, Cu), body-centered cubic (V, Cr, Fe), and hexagonal close packed (Ti, Zn) structures. These results indicate the presence of systematic trends in the band structures for the various elements and provide some justification for the application of the rigid band model to transition metals and their alloys.

I. INTRODUCTION

ENERGY bands have been calculated for a majority of the elements in the iron transition series using the augmented plane-wave (APW) method.[1,2] While the present results are preliminary in nature and not in any sense complete, they may be of some interest to experimentalists and theoreticians who are concerned with the electronic structure of the transition-series elements. The present results represent energy bands for three different crystal structures, with a variety of lattice constants. Despite the detailed differences that are imposed by symmetry requirements and variations in lattice constants, the results suggest some interesting and rather clear-cut trends in the band structure of these elements as one proceeds through the transition series. These calculations lend some support to the rigid band model for the transition series. They support the hope that systematic studies of the band structure of the transition-series elements can provide useful qualitative, and perhaps quantitative, information concerning their electronic structure.

As in all calculations involving d electrons, the results are sensitive to the choice of potentials. The crystal potentials used in these calculations were all constructed in an analogous manner, and were approximated by a superposition of atomic potentials. The method involves the use of Hartree-Fock solutions to the corresponding atomic problem[3] and the free-electron-exchange approximation.[4] The details of this method for constructing approximate crystal potentials have been described earlier,[5] though a brief resumé is presented in Sec. II of

this paper, along with other information pertaining to this present series of calculations. The energy bands along a single line of symmetry in the appropriate Brillouin zone are presented in Sec. III for Ar, Ti, V, Cr, Fe, Co, Ni, Cu, and Zn, while the last section contains a brief discussion of these results.

II. DESCRIPTION OF THE CALCULATIONS

In these calculations, the crystal potential has been approximated by a superposition of atomic potentials. The Coulomb and exchange contributions to the crystal potential are treated separately. An approximate crystal Coulomb potential and charge density in a given atomic cell is obtained by expanding the neutral atom Coulomb potentials and charge densities of neighboring atoms about the origin, using Löwdin's alpha function expansion,[6] keeping only the $l=0$ or spherically symmetric terms in these expansions. Using the free-electron-exchange approximation, the exchange potenial is proportional to the cube root of the superimposed atomic-charge densities.

The potentials obtained by this method are generally rather flat near the boundaries of the atomic cell, at least in the case of metals, so they are readily approximated by a "muffin-tin" type potential, as required by the APW method. The constant value of the potential outside the APW spheres is taken as the average value of the potential in this region. This usually results in a discontinuity in the potential at the sphere radius amounting to a few hundredths of a Rydberg.

In the construction of approximate crystal potentials for transition-series elements, there is frequently some ambiguity in choosing the most reasonable atomic configuration. This sort of difficulty can only be answered satisfactorily by experimental information and/or self-consistent energy-band calculations. For the present, we have been content to study the effect that changing the atomic configuration has on the band structure. In addition, there are magnetic effects which create additional complications in this series of elements. For simplicity, all magnetic effects have been neglected in these calculations, and the crystals have been assumed to be nonmagnetic in character.

The lattice constants which have been used in these calculations have generally been the room-temperature values as tabulated by Pearson.[7] The exceptions are those for Ar and Zn. The lattice constant for Ar is the low-temperature value obtained by Dobbs and Jones.[8] In the case of Zn, Harrison[9] has extrapolated the room-temperature lattice constants to low temperatures since the results are expected to be sensitive to the choice of c/a ratio. For purposes of comparison, his values have been used in these calculations. Table I contains a summary of the elements considered in these calculations, their structures, the values of the lattice constants, and the assumed atomic configurations.

TABLE I. In this table, we list the elements of the iron transition series, their structures, the lattice constants used in this series of calculations (in atomic units), and the assumed atomic configurations.

Element	Structure	a(au)	c(au)	Configuration
Ar	fcc	10.0346		$(3s)^2(3p)^6$
K				
Ca				
Sc				
Ti	hcp	5.5755	8.8503	$(3d)^3(4s)^1$
V	bcc	5.7225		$(3d)^4(4s)^1$
Cr	bcc	5.4512		$(3d)^5(4s)^1$
Mn				
Fe	bcc	5.4168		$(3d)^7(4s)^1$
Co	fcc	6.6975		$(3d)^8(4s)^1$
Ni	fcc	6.6590		$(3d)^9(4s)^1$
Cu	fcc	6.8309		$(3d)^{10}(4s)^1$
Zn	hcp	5.0120	9.1453	$(3d)^{10}(4s)^2$

III. RESULTS

The principal results of these calculations are presented in Fig. 1. These results represent plots of energy as a function of wave vector along lines of symmetry from the center to a boundary of the appropriate Brillouin zones. For the face-centered cubic structure (Ar, Co, Ni, and Cu), the bands are plotted from Γ along the Δ direction to the point X, using the notation of Bouckaert, Smoluchowski, and Wigner.[10] In the body-centered cubic structure (V, Cr, and Fe), the bands are plotted from Γ along the Δ direction to the point H. Finally, in the hexagonal close-packed structure (Ti and Zn), they start at Γ and proceed along the line T in the $k_z=0$ plane which terminates at the point K, one of the vertices of the hexagon (in the notation of Herring[11]).

The energy is in Rydbergs and the wave vectors for the different elements are drawn to scale for purposes of comparison. The horizontal dashed lines represent rough estimates of the Fermi energy for each element. For simplicity, some of the more highly excited bands have been omitted in some cases, particularly in the face-centered cubic structure, or in other situations, they have been sketched in by dashed lines.

In Fig. 2, it is shown what effect varying the atomic configuration has on the band structure of a typical element, namely vanadium. The bands to the right are the ones shown in Fig. 1 for vanadium; the ones to the left are those obtained from a potential which results from an atomic configuration containing an additional $4s$ electron and one less $3d$ electron. In general, this results in a narrowing of the $3d$ band and a decrease in

the energy separation between the top of the $3d$ band and the bottom of the $4s$-$4p$ bands.

IV. DISCUSSION

In the simplified picture of the energy bands for the iron transition-series elements, one finds a narrow $3d$ band in the midst of a rather broad $4s$-$4p$ band. The width of the $3d$ band and especially its position relative to the bottom of the $4s$-$4p$ band depend rather critically on the potential. Nevertheless, the results of Fig. 1 exhibit a reasonably smooth variation from element to element, especially for those substances having the same crystal structure. This seems to lend some support to the rigid band model for the transition-series elements, an approximation which has been of considerable value in understanding the electronic properties of these elements and their alloys.

There is a gradual narrowing of the $3d$ band as one progresses through the series. This effect was discussed by Slater in order to explain the occurrence of ferromagnetism in the latter part of the series.[12] In going from Cu to Zn, the $3d$ band suddenly drops about 0.5 Ry below the bottom of the $4s$-$4p$ bands, and its width

[12] J. C. Slater, Rev. Mod. Phys. 25, 199 (1953).

decreases to less than 0.1 Ry. As a result, the energy bands for zinc are very free-electron-like. For those elements where the 3*d* band falls in the middle of the 4*s*-4*p* bands, the interactions between states having the same symmetry causes considerable modification to the free-electron bands, though at points of symmetry, the effect is sometimes small. The bands for Ti and Zn demonstrate this effect nicely.

The results of Fig. 2 emphasize the uncertainty which is inherent in any energy-band calculation for a transition-series element. These uncertainties have been pointed out previously in the literature, particularly by Callaway.[13] These difficulties can only be cleared up satisfactorily with the aid of more detailed experimental information regarding the band structure of these elements in addition to self-consistent energy-band calculations.

The results presented here are not complete enough to permit detailed comparisons to be made with experiment or a discussion of the resulting Fermi surfaces. However, there are some striking similarities between the energy bands shown in Fig. 1 and the results obtained by earlier calculations. In particular, there is good qualitative agreement between the Cu results shown in Fig. 1 and the bands calculated by Segall[14] and also by Burdick.[15] Similarly, the results for Fe are in good agreement with the published results of Wood.[2] The agreement for Ar with the results of calculations by Knox and Bassani[16] is good, and has been described previously.[5] In the case of Cr, it is difficult to compare the present results with those of earlier calculations by Asdente and Friedel[17] since they neglect the interactions between the 3*d* band and the 4*s*-4*p* bands. However, the present results do justify, to some extent, the treatment of Cr by Lomer,[18] who used the results of Wood's iron calculations to discuss the energy bands in antiferromagnetic Cr.

In the case of Zn, the ordering of levels is identical with that obtained by Harrison.[9] This ordering differs from that obtained in earlier calculations for hexagonal close-packed metals by Herring and Hill for Be[19] and Falicov for Mg.[20] This change in ordering might be due to the presence of an occupied 3*d* band just below the 4*s*-4*p* bands. The results for Ti agree qualitatively with those obtained by Altmann and Bradley.[21] Finally, the Ni results are in good agreement with those obtained by Hanus.[22]

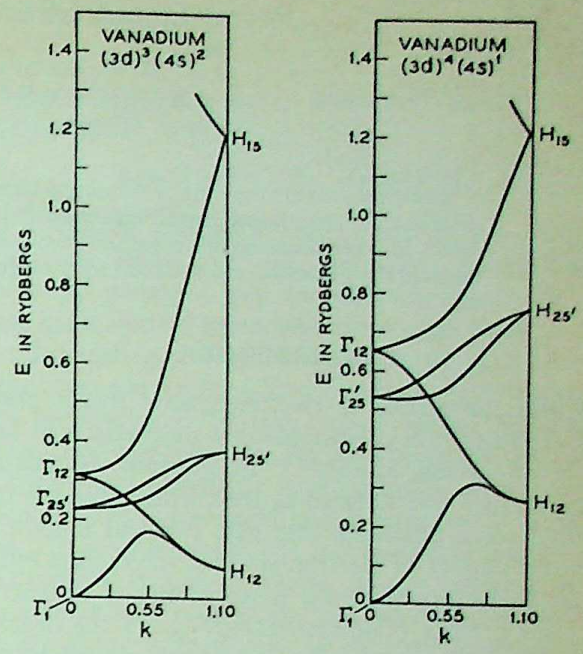

FIG. 2. Energy bands for vanadium along the line Δ obtained from two different potentials. The bands to the left resulted from an atomic configuration of $(3d)^3(4s)^2$ while those to the right involved a $(3d)^4(4s)^1$ configuration.

Fermi-Liquid Effects in Cyclotron Resonance

P. M. Platzman and K. C. Jacobs
Bell Telephone Laboratories, Murray Hill, New Jersey

(Received 19 November 1963)

The steady-state properties of transverse circularly polarized waves propagating along a static magnetic field in a uniform plasma (metal) are considered. Using the Landau theory of Fermi liquids, we compute the effect of correlations on the reflection properties of a semi-infinite metallic plasma. The expressions are numerically evaluated and discussed for a range of parameters pertinent to the alkalis.

I. INTRODUCTION

THE properties of electromagnetic waves propagating in a plasma along a magnetic field have been extensively studied.[1–3] In previous calculations the electrons were treated as the current carrying constituent of a noninteracting gas. For real metals the *a priori* neglect of electron-electron interaction effects is unsatisfactory since the mean energy of interaction of the electrons (Coulomb energy) is of the order of their mean kinetic energy. Under such conditions substantial correlation effects in the motion of the electrons may be expected. From a practical point of view, however, it is known that for a wide range of physical parameters, treatments which neglect explicit correlation effects provide an accurate description of the electromagnetic properties of metals and semimetals. We are interested in determining the range of physical parameters, frequency, external magnetic field, carrier density, etc., where the effect of electron-electron correlation may, hopefully, be measured experimentally.

In 1956, Landau[4] constructed a semiphenomenological theory of a system of fermions, such as He_3, interacting via a short-range two-body force. This work was later extended by Silin[5] to a Fermi liquid with long-range Coulomb interactions. We make use of the Fermi-liquid theory to compute the reflection properties of a semi-infinite slab of metal placed in a magnetic field oriented perpendicular to its surface. In this geometry for electromagnetic waves incident normally, it is known[1,3] that the metallic sample will exhibit an absorption edge at approximately the Doppler shifted cyclotron frequency.

$$\omega_c/\omega = 1+(q/q_0)(V_F/c)\,, \tag{1}$$

where ω_c is the electron cyclotron frequency, q is, crudely speaking, the wave number of the electromagnetic field in the medium, q_0 the wave number in free space, and V_F is the Fermi velocity. The resonance in the electrons motion which exhibits itself as a rapid fluctuation in the surface impedance of the sample is shifted from the value $\omega_c/\omega=1$. This comes about since the electrons traveling with the phase velocity of the wave see a Doppler shifted frequency. It is these electrons which interact most strongly with the wave. As a result the resonance in the impedance is shifted. Specifically we are interested in possible shifts in the position of, and modifications of the shape of the Doppler shifted electron-cyclotron resonance as the result of electron–electron interactions.

II. CALCULATION

The basic assumption of the Fermi-liquid theory is that it presupposes that as the interaction is turned on, the single-particle states in the neighborhood of the last occupied one remain approximate eigenstates of the interacting system, and that there is a one-to-one correspondence between these states and the single-electron states of the noninteracting Fermi gas. These approximate eigenstates are called quasiparticle states. For slowly varying external disturbances, the transport properties of the Fermi liquid are completely described by the quasiparticle distribution function $f(\mathbf{P},\mathbf{X})$ in momentum and configuration space.[6] (The external disturbance varies slowly enough in space so that the lack of commutivity of $\mathbf{P}$ and $\mathbf{X}$ is unimportant.) In equilibrium and at zero temperature the distribution of quasiparticles $f_0(\mathbf{P},\mathbf{X})$ is

$$\begin{aligned} f_0(\mathbf{P},\mathbf{X}) &= 1\,, \qquad |P|<P_F\,, \\ &= 0\,, \qquad |P|>P_F\,. \end{aligned} \tag{2}$$

For the spherically symmetric electron gas the quasiparticle energy is $E^0(P)=P^2/(2m^*)$, where m^* is an effective mass whose value depends on the dynamics of the interaction between quasiparticles. In nonequilibrium situations, the quasiparticle distribution function satisfies a transport equation similar to the Boltzmann equation. We are interested in the transport equation in the linear approximation, i.e., when the deviation from f_0 is small. If we write $f=f_0+f_1$, with

$f_1 \equiv \delta[E^0(P)-E_F]g$ the linearized transport equation for g becomes

$$\partial g/\partial t+\mathbf{V}\cdot\nabla_X(g+E_1)+(e/c)(\mathbf{V}\times\mathbf{H})\cdot\nabla_P(g+E_1) -e\mathbf{E}\cdot\mathbf{V}=-\nu_c g. \quad (3)$$

The quantity ν_c is a phenomenological short-range collision term which permits the system to relax to equilibrium; $V_\alpha \equiv \partial E^0(P)/\partial P_\alpha = P_\alpha/m^*$ is the velocity of the quasiparticles and

$$E_1=\int S(\mathbf{P},\mathbf{P}')\delta[E_F-E^0(P')]g(\mathbf{P}',\mathbf{X}) \times[d^3P'/(2\pi\hbar)^3] \quad (4)$$

is the change in energy of the quasiparticles produced by a change in their distribution function.

The correlation, or interaction function $S(\mathbf{P},\mathbf{P}')$ is the basic quantity characterizing the Fermi liquid. Owing to the presence of the delta function in the distribution function f_0 and in the transport equation, the value of $S(\mathbf{P},\mathbf{P}')$ is only of interest for $|P|=|P'|=P_F$, where P_F is the Fermi momentum. $S(\mathbf{P},\mathbf{P}')$ may then be considered to be a function of the angle between $\mathbf{P}$ and $\mathbf{P}'$. It is conveniently represented by an infinite sequence of Legendre polynomials.

$$S(\hat{P}\cdot\hat{P}')=\textstyle\sum_n S_n P_n^{(0)}(\cos\theta)\,, \quad (5)$$

where $\hat{P}$ is a unit vector in the direction of $\mathbf{P}$. For convenience, we define a set of dimenionsless quantities

$$\delta_0 \equiv S_0 m^* P_F/(2\pi)^2\hbar^3$$
$$\delta_n \equiv [S_n m^* P_F/(2\pi)^2\hbar^3][(n-1)!/(n+1)!]n\geq 1. \quad (6)$$

The correlation function $S(\hat{P}\cdot\hat{P}')$ contains all the information pertaining to explicit dynamical many-body effects. The limit $S\rightarrow 0$ is the free electron or Hartree limit. In this limit the transport equation, Eq. (3) becomes the usual Vlasov equation and the only "correlation" effect which is included is the self-consistent electromagnetic field.

The correlation function is as important to the many electron problem as the shape of the Fermi surface is in the one-electron problem. Unfortunately, the function $S(\hat{P}\cdot\hat{P}')$ (for the region of metallic densities), cannot be computed from first principles.[7] Hopefully then a transport experiment of the kind to be considered here might enable one to measure the characteristics of the scattering function $S(\hat{P}\cdot\hat{P}')$. Ideally one would like to perform an experiment in which a specific moment of the scattering function is measured. It was first pointed out by Landau[4] that the zeroth and first moments of the scattering function were simply related to two elementary properties of the quasiparticle gas. The clothed mass m^* of the quasiparticles is related to the first moment S_1 by

$$m^*/m=1+\tfrac{1}{3}\delta_1 \quad (7)$$

and the velocity of ordinary sound v_S is related to the zeroth moment S_0 by

$$v_S=(\delta_0+1)^{1/2}[P_F/(3mm^*)^{1/2}]. \quad (8)$$

A cyclotron resonance experiment in the extreme anomalous limit, in the so-called Azbel'-Kaner geometry,[8] measures only the effective mass.[9] On the other hand, the cyclotron resonance experiment in the so-called Galt geometry[10] involves, as we shall see, all of the moments. In the Galt geometry a static magnetic field perpendicular to the surface of the sample is utilized and the reflection (or absorption) of circularly polarized electromagnetic waves propagating along the magnetic field is measured as a function of the applied field. The solution, neglecting correlations, of the coupled Maxwell-Boltzmann equations in the presence of a single boundary (assuming specular reflection of the carriers at the surface) may be reduced to the solution of an equivalent infinite medium problem.[3] The final expression for the surface impedance Z is

$$\frac{Z}{Z_0}=(2i/\pi)\int_0^\infty \frac{dq}{[q^2-\epsilon(q,\omega)]}, \quad (9)$$

where Z_0 is the impedance of free space. The quantity $\epsilon(q,\omega)$ is the finite wave number and frequency-dependent dielectric constant for the infinite medium, $[\epsilon(q,\omega)\equiv 1+\sigma^+(q,\omega)/i\omega]$.

The quantity E_1 is Eq. (4) is related to a first-order change in the distribution function by the relationship

$$E_1=\int S(\mathbf{P},\mathbf{P}',\mathbf{X},\mathbf{X}')\delta[E_F-E^0(P')]g(\mathbf{P}',\mathbf{X}') \times\frac{d^3P'd^3X'}{(2\pi)^3\hbar^3}. \quad (10)$$

In writing Eq. (4) we have assumed that $S(\mathbf{P},\mathbf{P}',\mathbf{X},\mathbf{X}')=S(\mathbf{P},\mathbf{P}')\delta(\mathbf{X}-\mathbf{X}')$. With this assumption the spatial part of the problem is identical with that in the noninteracting case. For an interacting gas of quasiparticles in real materials correlations are not local in space but do in fact extend over distances of the order of a Debye length ($\lambda_D \simeq V_F/\omega_P$). For metallic densities this is of the order of the interparticle spacing. The Debye length is small compared with distances over which the field varies appreciably, typically distances of the order of the high-frequency classical skin depth ($\lambda_S \simeq c/\omega_P$), so that to a good approximation we can neglect nonlocal effects. With the locality assumption on the function

[7] C. Herring has recently computed the scattering function S as a power series in r_s ($r_s \equiv n^{1/3}\,a_H$ where n is the electron density and a_H is the Bohr radius) for metals $r_s \approx 2$–6 (private communication).

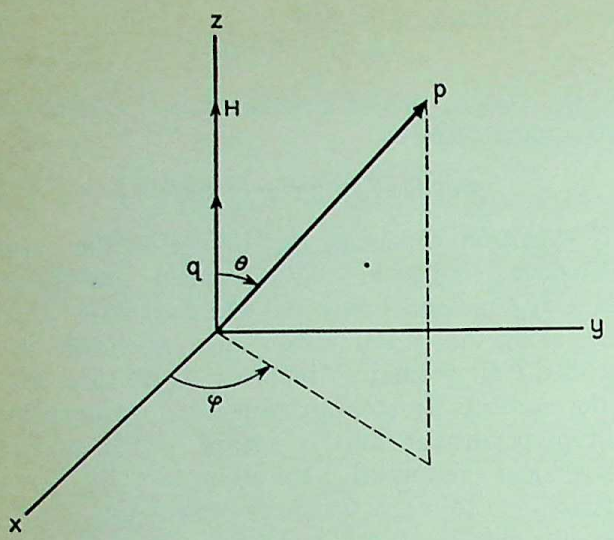

FIG. 1. Polar coordinate system used for solution of the transport equation, Eq. (3). H is the magnetic field, q is the propagation vector, and P is the quasiparticle momentum.

$S(\mathbf{P},\mathbf{P}',\mathbf{X},\mathbf{X}')$, the expression for the impedance within the framework of the Fermi-liquid theory is still given by Eq. (9). However, the dielectric constant $\epsilon(q,\omega)$ will now include the effects of correlations.

This dielectric constant is obtained by linearizing the transport equation, Eq. (2), with an rf field varying as $\exp(i\mathbf{q}\cdot\mathbf{X}-\omega t)$ and solving for the induced current. The current is given by

$$I^\alpha(q)=\frac{ne}{m}\int\frac{d^3P}{(2\pi)^3\hbar^3}P^\alpha g(\mathbf{P},q)\delta(E_P{}^0-E_F) \qquad (11)$$

or, equivalently, using Eq. (4)

$$I^\alpha(q)=\frac{ne}{m^*}\int\frac{d^3P}{(2\pi)^3\hbar^3}P^\alpha(g+E_1)\delta(E_P{}^0-E_F)\,. \qquad (12)$$

We choose our coordinate system (see Fig. 1) so that the static magnetic field H and the propagation vector $\mathbf{q}$ point along the z axis. The angles θ and Φ are polar angles specifying the direction of $\mathbf{P}$. For a right-handed circularly polarized wave ($\mathbf{E}=E_x\hat{U}x+iE_y\hat{U}_y$) the transport equation for $g(\mathbf{P},q)$ is,

$$-i\tilde{\omega}g(\mathbf{P},q)+\frac{iqP}{m^*}\cos\theta g(P,q)+\omega_c{}^*\frac{\partial g}{\partial\Phi}$$
$$+\left[\frac{iqP}{m^*}\cos\theta+\omega_c{}^*\frac{\partial}{\partial\Phi}\right]$$
$$\times\int d^3P'/(2\pi\hbar)^3S(\mathbf{P},\mathbf{P}')\delta(E_F-E_P{}^0)g(\mathbf{P}',q)$$
$$\times eEe^{i\Phi}\frac{P}{m^*}\sin\theta, \qquad (13)$$

where $\omega_c{}^*=|eH/m^*c|$ and $\tilde{\omega}=\omega+i\nu_c$.

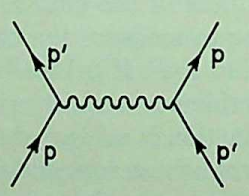
If we set $g(\mathbf{P},q)\equiv g(\theta,\Phi)=g(\theta)e^{i\Phi}$, then it is easily shown that

$$g(\theta)=\frac{ieEV_F{}^*\sin\theta}{\xi}+\frac{(qV_F{}^*\cos\theta+\omega_c{}^*)}{\xi}\Lambda(\theta)\,, \qquad (14)$$

where $V_F{}^*=P_F/m^*$ and

$$\xi=(\tilde{\omega}-\omega_c{}^*-qV_F{}^*\cos\theta)\,. \qquad (15)$$

The quantity $\Lambda(\theta)$ is



$$\Lambda(\theta)=\sum_{n=0}^{\infty}\delta_nP_n{}^{(1)}(\cos\theta)$$
$$\times\int_\pi^0 g(\theta')P_n{}^{(1)}(\cos\theta')d(\cos\theta')\,. \qquad (16)$$

Equation (14) is an infinite set of coupled linear equations for the quantities $\Omega_n=\int_\pi^0 P_n{}^{(1)}(\cos\theta)g(\theta)d(\cos\theta)$. If we terminate the spherical harmonic expansion for $S(\hat{P}\cdot\hat{P}')$ after a finite number of terms, then Eq. (16) may be solved self-consistently for the quantity $g(\theta)$. Knowing $g(\theta)$, we may substitute into Eq. (11) and evaluate the current.

For the purposes of this paper we will include the first three moments of $S(\hat{P}\cdot\hat{P}')$ S_0, S_1, and S_2. We have no real justification for terminating this series after so few terms; however, there are at least some crude arguments which suggest that a Legendre expansion for $S(\hat{P}\cdot\hat{P}')$ converges rapidly. Landau has shown that the function $S(\hat{P}\cdot\hat{P}')$ is proportional to the negative of the forward scattering amplitude of two quasiparticles. A typical type of exchange scattering diagram which enters into a microscopic calculation of $S(\hat{P}\cdot\hat{P}')$ is shown in Fig. 2. The dashed line is a bare Coulomb line and the solid lines represent electron (hole) propagators. This type of scattering diagram contributes a term to $S(\hat{P}\cdot\hat{P}')$ of the form

$$S_{\text{exch.}}(\hat{P}\cdot\hat{P}')\sim\frac{-e^2}{|\mathbf{P}'-\mathbf{P}|^2\epsilon_L(|\mathbf{P}'-\mathbf{P}|,0)}\,, \qquad (17)$$

where $\epsilon_L(q,0)$ is the zero-frequency longitudinal dielectric constant. If ϵ_L is computed by summing the

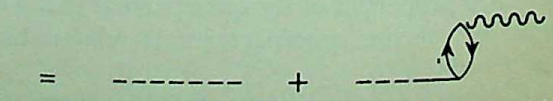


FIG. 2. A typical type of exchange scattering diagram which contributes to $S(\hat{P}\cdot\hat{P}')$. Solid lines are electron propagators and dashed lines represent Coulomb propagators.

simple set of bubble diagrams shown in Fig. 2 (RPA approximation), we find

$$\epsilon_L(q,0)=1+(q_D^2/q^2)F(q)\,, \tag{18}$$

where $F(q)\approx 1$ for $q\ll q_F$ and $F(q)\approx\frac{1}{2}$ for $q=2q_F$. Using this expression for the dielectric constant, we find

$$S(0)/S(\pi)=\tfrac{1}{2}[1+8P_F^2/q_D^2]\,. \tag{19}$$

For potassium $S(0)/S(\pi)\approx 0.7$ so that on the basis of this crude computation the scattering is roughly spherical.

If we truncate Eq. (5) after three terms, solve Eq. (16) and substitute into Eq. (11), we find for the scalar conductivity

$$\sigma^+=\tfrac{3}{4}\omega_P^2 iV^*\Bigg[1+4\delta_1/3-\tilde{\omega}\delta_1 V^*-\frac{(1+4\delta_1/3)}{[1+(V^*/\tilde{\omega}W^{*2})(1/(9\delta_2)+4/15-\omega\gamma W^*)]}\Bigg]^{-1}, \tag{20}$$

where $\gamma=(\tilde{\omega}-\omega_c^*)/qV_F^*$, and $\omega_P=(4\pi ne^2/m)^{1/2}$. The functions V^* and W^* are defined by

$$V^*=\int_\pi^0 \frac{\sin^2\theta d(\cos\theta)}{(\tilde{\omega}-\omega_c^*-qV_F^*\cos\theta)}, \tag{21}$$

$$W^*=\int_\pi^0 \frac{\sin^2\theta\cos\theta d(\cos\theta)}{(\tilde{\omega}-\omega_c^*-qV_F^*\cos\theta)}. \tag{22}$$

The conductivity, although it is reasonably complicated, approaches some rather simple and physically meaningful limiting values. In the limit $q\to 0$, σ_+ approaches

$$(\sigma_+)_{q\to 0}=i\omega_P^2/(\tilde{\omega}-\omega_c)\,. \tag{23}$$

There are no effects due to correlations in this limit. This is a consequence of the fact that total momentum is conserved in electron-electron collisions. The induced-current (for a zero wave vector) electric field is not affected by the electron-electron interactions. In the limit $\omega/\omega_c\to 0$, the effect of correlations to lowest order in ν_c/ω_c vanishes. This is true not only for our truncated scattering function, but for a general scattering function as well. If we examine the transport Eq. (3) and the second expression for the current Eq. (12), then neglecting the relaxation term and the time derivative term we see that $(g+E_1)$ satisfies the usual transport equation, without correlations. The energy delta function in Eq. (12), is just sufficient to produce a factor m^* canceling the $1/m^*$ in front of the integral leading to the uncorrelated conductivity.

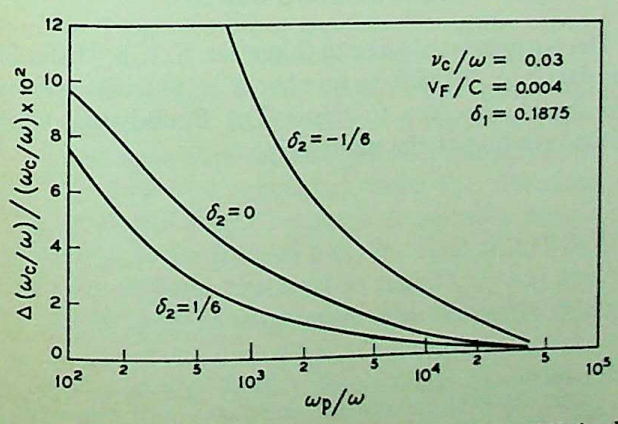

FIG. 3. A plot as a function of ω_p/ω of the relative shift in the position of the Doppler shifted absorption edge due to correlation effects.

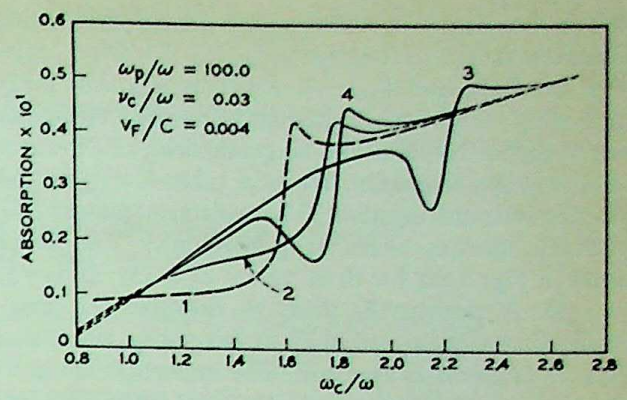

FIG. 4. A plot of the Doppler shifted absorption edge as a function of magnetic field. The plasma frequency, collision frequency and Fermi velocity are fixed. The four curves show the effect of correlation on the edge. The curve labeled (1) has a $\delta_1=0$ and a $\delta_2=0$, i.e., uncorrelated. Curve (2) has $\delta_1=0.1875$, $\delta_2=0$. Curve (3) has $\delta_1=0.1875$, $\delta_2=-0.166$, and curve (4) has $\delta_1=0.1875$, $\delta_2=-0.05$.

III. EVALUATION AND DISCUSSION OF THE SURFACE IMPEDANCE

Typically, the absorption coefficient of a semi-infinite metallic plasma exhibits a rather sharp resonance at the Doppler shifted resonance frequency.[11] If we substitute for q in Eq. (1), the value which is obtained from a simple analysis which leaves out nonlocal effects, i.e.,

$$q^2/q_0^2=-\omega_p^2/[\omega(\omega-\omega_c)]\,. \tag{24}$$

Then we may rewrite the approximate Doppler shifted resonance condition Eq. (1) as

$$\omega_c/\omega=1+[(V_F/c)(\omega_p/\omega)]^{2/3}. \tag{25}$$

At low frequencies, where $(\omega_p/\omega V_F/c)\gg 1$ and $\omega_c/\omega\gg 1$, the effects of correlations are not observable. At higher frequencies, where $\omega_p/\omega V_F/c\sim\omega_c/\omega\sim 1$, correlations are important.

Since the simple resonance condition, Eq. (24), at these "high frequencies" is now a function of the "mass" of the particles, in this case the bare mass, and since correlations do play a role, it seems natural to ask what mass comes into play. There are, of course, two masses in the problem; the so-called bare mass and the clothed mass [see Eq. (7)]. In Fig. 3 we have plotted the

shift in frequency of the Doppler edge from its uncorrelated value as a function of (ω_p/ω). For fixed values of $(\nu_c/\omega)=0.03$ and $V_F/c=0.004$ there is a shift away from what might be called a bare-mass resonance toward higher values of the magnetic field, i.e., towards a clothed mass resonance. We have taken $\delta_1=\frac{3}{16}$ so that the effective mass equals 1.25 bare electron masses (the observed effective mass in potassium).[12] The three curves in Fig. 3 are for three values of δ_2 ($\delta_2=0$, $\delta_2=\frac{1}{6}$, $\delta_2=-\frac{1}{6}$). A positive δ_2 tends to decrease the magnitude of the computed shift in frequency whereas a negative δ_2 increases the shift. The important thing to note here is that the resonance occurs at *neither* the frequency determined by the bare mass nor by the clothed mass. *The shift is a dynamical function of the frequency.*

In Fig. 4 we have plotted the actual absorption line for fixed values of the plasma frequency $\omega_p/\omega=100$, Fermi velocity, collision frequency, and δ_1. The effect of a negative δ_2 on the line shape is rather striking. It produces an over-all smearing of the line relative to the uncorrelated line. The magnitude of the steeply rising portion of the absorption curve is severely reduced. In addition, a negative δ_2 causes the absorption edge to exhibit a rather prominent minimum. In some cases (i.e., for the case $\delta_2=-\frac{1}{6}$ or $-\frac{1}{10}$) the minimum or hole in the absorption edge effectively causes a splitting of the edge into two peaks.

Physically, we can understand the origin of this decrease in absorption. Suppose for the purpose of this rather crude argument that the electric field inside the metal could be characterized by a single wave number q, as it can be in the local or classical theory. The edge in the absorption is due to a sharp increase in the conductivity when $\omega_c/\omega\approx(1+qV_F/\omega)$. The electrons at the Fermi velocity traveling in the direction of the wave see a static dc field spiral out around the lines of force and pick up energy from the field. Suppose we now ask ourselves if it is possible to introduce a mechanism which, in this region of increasing conductivity, would tend to decrease the induced current or conductivity, thus producing an associated dip in the absorption edge. Electron interactions can produce just this effect. As the quasiparticles (the current carriers in a Fermi liquid theory) are dragged through the surrounding, now slightly incompressible fluid, they create a backflow by pushing other quasiparticles out of their way. This backflow carries current. At a definite wave number q and frequency ω, it is possible for the backward flowing current to exactly cancel the forward flowing current so that the conductivity goes to zero. For the circularly polarized mode we simply require that

$$\int g(\theta)\sin\theta d(\cos\theta)\sim\Omega_1=0. \tag{26}$$

This implies that

$$1+\frac{V^*}{\tilde{\omega}W^{*2}}\left(\frac{1}{9\delta_2}+\frac{4}{15}-\tilde{\omega}\gamma W^*\right)=0. \tag{27}$$

For a finite δ_2 (second moment) it is possible to find at least one solution to Eq. (27) (to zeroth order in ν_c/ω). The dips in the conductivity, which show up in this simple model are characteristic of the interacting Fermion system. Had we retained more terms in the multipole expansion of the scattering function, it is likely that there would exist multiple solutions of Eq. (27). In the actual boundary value problem, q is not well defined and the zero in the conductivity appears as a minimum in the absorption curve. If the minimum happens to fall in the high field or classical region of the curve, then the magnitude of the effect is reduced since in this limit $q\rightarrow 0$ and there are no effects due to correlations.

The observation of correlation effects in the alkali metals, unfortunately, is extremely difficult since the magnetic fields required in order to keep the Dopper shifted edge in the neighborhood of the cyclotron frequency are enormous. However, experiments could be performed in semimetals, semiconductors, or doped insulators.

One should look for a material, preferably one with a simple band structure, which has an $r_s>1$. In addition, $\omega_p/\omega v_F/c\sim\omega_c/\omega\sim 1$ and $\omega/\nu_c\gg 1$. The frequency range in which one can work will primarily be limited by the magnetic fields which are available.

Low-Field de Haas–van Alphen Effect in Copper*

A. S. Joseph
North American Aviation Science Center, Canoga Park, California
AND
A. C. Thorsen
Atomics International Division of North American Aviation, Inc., Canoga Park, California
(Received 2 January 1964)

The de Haas–van Alphen effect has been observed in a copper single crystal by means of a null-deflection torsion balance technique. Detailed measurements have been carried out which provide an accurate determination of the topology of the Fermi surface necks in copper. Effective mass values are found to be in excellent agreement with cyclotron resonance results. Unusual behavior observed in the angular dependence of the amplitude of the oscillatory torque is attributed to the spin-splitting factor in the theoretical expression for the magnetization.

I. INTRODUCTION

THE first observation of the de Haas–van Alphen effect in copper by Shoenberg was accomplished by means of an impulsive field technique. His detailed results[1] confirmed the model of the Fermi surface proposed by Pippard,[2] and demonstrated conclusively that the Fermi surface deviates from sphericity and is multiply connected along the ⟨111⟩ directions, forming "necks" at the hexagonal faces of the Brillouin zone. The precise size and shape of the necks, however, could not be ascertained with pulsed magnetic fields. In this paper we report on detailed low-field measurements of the de Haas–van Alphen (dHvA) effect in copper resulting in accurate determinations of the neck topography and the associated effective masses. In addition, we report on what we believe to be the first unequivocal observation of the vanishing of the amplitude of the dHvA oscillations due to the zero value of the spin-splitting factor for $m^*=0.5m_0$ (and $g=2$).

II. EXPERIMENTAL

The measurements reported herein were made with a torsion balance apparatus which has been described in detail in a previous publication.[3] Magnetic fields up to 40 kG were supplied by a 22-in. Varian magnet, and were measured to within 0.1% with a rotating coil probe. The magnetic fields were swept automatically at the slow rate of ≈200–400 G/min to reduce the effects of eddy currents in the sample. The copper single crystal, supplied by K. R. Garr of Atomics International, was grown by the Bridgeman technique from a 99.999% pure rod purchased from the American Smelting and Refining Company. A suitable sample was spark cut in the form of a 0.1-in.-diam ×0.15-in.-long cylinder and was mounted so that the [1$\bar{1}$0] axis was along the axis of suspension. The magnetic field could thus be rotated in the (1$\bar{1}$0) plane of the crystal and was oriented in this plane to within 1°.

III. RESULTS AND DISCUSSION

The values of the period of the dHvA oscillations arising from extremal orbits around the necks are shown in Fig. 1. The period has a maximum value of 4.64×10^{-8} G^{-1} along the [111] axis (≈12% greater than that reported in Ref. 1) corresponding to a minimum cross-sectional area of 2.06×10^{15} cm^{-2}. As the field is rotated away from the [111] direction the period decreases and can be determined over an angular range of approximately 48°. To within the experimental accuracy, the data can be represented by the expression

$$\frac{P(\theta)}{P(0)}=\frac{m^*(0)}{m^*(\theta)}=\cos\theta\left(1-\frac{m_t}{m_l}\tan^2\theta\right)^{1/2}, \qquad (1)$$

with $m_t/m_l=2.55\pm0.10$, indicating that the shape of

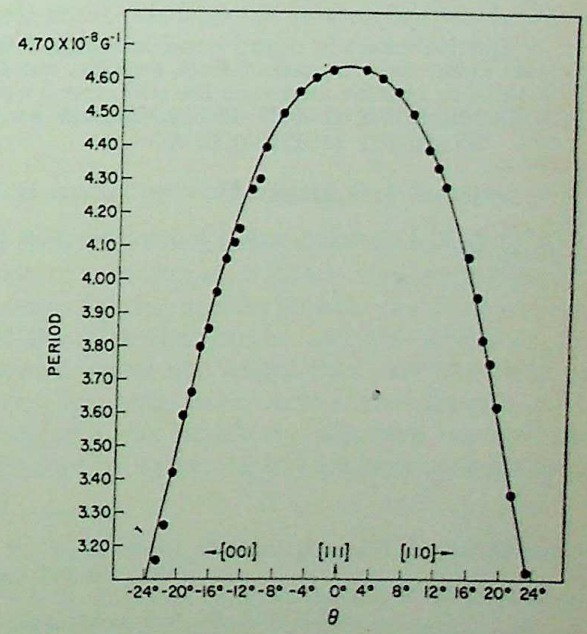

FIG. 1. de Haas-van Alphen period in copper versus orientation in the (1$\bar{1}$0) plane. The solid line is a plot of Eq. (1) with the parameter $m_t/m_l=2.55$.

the neck closely approximates the form of a hyperboloid of one sheet, and is hence similar to that of nickel.[4] In the above equation, θ is the angle measured from the [111] axis in the $(1\bar{1}0)$ plane, and m_t and m_l are the transverse and longitudinal effective masses.

At several angles the effective mass was determined from the temperature dependence of the amplitude of the oscillations. These results are shown in Fig. 2 and are compared with Eq. (1), indicated by the solid line. The theoretical curve was normalized to the value $m^*(13°)=0.5m_0$ at $\theta=\pm 13°$ for reasons to be discussed below. The data indicate a value of effective mass along the [111] axis of $0.45m_0\pm 3\%$. These results are in excellent agreement with the masses determined by Koch, Stradling, and Kip[5] by means of cyclotron resonance.

In Fig. 3 the amplitude of the oscillatory torque is plotted as a function of θ for a constant magnetic field. At $\theta=0$, this amplitude vanishes as is always the case for an extremum in the magnitude of the period. The torque amplitude increases initially with θ, passes through a maximum and goes to zero at $\theta=\pm 13°\pm 1°$. For larger angles the amplitude again increases and then decreases, finally vanishing at $\theta\approx\pm 24°$. We attribute the vanishing of the amplitude at $\theta\approx\pm 13°$ to the effect of spin-splitting of the Landau levels. This effect is manifested in a cosine multiplicative factor in the theoretical expression for the magnetization. The factor can be expressed as $\cos[\pi g m^*/2m_0]$, where g is the spectroscopic splitting factor, and m^* is the effective mass. It was introduced by Sondheimer and Wilson[6] and Dingle[7] for the case when m^* differs from m_0, and is given above in the generalized form derived by Cohen and Blount.[8] If the reasonable assumption that $g=2$ is made, then the amplitude should vanish when $m^*=0.5\ m_0$. Our experimental mass values do indeed approach this value for $\theta\approx\pm 13°$, evidencing remarkable agreement with the theory.

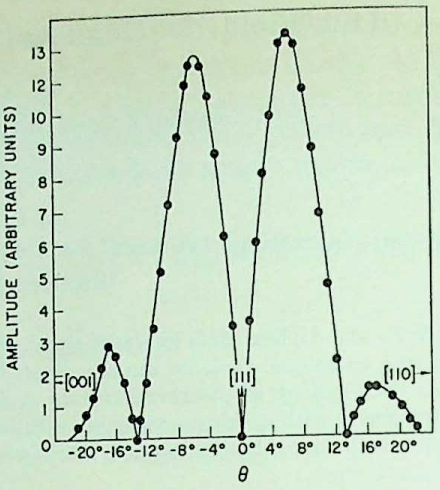

FIG. 3. Amplitude of the oscillatory torque at constant magnetic field (in arbitrary units) versus orientation in the $(1\bar{1}0)$ plane.

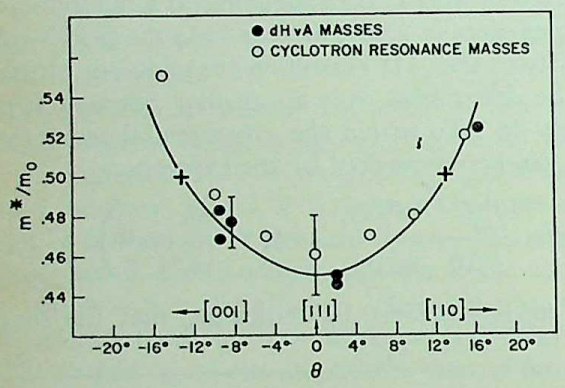

FIG. 2. Effective masses in copper versus orientation in the $(1\bar{1}0)$ plane. Open circles are data of Koch, Stradling, and Kip (Ref. 5), found by cyclotron resonance. The solid curve is a plot of Eq. (1) normalized to a value $m^*=0.5\ m_0$ at the points denoted by crosses.

ACKNOWLEDGMENTS

The authors wish to thank R. E. Gile for his assistance in taking the data and D. G. Swarthout for orienting the crystal. We are indebted to K. R. Garr for supplying the high-purity single crystal of copper used in this study and to J. K. Koch, R. A. Stradling, and A. F. Kip for communicating their cyclotron resonance data prior to publication.

Lattice Dynamics and Phase Transitions of Strontium Titanate

R. A. COWLEY*
Crystallographic Laboratory, Cavendish Laboratory, Cambridge, England
(Received 16 December 1963)

The crystal dynamics of strontium titanate has been studied both experimentally and theoretically. The frequency versus wave-vector dispersion curves for some of the normal modes propagating along the [0,0,1] direction have been measured by neutron spectrometry at 90 and 296°K. The experiments were performed at the Chalk River Laboratories of Atomic Energy of Canada Ltd., using a triple-axis crystal spectrometer. The temperature dependence of the transverse optic mode of the lowest frequency has been found to be in agreement with the temperature dependence of the dielectric constant, as predicted by Cochran. The experimental results have been used to obtain the parameters of several models, more than one of which gives reasonable agreement with the experimental results. It is suggested that the anomalous behavior of the elastic properties and the phase transition at 110°K are associated with an accidental degeneracy of two branches of the dispersion curves; the longitudinal acoustic branch and the transverse optic branch of lowest frequency. The origin of the temperature dependence of this transverse optic mode and the relevance of lattice dynamics to the phase transitions in other perovskites are discussed.

I. INTRODUCTION

THE lattice dynamics of strontium titanate has been studied both theoretically and experimentally, in an attempt to understand the lattice dynamics of a ferroelectric material. Anderson[1] and Cochran[2] have independently suggested that the anomalous temperature dependence of the static dielectric constant of ferroelectrics is associated with the temperature dependence of a transverse optic mode of vibration. Recently, this low-frequency mode of vibration has been observed experimentally in barium and strontium titanates, by using infrared spectrometry[3,4] and in strontium titanate by using neutron spectrometry.[5]

In this paper experimental measurements are presented of some of the frequency versus wave-vector dispersion curves for normal modes propagating in the [0,0,1] direction of strontium titanate. These dispersion curves were determined by neutron spectrometry using the triple-axis crystal spectrometer[6] at the N.R.U. reactor at the Chalk River Laboratories of Atomic Energy of Canada Limited.

The simplest model which is used to describe the lattice dynamics of ionic crystals is the rigid-ion model.[7,8] In this model the ions interact with one another through both long-range electrostatic forces and short-range repulsive forces between neighboring ions. This model has been shown to be inadequate to describe the measured dispersion curves of two alkali halides, sodium iodide[9,10] and potassium bromide.[10] These experimental results showed that a more satisfactory model was the shell model,[9] which takes account of the polarizability of the ions in both electrostatic and short-range forces.

The experimental measurements on strontium titanate have been used to obtain the parameters of both rigid-ion models and shell models. These parameters show that it is possible to obtain the large changes in the frequency of the lowest transverse optic mode by changing the values of the parameters only slightly.

Recently, it has been found that the ultrasonic attenuation in strontium titanate increases dramatically below 110°K, while the elastic constants show an anomalous temperature dependence.[11,12] A possible explanation for these observations is put forward in terms of an instability of the crystal arising from the accidental degeneracy of two branches of the dispersion curves. Finally the results are discussed with particular reference to the origin of ferroelectricity in the perovskite structure.

II. THEORY OF THE LATTICE DYNAMICS OF STRONTIUM TITANATE

1. Symmetry

Some of the properties of the normal modes of vibration of a crystal are a direct consequence of its symmetry. The degeneracies between the different branches of the dispersion curves, and the separation of the normal modes into longitudinal and transverse vibrations for some wave vectors are examples of these properties. For simple crystals these relations can be obtained by inspection, but for more complicated crys-

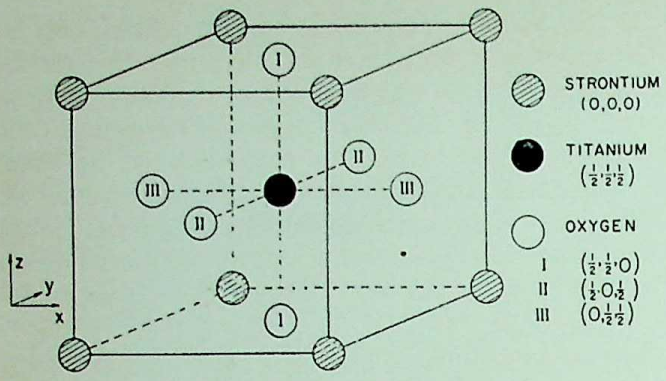

FIG. 1. The crystal structure of strontium titanate.

tals a more systematic procedure is given by using group theory.[13]

The normal modes of vibration are classified by assigning them to an irreducible representation of the space group of the crystal. A representation for the normal modes is obtained by choosing as a set of basis vectors the displacement of each ion in turn along a coordinate axis. If the character of a symmetry operation S is $\chi(S)$ in this representation, and its character in the λ irreducible representation is $\chi^\lambda(S)$, then

$$\chi(S)=\sum_\lambda C_\lambda \chi^\lambda(S), \qquad (1)$$

where C_λ is the number of times the λ irreducible representation occurs in the original representation.

When the normal modes of the crystal are described by Bloch waves, the irreducible representations of the symmorphic space groups can be obtained from the irreducible representations of the little group, which is that point group which leaves the wave vector unchanged. The irreducible representations are then obtained from Eq. (1) and from the characters of the irreducible representations of the point groups.[13,14]

The structure of strontium titanate is cubic perovskite, and the space group is $Pm3m$. The ions are situated on five interpenetrating simple cubic lattices as shown and labeled in Fig. 1. The characters of the different symmetry elements in the original representation are listed in Appendix I.

(a) $\zeta=(0,0,0)$

The little group is $m3m$, and the irreducible representations are

$$4\Gamma_{15}+\Gamma_{25}.$$

This result is, however, incorrect because the effect of the macroscopic electric field has been neglected. This electric field splits the degeneracy of some of the normal modes because the boundary conditions for the longitudinal and transverse modes differ.[8] The degeneracies will be lifted for those normal modes which transform like an ordinary vector. Since an ordinary vector transforms like Γ_{15}, the degeneracies associated with three of the four irreducible representations Γ_{15} are split. The fourth irreducible representation corresponds to a uniform translation of the whole crystal. There are, therefore, the three acoustic modes, $\omega=0$, a triply degenerate normal mode Γ_{25}, and three longitudinal and doubly degenerate transverse optical modes.

(b) $\zeta=(0,0,\zeta)$

The little group is $4mm$, and the irreducible representations are

$$4\Delta_1+\Delta_2+5\Delta_5.$$

The normal modes Δ_1 and Δ_2 are longitudinally polarized modes, while those represented by Δ_5 are doubly degenerate transverse modes.

At the zone boundary the little group is $4/mmm$, and the irreducible representations are

$$2M_1+2M_2'+M_3+3M_5+2M_5'.$$

M_5 and M_5' correspond to doubly degenerate transverse modes, while the other modes are longitudinally polarized.

(c) $\zeta=(\zeta,\zeta,0)$

The little group is mm except at the zone boundary, where it is $4/mmm$. The irreducible representations are

$$5\Sigma_1+\Sigma_2+5\Sigma_3+4\Sigma_4,$$

and

$$M_1+M_2+M_2'+M_3+2M_3'+M_4+M_5+3M_5'.$$

There are no degeneracies at general points, but at the zone boundary there are four doubly degenerate normal modes.

(d) $\zeta=(\zeta,\zeta,\zeta)$

The little group at a general point is $3m$ and its irreducible representations are

$$4\Lambda_1+\Lambda_2+5\Lambda_3.$$

At the zone boundary the little group symmetry is increased to $m3m$ and the irreducible representations are

$$\Gamma_2'+\Gamma_{12}'+\Gamma_{25}+\Gamma_{25}'+2\Gamma_{15}.$$

The irreducible representation Λ_3 corresponds to doubly degenerate normal modes, while at the zone boundary there are four triply degenerate normal modes, one doubly degenerate pair and a single normal mode.

2. Models

In the last section we found the properties of the normal modes which can be deduced from the symmetry of the crystal. In order to evaluate the frequencies of any of the normal modes, a particular model must be

[13] V. Heine, *Group Theory in Quantum Mechanics* (Pergamon Press, Inc., New York, 1960).
[14] G. F. Koster, *Solid State Physics*, edited by F. Seitz and D. Turnbull (Academic Press Inc., New York, 1957), Vol. V.

employed for the interactions between the ions. The simplest model which has been used for ionic crystals is the rigid-ion model.[7,8] The equation of motion for this model is then written in the harmonic approximation as

$$M_K\omega^2\mathbf{U}(K)=\sum_{K'}(\mathbf{R}_{KK'}+Z_K\mathbf{C}_{KK'}Z_{K'})\mathbf{U}(K'), \quad (2)$$

where the notation is the same as that of Woods *et al.*[9]

This model does not satisfactorily account for the dispersion curves of the alkali halides,[9,10] because it neglects the polarizabilities of the ions. These polarizabilities can be introduced by using the shell model.[2,9] The equations of motion of the shell model in the harmonic approximation[9] are

$$\begin{aligned} M_K\omega^2\mathbf{U}(K)&=\sum_{K'}(\mathbf{R}_{KK'}+Z_K\mathbf{C}_{KK'}Z_{K'})\mathbf{U}(K') \\ &\quad+\sum_{K'}(\mathbf{T}_{KK'}+Z_K\mathbf{C}_{KK'}Y_{K'})\mathbf{W}(K'), \\ 0&=\sum_{K'}(\mathbf{T}_{K'K}+Y_K\mathbf{C}_{KK'}Z_{K'})\mathbf{U}(K') \\ &\quad+\sum_{K'}(\mathbf{S}_{KK'}+Y_K\mathbf{C}_{KK'}Y_{K'})\mathbf{W}(K'). \end{aligned} \quad (3)$$

The matrices $\mathbf{T}_{KK'}$ and $\mathbf{S}_{KK'}$ give the short-range interactions between the displacements and the electronic dipole moments, and between the electronic dipole moments, respectively. In general, the elements $\mathbf{R}_{KK'}$, $\mathbf{T}_{KK'}$ and $\mathbf{S}_{KK'}$ are all different and must be specified by different short-range force constants. However the shell charges Y_K can be chosen so that $\mathbf{R}_{KK'}=\mathbf{T}_{KK'}$ when the wave vector is zero,[15] and it was further assumed that they are then equal for all wave vectors. The validity of this approximation and the further approximation that $\mathbf{S}_{KK'}=\mathbf{R}_{KK'}+\mathbf{k}_K\delta_{KK'}$ are discussed by Cowley, Cochran, Woods, and Brockhouse.[15] The model then corresponds to a shell model in which all the short-range forces act through the shells.

In actual calculations the short-range forces were assumed to be axially symmetric. If the equilibrium condition is imposed then these forces become central forces and the elastic constants obey Cauchy's relation, $C_{12}=C_{44}$. In practice, this relation is nearly satisfied, but the equilibrium condition was not imposed on the models described below.

For each type of short-range interaction two parameters are needed to specify axially symmetric forces. These parameters were chosen to be the derivatives of a potential function parallel and perpendicular to the line joining the interacting ions. These were defined in a similar way to those used for the alkali halides.[7,9,15]

The forces were specified by

$$\left(\frac{\partial^2V}{\partial r^2}\right)_{\parallel}=\frac{e^2A_i}{2v}, \quad \left(\frac{\partial^2V}{\partial r^2}\right)_{\perp}=\frac{e^2B_i}{2v},$$

where the suffix i is one for strontium-oxygen, two for titanium-oxygen, and three for oxygen-oxygen forces. Each type of force was assumed to act only between nearest neighbors. The short-range contributions to the dynamical matrix were then evaluated by the usual procedure,[8] and the elements are listed in Appendix II.

The ionic charges were specified by two charges; that on the strontium ion was Z_1e and on the titanium ion Z_2e. The charge on the oxygen ion is then $Z_3e=-\frac{1}{3}(Z_1+Z_2)e$.

The polarizabilities of the ions were specified in a similar way to that used for the alkali halides.[9,15] These polarizability parameters were chosen so that they were independent of the choice of the shell charges. The electrical polarizability was defined as

$$\alpha_i=Y_i^2/[k_i+(T_{ii})_0],$$

and the short-range polarizability as

$$d_i=-Y_i(T_{ii})_0/[k_i+(T_{ii})_0],$$

where the suffix i has values 1 for the strontium ion, 2 for the titanium and 3 for the oxygen, and $(T_{11})_0=2A_1+4B_1$, $(T_{22})_0=A_2+2B_2$. The oxygen-ion polarizabilities are not isotropic, so that the polarizability was defined in terms of a mean $(T_{33})_0$ given by,

$$(T_{33})_0=\tfrac{1}{3}(2A_1+4B_1+A_2+2B_2+4A_3+8B_3).$$

The most complicated rigid-ion model of the crystal, then, has eight adjustable parameters, six for the short-range forces and two for the ionic charges, while for a shell model there are fourteen parameters, the same eight and six polarizability parameters.

3. Calculation of Dielectric and Elastic Constants

The frequencies of the normal modes of vibration can be obtained by solving Eq. (2) for a rigid-ion model, or Eqs. (3) for a shell model. Once a particular set of parameters has been chosen, their solution is quite straightforward when the electrostatic coupling coefficients are known. These coefficients were calculated using the EDSAC II computer at the Cambridge University Mathematical Laboratory, and their values for the (0,0,1) direction have already been reported.[16] These and the coefficients for the (1,1,0) and (1,1,1) directions are listed in Appendix III.

The dielectric constants can be evaluated in terms of the parameters introduced above.[2,17] The high-frequency dielectric constant is given by Eq. (2.44) of Ref. 17 and the static dielectric constant by Eq. (2.34). In practice the high-frequency dielectric constant was evaluated explicitly and the static dielectric constant obtained from the Lyddane-Sachs-Teller relation as extended by Cochran.[2]

The elastic constants were evaluated explicitly using the method of long waves as developed by Born and Huang[8] and Cowley.[17] Since every ion is situated at a center of symmetry, the polarizabilities do not affect the elastic constants. The electrostatic contributions were evaluated numerically.[16] The elastic constants are given by:

$$C_{11}=(2e^2/vr)[\tfrac{1}{8}(2A_1+2B_1+A_2+2A_3+2B_3)+0.16485(Z_1^2+Z_2^2)-0.78348Z_3^2-1.0721Z_1Z_2+2.67981Z_2Z_3-1.27803Z_1Z_3],$$

$$C_{12}=(2e^2/vr)[\tfrac{1}{8}(A_1-5B_1-B_2+A_3-5B_3)-0.55532(Z_1^2+Z_2^2)-1.60946Z_3^2+0.26873Z_1Z_2-1.43585Z_2Z_3+0.05648Z_1Z_3],$$

$$C_{44}=(2e^2/vr)[\tfrac{1}{8}(A_1+3B_1+B_2+A_3+3B_3)-0.08242(Z_1^2+Z_2^2)+0.39174Z_3^2+0.53605Z_1Z_2-1.33991Z_2Z_3+0.63902Z_1Z_3].$$

The electrostatic cohesive energy is $(e^2/r)\alpha_M$, where α_M, the Madelung constant, is given by

$$1.25950(Z_1^2+Z_2^2)+4.57109Z_3^2+0.79260Z_1Z_3-0.667170Z_2Z_3+0.48362Z_1Z_2.$$

The equilibrium condition is then

$$4\alpha_M+12(B_1+B_3)+3B_2=0.$$

This last equation when substituted into the equation for C_{12} gives $C_{12}=C_{44}$. r is half the lattice parameter and v the volume of the unit cell, $v=8r^3$.

III. THE EXPERIMENTS

1. Experimental Methods

The excellent single crystal of strontium titanate was a 150-carat boule provided by the Titanium Division of the National Lead Company. The mosaic spread was measured against that of a silicon crystal and was 0.25 deg. The crystal, which had [1,0,0] aligned along the length of the boule, was mounted in a metal cryostat, and could be either cooled or heated from above. It was aligned *in situ* by using neutrons.

The experiments were carried out by using a triple-axis crystal spectrometer.[6]

The integrated intensity of a neutron group, obtained using the "constant Q" technique,[6] is given in the harmonic approximation by[9]

$$\sigma=\frac{\hbar}{8\pi^2}\frac{|\mathbf{k}'|}{|\mathbf{k}_0|}\frac{H(\mathbf{q}j)^2}{\omega(\mathbf{q}j)}\left\{\begin{matrix}N(\mathbf{q}j)\\N(\mathbf{q}j)+1\end{matrix}\right\}.$$

$H(\mathbf{q}j)$ is the structure factor for the mode and is given by

$$H(\mathbf{q}j)=|\sum_K \exp(2\pi i\boldsymbol{\tau}\cdot\mathbf{R}(0K))\mathbf{Q}\cdot\mathbf{e}(K,\mathbf{q}j)b_K M_K^{-1/2}\times\exp(-W(K))|.$$

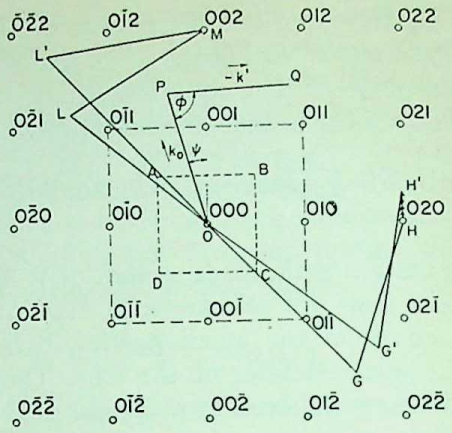

FIG. 2. The (1,0,0) plane of the reciprocal lattice of strontium titanate. The Brillouin zone is labeled ABCD and the area in which the reduced structure factor repeats is enclosed by (0,1,1), (0,1,$\bar{1}$), (0,$\bar{1}$,$\bar{1}$) and (0,$\bar{1}$,1). OLM and OL'M demonstrate the "constant-Q" technique in which the spectrometer is controlled so as to keep the momentum transfer constant while varying the energy transfer, while OGH and OG'H' shows the constant-energy technique in which the momentum is kept along the desired direction.

If a normal mode is propagating along the [0,0,1] direction then the motion of all the ions is either transverse or longitudinal. The dependence of the structure factor on the wave-vector transfer can then be separated out if we assume the Debye-Waller factors for the different atoms to be equal. We can then introduce a reduced structure factor for the normal mode

$$h(\mathbf{q}j)=|\sum_K \exp(2\pi i\boldsymbol{\tau}\cdot\mathbf{R}(0K))e(K,\mathbf{q}j)M_K^{-1/2}b_K|.$$

This reduced structure factor is periodic in reciprocal space. Figure 2 shows the (1,0,0) plane of the reciprocal lattice of strontium titanate. The Brillouin zone is labeled as ABCD, while the reduced-structure factor repeats over a larger unit in reciprocal space, enclosed on Fig. 2 by the reciprocal lattice points (0,$\bar{1}$,1), (0,1,1), (0,1,$\bar{1}$), and (0,$\bar{1}$,$\bar{1}$). Because the structure factor repeats over a larger volume in reciprocal space than the frequencies, there are several different points in reciprocal space at which phonons of the same wave vector have different reduced-structure factors. In the (1,0,0) plane there are four corresponding to reciprocal-lattice vectors, $\boldsymbol{\tau}$: (0,0,0), (0,1,0), (0,0,1) and (0,1,1).

The reduced-structure factor squared has been calculated for each of these different positions for normal modes propagating in the (0,0,1) direction, by using model IV of Sec. IV. The results are shown in Fig. 3.

2. Measurements of the Dispersion Curves

Measurements have been made at 90°K of four of the transverse branches and of most of three of the longitudinal branches. The measured branches are those with the lower frequencies. The results are illustrated in Figs. 7 and 9, where they are compared with several of the models described in the next section. The highest frequency transverse optic branch and the two highest

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

frequency longitudinal optic branches were not measured because of the extra difficulty in measuring these high frequencies. Unfortunately it was not possible to complete the measurements on the longitudinal acoustic branch with the crystal in the (1,0,0) plane.

Less complete measurements were made of three of the transverse branches and the longitudinal acoustic branch at 296°K. The results are shown in Figs. 7 and 9, where they are compared with calculations using several of the models described in the next section.

The frequencies of the normal modes with long wavelength, $\mathbf{q}=0$, can also be obtained by using infrared spectroscopy. Strontium titanate has been studied by Last,[18] Barker and Tinkham[3] and by Spitzer *et al.*[4] The frequencies of the transverse modes can be obtained directly from these measurements, and those of the longitudinal modes by using a result due to Kurosawa,[19] as explained by Cochran and Cowley.[20] In Table I the results of the infrared and neutron techniques are listed, for the $\mathbf{q}=0$ modes.

Since in strontium titanate each ion is situated at a center of symmetry, its Raman spectrum is a second-order spectrum and depends upon the joint density of states for the phonons. Narayanan and Vedam[21] have erroneously interpreted their results as a first-order spectrum.

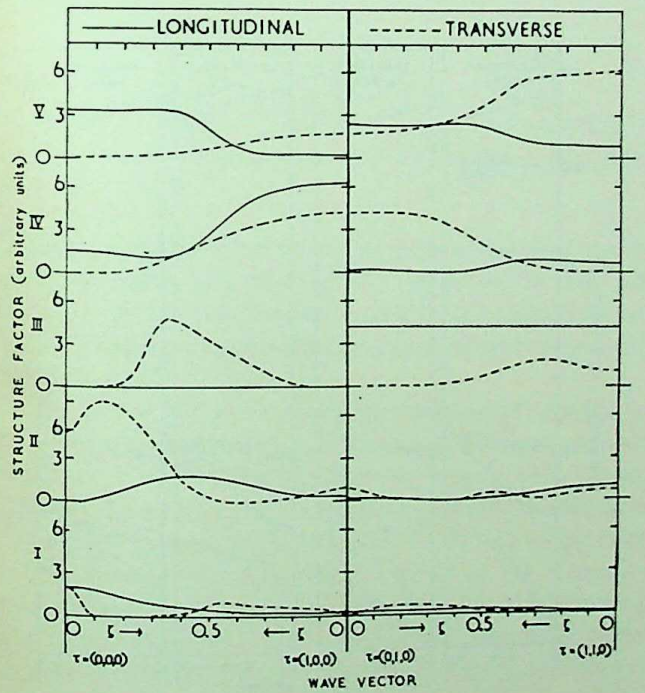

FIG. 3. The reduced structure factor for normal modes propagating along the $(\zeta,0,0)$ direction calculated using model IV of Sec. IV. The solid lines show longitudinal modes and the transverse modes are polarized along the y direction and shown by dotted lines. The modes are labeled in order of increasing frequency.

Longitudinal			
ν_1	5.10*	...	5.25
ν_2	7.95*	...	...
ν_3	...	14.5	13.8
ν_4	...	24.5	24.9

3. The Temperature Dependence of the Lowest Frequency Transverse Optic Mode

Cochran[2] has shown that, if the static dielectric constant of a crystal follows a Curie law temperature dependence,

$$\epsilon^0=C/(T-T_c), \tag{4}$$

the temperature dependence of the $\mathbf{q}=0$ transverse optic mode with lowest frequency is expected to be

$$\omega_T^2=K(T-T_c). \tag{5}$$

Mitsui and Westphal[22] and Weaver[23] have shown that the static dielectric constant above 70°K follows a Curie Law with a Curie temperature of about 35°K.

The $\mathbf{q}=0$ mode of the transverse optic branch with lowest frequency has been studied at five different temperatures, and the neutron groups obtained at three of these temperatures are shown in Fig. 4. The increase in intensity on the low-frequency side of the 90°K group is due to the elastic and acoustic mode scattering associated with the (0,2,0) reciprocal lattice point. The asymmetry of some of the groups and the change in the width of the neutron groups with temperature are probably largely due to effects associated with the finite resolution of the spectrometer.

Figure 5 shows a plot of the frequencies squared against temperature for this normal mode. The excellent straight line gives ample evidence for Eq. (5), and the validity of discussing ferroelectrics as a problem in lattice dynamics, as suggested by Cochran.[2] The Curie temperature is given by the intercept of the straight line with the temperature axis, which yields a Curie temperature of 32 ± 5°K, which is in excellent agreement with the dielectric constant measurements.[22,23]

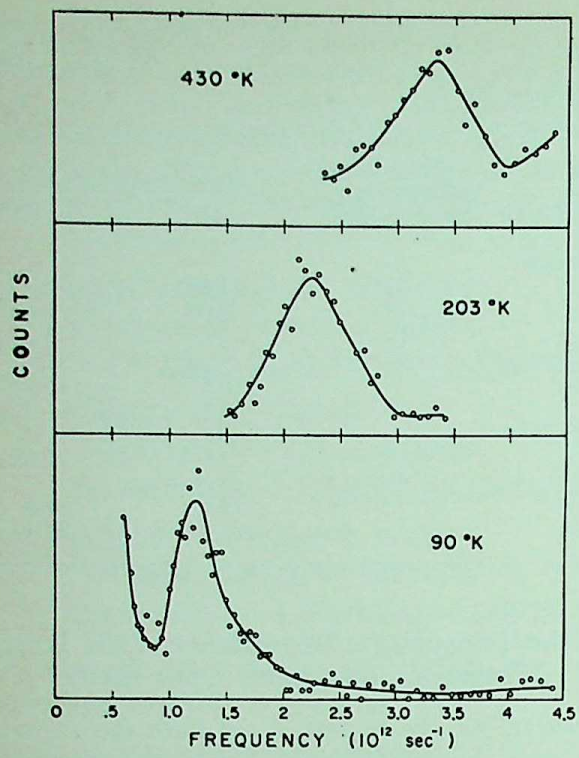

FIG. 4. Neutron groups for the q=0 lowest frequency transverse optic mode at three different temperatures.

4. The Temperature Dependence of the Transverse Acoustic Branch

Recent measurements of the elastic constants of strontium titanate[11,12] have shown that on cooling from room temperature, C_{44} at first increases, but near 110°K it decreases quite dramatically.[11]

Neutron measurements have been made of the $\zeta=(0,0,0.2)$ transverse acoustic mode to see if a similar temperature dependence is found at these higher frequencies. The results are shown in Fig. 6 and there is clearly no evidence for any discontinuity at 110°K, within the limits of experimental error.

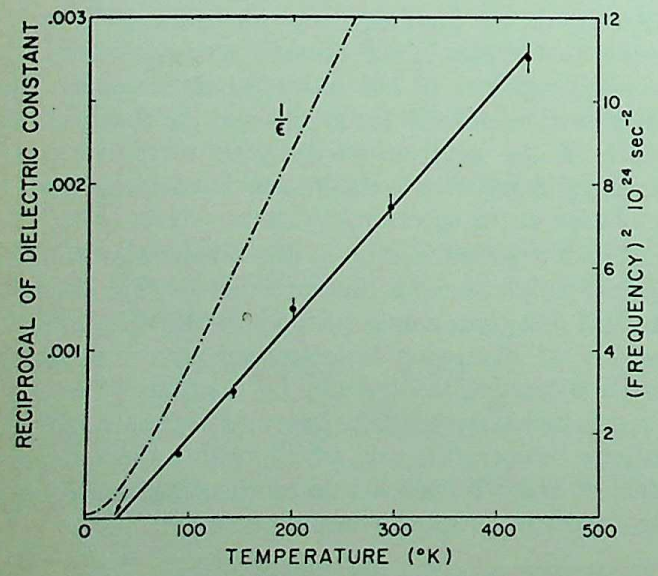

FIG. 5. A plot of the frequency squared against temperature for the q=0 lowest frequency transverse optic mode. The dotted line shows the reciprocal of the static dielectric constant (Refs. 22 and 23).

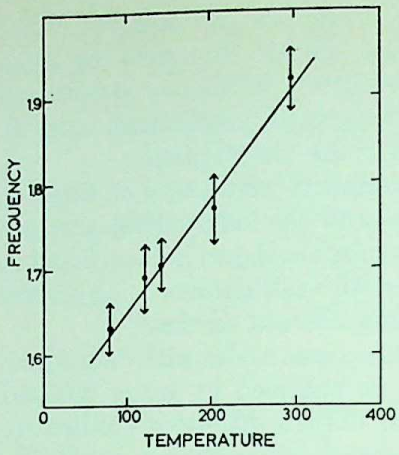

FIG. 6. A plot of the frequency (10^{12} c/sec) against temperature (°K) for the $\zeta=(0.2,0,0)$ transverse acoustic mode.

The ultrasonic measurements also showed anomalous attenuation below 110°K, but no anomalous broadening of the neutron groups at 90°K was detected for either the longitudinal or transverse acoustic branches.

IV. MODELS

The theory of the lattice dynamics of strontium titanate was described in Sec. II. In this section we discuss the results obtained when the parameters of these models are fitted to the experimentally measured elastic[24] and dielectric constants,[22,23,25] and to the fre-

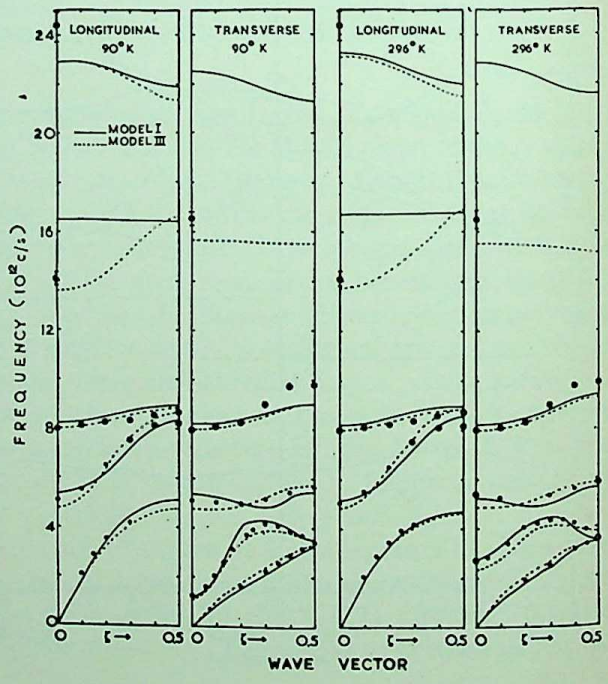

FIG. 7. The dispersion curves for model I (solid line) and model III (dotted line) for the normal modes propagating along the $(\zeta,0,0)$ direction. The experimental measurements are taken from both neutron and infrared results. (See Refs. 3 and 4.) The irreducible representations at the zone boundary are for the longitudinal modes M_2', M_1, M_3, M_1, M_2' in order of increasing frequency, while for the transverse modes they are M_5, M_5', M_5, M_5', M_5 (model I) and M_5', M_5, M_5, M_5', M_5 (model III).

quencies of the normal modes as measured by infrared[3,4] and neutron spectrometry, as described in the last section. The fitting was performed by a nonlinear least-squares analysis and the numerical work was done using the EDSAC II computer.

Results have been obtained for several models at both 90 and 296°K. The parameters of these models are listed in Table II, while their agreement with the experimental elastic and dielectric constants is shown in Table III. The agreement with the measured dispersion relations is shown for models I and III in Fig. 7 and for models IV and V in Fig. 9. The dispersion relations in the (1,1,0) and (1,1,1) directions have also been calculated for some of the models and are shown in Figs. 8 and 10.

A particularly interesting feature of the models is that the large charges in the frequencies of the transverse optic mode with lowest frequency have been obtained with comparatively small changes in the parameters of the models. Model VI, for example, has the ionic charges and polarizabilities of model V at 296°K but fits the 90°K measurements with only small changes in the short-range force constants.

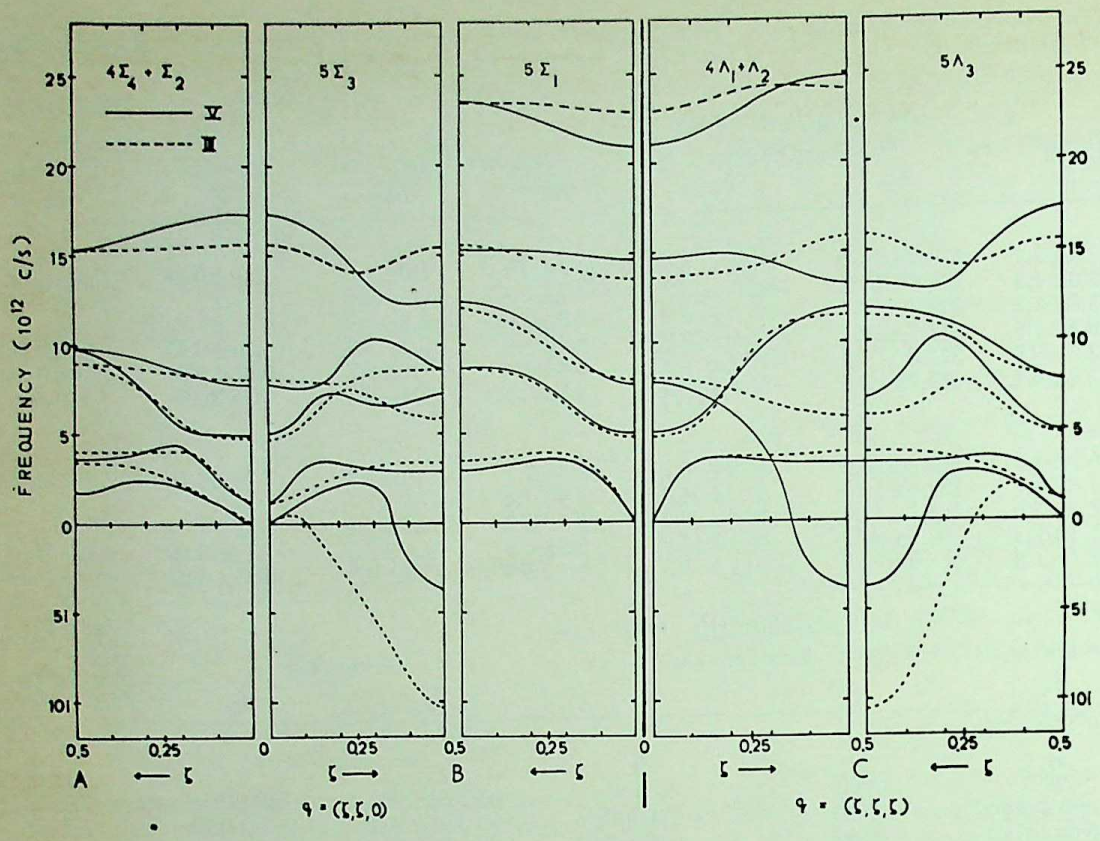

FIG. 8. The dispersion curves in the $(\zeta,\zeta,0)$ and (ζ,ζ,ζ) directions for models III and V at 90°K. The irreducible representations in order of increasing frequency are at the point (A); M_2', M_3', M_5, M_3' (model III), and M_3', M_2', M_5, M_3' (model V). At the point (B) they are M_2, M_5', M_3, M_5', M_1, M_5', M_4 for model III and M_3, M_5', M_2, M_5', M_5', M_1, M_4 for model V, while at the zone boundary (C) they are Γ_{12}', Γ_{15}, Γ_{25}, Γ_{15}, Γ_{25}', Γ_2' (model III), and Γ_{25}, Γ_{15}, Γ_{12}', Γ_{25}', Γ_{15}, Γ_2' (model V).

V. THE 110°K PHASE TRANSITION

1. The Temperature Dependence of the Elastic Constants

The temperature dependence of the elastic constants of crystals has been discussed by several authors.[8,26] The potential energy of the crystal is expanded in a double power series of the deformation parameters and of the phonon coordinates, Eq. (40.4) of Ref. 8.

If this expansion is taken about the equilibrium configuration of the lattice at each temperature, then the isothermal elastic constants can be obtained from[8,26]

$$(\alpha\beta,\gamma\delta)=\Phi_{\alpha\beta\gamma\delta}(--)+\sum_{\mathbf{q}}\sum_{j}\Phi_{\alpha\beta\gamma\delta}(--,\mathbf{q}j-\mathbf{q}j)(\hbar/2(\mathbf{q}j))(2n(\mathbf{q}j)+1)+\sum_{jj'}{}'\sum_{\mathbf{q}}\Phi_{\alpha\beta}(-,\mathbf{q}j-\mathbf{q}j')$$
$$\times\Phi_{\gamma\delta}(-,-\mathbf{q}j\mathbf{q}j')\frac{\hbar}{2\omega(\mathbf{q}j)}\left(\frac{2n(\mathbf{q}j)+1}{\omega^2(\mathbf{q}j)-\omega^2(\mathbf{q}j')}\right)-\sum_{j}\sum_{\mathbf{q}}\Phi_{\alpha\beta}(-,\mathbf{q}j-\mathbf{q}j)\Phi_{\gamma\delta}(-,\mathbf{q}j-\mathbf{q}j)$$
$$\times\left[\frac{\hbar}{4\omega(\mathbf{q}j)^3}(2n(\mathbf{q}j)+1)+\frac{\hbar^2}{2\omega(\mathbf{q}j)^2kT}n(\mathbf{q}j)(n(\mathbf{q}j)+1)\right]. \quad (6)$$

The notation is similar to that of Born and Huang.[8] The elastic constants are then given by

$$C_{\alpha\beta\gamma\delta}{}^{\mathrm{iso}}=(1/4V)[(\alpha\beta,\gamma\delta)+(\alpha\beta,\delta\gamma)+(\beta\alpha,\gamma\delta)+(\beta\alpha,\delta\gamma)].$$

The adiabatic and isothermal elastic constants are related by macroscopic relations, which in Voigt's notation are

$$C_{11}{}^{\mathrm{ad}}-C_{11}{}^{\mathrm{iso}}=C_{12}{}^{\mathrm{ad}}-C_{12}{}^{\mathrm{iso}}$$
$$=(TV\alpha^2/C_V)(C_{11}{}^{\mathrm{iso}}+2C_{12}{}^{\mathrm{iso}})^2,$$
$$C_{44}{}^{\mathrm{ad}}-C_{44}{}^{\mathrm{iso}}=0.$$

The third term in the expression (6) for the elastic constants is particularly of interest. The summation is over all the different pairs of normal modes with a particular wave vector and belonging to different branches of the dispersion relations. Figure 11 shows the longitudinal-acoustic and transverse-optic dispersion curves at 296°K and at 90°K. At the higher temperature the curves are well separated, but at 90°K they appear to be almost degenerate over a considerable region of wave-vector space. Since at zero wave vector the temperature dependence of the transverse optic mode is given by Eq. (5), it might be expected that the temperature dependence of the denominator in the third term of Eq. (6) for these two normal modes is given by

$$\omega^2(\mathbf{q}j)-\omega^2(\mathbf{q}j') \quad \alpha \quad T-T_A,$$

[26] G. Leibfried and W. Ludwig, in *Solid State Physics*, edited by F. Seitz and D. Turnbull (Academic Press Inc., New York, 1961), Vol. 12.

where T_A is the temperature at which they become degenerate. The above temperature dependence can also be obtained by using a lowest order anharmonic theory of the temperature dependence of the normal modes.

The other factors in the expression for the elastic constants are either independent of temperature or as a first approximation can be written as proportional to temperature in a limited temperature range. The elastic constant is then given by an expression of the type

$$C_{\alpha\beta,\gamma\delta}=A+BT+C/(T-T_A). \quad (7)$$

The coefficients A, B, C can, in principle, be obtained from the matrix elements and summations over the normal modes. The coefficient C would be particularly difficult to evaluate, because it depends on the detailed shape of the dispersion curves near the degeneracy.

The temperature dependence of the elastic constants has been measured above 110°K by Bell and Rupprecht,[11] who obtained

$$C_{11}=3.341\times10^{12}[1-2.62\times10^{-4}(T-T_A)-0.0992/(T-T_A)],$$
$$C_{12}=1.049\times10^{12}[1-1.23\times10^{-4}(T-T_A)+0.1064/(T-T_A)], \quad (8)$$
$$C_{44}=1.267\times10^{12}[1-1.30\times10^{-4}(T-T_A)-0.1242/(T-T_A)],$$

with $T_A=108$°K.

These results are clearly in agreement with the temperature dependence predicted by Eq. (7). Bell and Rupprecht[11] also found that the ultrasonic attenuation increases dramatically near 110°K. The ultrasonic attenuation can be calculated in an exactly similar way to the elastic constant[27] and arises when the frequency Ω of the ultrasonic wave is such that

$$\Omega=\omega(\mathbf{q}j)-\omega(\mathbf{q}j'). \quad (9)$$

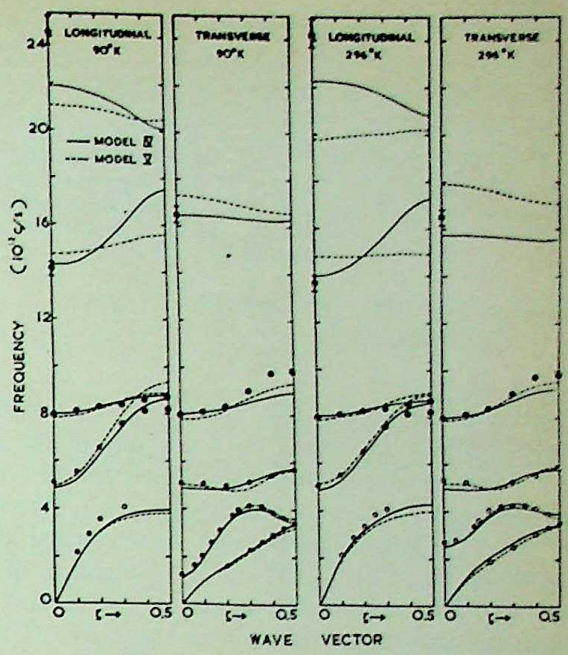

FIG. 9. The dispersion curves for model IV (solid line) and model V (dotted line) for normal modes propagating along the $(\zeta,0,0)$ direction. The experimental measurements are taken from both neutron and infrared spectrometry. (See Refs. 3 and 4.) The irreducible representations at the zone boundaries are for the longitudinal modes M_2', M_1, M_3, M_1, M_2' except for model V at 90°K which gives M_2', M_2, M_1, M_1, M_2' while for the transverse modes they are M_5, M_5', M_5, M_5', M_5. The irreducible representations are listed in order of increasing frequency.

If the transverse optic mode is almost degenerate with the longitudinal acoustic mode in this temperature region over a considerable region of q space, as suggested by Fig. 11, then there will be many normal modes for which Eq. (9) can be satisfied and the ultrasonic attenuation will be large.

2. The Transition

The elastic constants of the crystal will become negative just above T_A, Eqs. (8). When the elastic constants

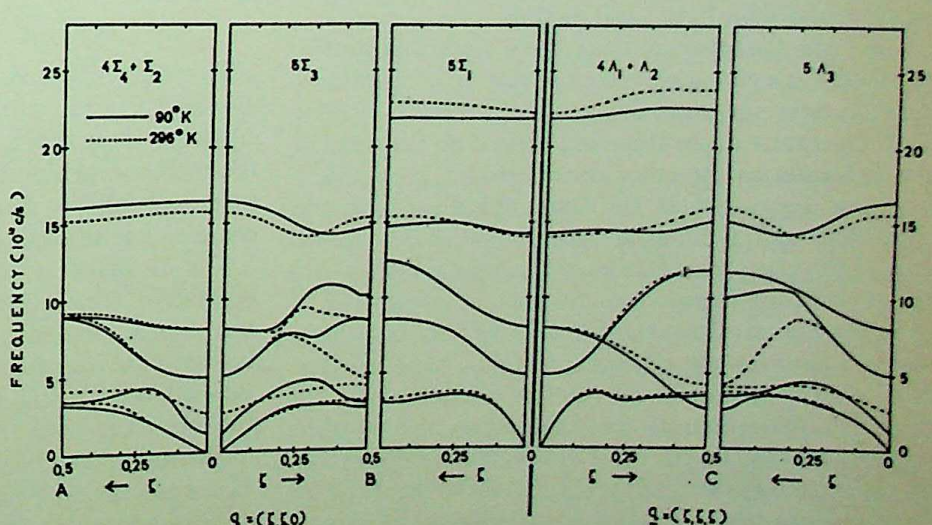

FIG. 10. The dispersion curves of model IV in the $(\zeta,\zeta,0)$ and (ζ,ζ,ζ) directions. In order of increasing frequency the irreducible representations are for the zone boundary (A) M_3', M_2', M_5, M_3' (90°K) and M_2', M_3', M_5, M_3' (296°K), for the zone boundary (B) M_3, M_5', M_5', M_2, M_1, M_5', M_4 (90°K) and M_5', M_3, M_2, M_5', M_1, M_5', M_4, while for the zone boundary (C) they are Γ_{25}, Γ_{15}, Γ_{12}', Γ_{15}, Γ_{25}', Γ_2' (90°K) and Γ_{15}, Γ_{25}, Γ_{12}', Γ_{15}, Γ_{25}', Γ_2' (296°K).

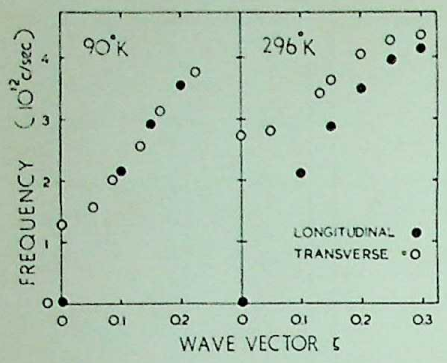

FIG. 11. The longitudinal acoustic and lowest transverse optical branches at 90 and 296°K.

become zero the crystal will undergo a spontaneous deformation to a new structure, the extent of the deformation depending upon the third- and fourth-order elastic constants. Since the elastic constant C_{44} becomes negative at the highest temperature, a tetragonal low-temperature structure can result by combining three shear distortions along different axes in the crystal. A tetragonal structure of strontium titanate below 110°K has been found by Rimai and deMars.[28] In this transition the volume of the crystal does not change, and it is extremely likely that the crystal splits up into small domains, with the major tetrad axis, the z direction in the domain, along different cube axes.

The elastic constants and the free energy of the crystal depend not only on the frequencies $\omega(\mathbf{q}j)$ and $\omega(\mathbf{q}j')$ which are nearly degenerate, but also on the number of these normal modes which are nearly degenerate. The temperature dependence of the distortion can then be estimated if we assume that its magnitude is proportional to the difference in the number of normal modes just above the degenerate frequency to those just below this. The frequencies squared of the transverse optic modes are linearly temperature-dependent, while the deformation is limited by the third-order elastic constants which are assumed to be independent of temperature. The temperature dependence of the distortion is then proportional to $(T_A-T)^{1/2}$ as found experimentally by Rimai and deMars.[28]

The discussion given above is very crude and cannot be expected to give satisfactory results at temperatures far away from the transition temperature. In particular the temperature dependence will depend on the effect of the distortion on the other normal modes, particularly near the degeneracy in the longitudinal acoustic and transverse optical branches, the temperature dependence of the population factors of the normal modes, and the effect of the domain structure on the free energy.

Below the transition the behavior of the elastic constants and ultrasonic attenuation will be very complex. The elastic constants will be an average over the different orientations of the domains, as well as being strongly affected by the exact details of the degeneracies of the normal modes and their behavior in the distorted crystal. The ultrasonic attenuation will also be anomalous because of reflection of the ultrasonic waves at the surfaces of the domains, as suggested by Bell and Rupprecht.[11]

[28] L. Rimai and G. A. deMars, Phys. Rev. 123, 702 (1962).

3. The Dielectric Properties

Below 110°K the frequencies of the normal modes of vibration will be altered by the distortion of the crystal. It is likely that the frequency of the transverse optic mode will be particularly sensitive because of the large changes which occurred when small changes were made in the parameters of the models of Sec. IV. If the lattice spacing decreases by δa along the x and y directions and increases by $2\delta a$ along the unique z axis, the frequency of a transverse optical mode depends upon whether it is polarized along or perpendicular to the z axis.

The changes in the frequencies due to the distortion can be estimated from the volume dependence of the frequencies in the cubic structure. Equation (5) for the frequency will be modified to

$$\omega_z^2=K(T-T_c)+2\delta aB\,,$$
$$\omega_x^2=K(T-T_c)-\delta aB\,,$$

where ω_z is the normal mode polarized along the z axis and $B=d\omega^2/da$.

The distortion of the crystal then changes the Curie temperature by $-2\delta aB/K$ for displacements along the z axis, and by $\delta aB/K$ for those perpendicular to it.

The dielectric constant of a large crystal can then be estimated by assuming that there are an equal number of domains orientated with the z axis along each of the three original cube axes. The average dielectric constant is then

$$\frac{1}{\epsilon^0}=\frac{1}{3}\left(\frac{T-T_c+(2\delta aB/K)}{C}+2\frac{T-T_c-(\delta aB/K)}{C}\right),$$

and therefore,

$$\epsilon^0=C/(T-T_c).$$

The dielectric constant of a bulk sample of the distorted crystal is then identical with that of the crystal if there was no distortion. This result explains the rather surprising experimental result[11,22,23] that the reciprocal of the dielectric constant does not even change slope through the 110°K transition.

The distortion does however influence the low-temperature dielectric properties. Since the Curie temperature is raised in one direction, some of the domains can become polarized above T_c. This spontaneous polarization will occur along different directions in the crystal, corresponding to the different orientations of the domains, and will be frozen in to a particular configuration by the domain pattern produced by the 110°K transition.

The dielectric behavior at low temperatures will therefore be extremely complicated. Deviations from the Curie law will be caused by the spontaneous

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

polarization of some of the domains. Further and probably larger deviations will be caused by quantum effects. Barrett[29] demonstrated how these occur by using a Slater model of a ferroelectric, and very similar conclusions can be obtained by using a lattice dynamical approach. These two effects can probably account for the deviations from a Curie law found experimentally.[22,23]

When an electric field is applied the crystal shows a remanence polarization[22] at temperatures above 50°K, the size of this remanence polarization increasing as the temperature decreases. This polarization may be produced by the electric field aligning the spontaneous polarization of some of the domains, which is then frozen in by the domain structure when the field is released. The increase in magnitude with decreasing temperature arises because more and more domains become spontaneously polarized. The distortion required to shift the Curie temperature to 50°K, an increase of about 15°K, can be estimated from the measurements of the pressure dependence of the Curie temperature,[30] while the sign of the distortion is given by the change in free energy of the crystal. The change in the vibrational part of the free energy due to the changes in the frequency of the transverse optic mode show that the domains are probably elongated along the unique z axis. The dependence of the Curie temperature on lattice spacing is

$$\frac{dT_c}{da}=\frac{1.2\times10^4}{a}.$$

For an increase in Curie temperature of 15°K, the increase in length along the tetragonal axis is 0.005 Å, while the contraction perpendicular to the axis is 0.0025 Å. These distortions are very small, and could easily have been missed in the x-ray diffraction work quoted by Bell and Rupprecht.[11]

VI. DISCUSSION

1. The Parameters of the Models

The parameters for the rigid-ion model (I) show that both the short-range forces between the titanium and oxygen ions and the titanium and oxygen ionic charges are considerably smaller than for the shell models. This decrease in magnitude must in some way compensate for the neglect of the polarizabilities of the ions.

The parameters of all of the shell models are far more similar to one another than they are to the rigid-ion models. The parameters specifying the short-range forces in models II and III, in which the ionic charges were kept fixed, are very similar, but when the ionic charges were allowed to vary in models IV and V there was a decrease in the strontium-oxygen forces and a slight increase in the titanium-oxygen forces. These changes are accompanied by a decrease in the ionic charge of the strontium ions and an increase of the charge on the titanium ions.

It is of interest to compare the parameters of the short-range forces with those obtained by the method suggested by Fowler.[31] Devonshire,[32] Kinase,[33] and Dvorak and Janovec[34] have used these forces to describe the forces in perovskite ferroelectrics. In the notation of Sec. II.2, the parameters of their forces are:

$$A_1=30.1 \quad A_2=429.1 \quad A_3=63.5$$
$$B_1=-2.74 \quad B_2=-41.53 \quad B_3=-6.16.$$

Although these force constants are significantly different from those of any of the models of Sec. IV, they do exhibit some of the principal features; for example, A_2 is by far the largest. Nevertheless, the frequencies of the normal modes of vibration are so sensitive to small changes in the parameters that these short-range force constants do not give an adequate description of the interactions.

When the ionic charges were allowed to vary in the shell models (IV, V), the charge on the titanium ion becomes larger than four, and on the strontium ion about one electronic charge. The charge on the oxygen ions remains at nearly two. These results suggest that the bonding in strontium titanate is more nearly ionic than covalent in character.

There is a considerable reduction in the error of the models when the short-range polarizabilities of the positive ions are allowed to vary (III, IV). These polarizabilities of the positive ions come out either very small or negative, and cannot be readily understood in terms of the shell model. These results are exactly similar to those found for the alkali halides, potassium bromide and sodium iodide.[15] In an exactly analogous way to the alkali halides, when the titanium ion's electrical polarizability was allowed to vary (V) the polarizability of the positive ion was larger than the crystal polarizability,[35] while the polarizability of the oxygen ions was reduced. It was shown[15] that these surprising polarizability parameters could arise in the alkali halides from the neglect of the quadrupole moments produced on the negative ions. A similar explanation can be advanced here in terms of the quadrupole moments of the oxygen ions.

A surprising feature of the polarizabilities of the oxygen ions is their anisotropy. For example, the electrical polarizability of the oxygen ions for the 90°K model V is $2\frac{1}{2}$ times as large in the strontium-oxygen plane as in the titanium-oxygen direction. The short-range polarizability in the titanium-oxygen direction is -1.41, while it is 0.615 in the strontium-oxygen plane.

These polarizability parameters suggest that the electronic wave functions of the oxygen ions may be considerably distorted from spherical, and that the shell parameters Y_3 and k_3, which were assumed to be isotropic, should be different for different directions.

2. The Motion of the Ions in the Normal Modes

There has been considerable discussion as to the nature of the ionic displacements in the transverse optic modes of strontium titanate. The polarization vectors for these normal modes have been obtained for several of the models described earlier, and are listed in Table IV for model IV. The lowest frequency transverse optic mode is found to be predominantly a vibration of the titanium ion against the rest of the structure.

If the crystal becomes unstable against the lowest frequency transverse optic mode of vibration, it might be expected that the displacements of the ions would resemble the pattern of the displacements in the transverse optic mode of vibration.[2] It is therefore of interest to compare the displacements of the ions with the measured displacements of the ions in tetragonal barium titanate,[36] and these are also shown in Table IV. Considering the difference in the masses, sizes and polarizabilities of strontium and barium ions, the displacements of the ions in barium titanate are fairly similar to those in the lowest transverse optic mode of strontium titanate.

3. The Temperature Dependence of the Transverse Optic Modes

One of the most interesting features of strontium titanate is the temperature dependence of the transverse optic mode of lowest frequency. The difference between the parameters of the models which were fitted to the measurements at 90°K and those fitted to the 296°K measurements are not large, and model VI shows that it is possible to obtain the temperature dependence by changing the parameters of the short-range interactions by quite small amounts. These results show that only quite small changes in the parameters of the interactions can give rise to the observed temperature dependence.

The temperature dependence of the normal modes in potassium bromide has been investigated both experimentally[10] and theoretically.[15] The changes in the parameters of the models, which are needed to reproduce the changes in the frequencies of the normal modes from 90 to 400°K, are fractionally very similar to those required for strontium titanate. We can therefore conclude that, broadly speaking, it is not necessary to invoke any mechanism to explain the temperature dependence in strontium titanate, other than what is present in the alkali halides.

The temperature dependence of the normal modes in sodium iodide and potassium bromide has recently been shown to arise largely from the anharmonic interactions between the normal modes.[37] Quantitative calculations of the anharmonic effects in strontium titanate, which will be reported elsewhere, suggest that a similar mechanism is responsible for the temperature dependence of its normal modes.

The anomalous behavior of the normal modes in strontium titanate compared with the alkali halides is associated with the difference in the dynamical matrices of the two crystals. In the alkali halides, the frequencies of the normal modes are all fairly similar in magnitude (apart from the elastic constants region of the acoustic branches). For strontium titanate, on the other hand, there is a very large difference between the frequencies of the optical modes. At 90°K the ratio of the highest to lowest eigenvalue (frequency squared) of the dynamical matrix is as large as 400:1. A change in the parameters of only 0.25% will then hardly alter the largest eigenvalue but can drastically alter the smallest. The ferroelectric character of these perovskites then arises from the almost perfect cancellation of the strong short-range and Coulomb interactions for one particular normal mode. A small change in either of these strong interactions has a drastic effect on the frequencies of this normal mode.

TABLE IV. The displacements of the ions in the $q=0$ modes of model IV at 90°K, polarized along the z direction, and expressed so that the eigenvectors of the dynamical matrix are normalized and orthogonal. The numbering of the modes is in order of increasing frequency.

4. Unstable Normal Modes in the (1,1,0) and (1,1,1) Directions

Several of the models described in Sec. IV show instabilities against some of the normal modes of vibration propagating along the (1,1,0) and (1,1,1) directions. Examples of these are shown in Fig. 8 for models III and V. It is unlikely that these instabilities occur in strontium titanate and in this respect those models

[36] B. C. Frazer, H. R. Danner, and R. Pepinsky, Phys. Rev. **100**, 745 (1955).

[37] R. A. Cowley, Phys. Chem. Solids (to be published).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which show them are unrealistic. However, these instabilities may well occur in some of the perovskite materials which have phases that are slightly distorted forms of the cubic perovskite structure. For example, $CdTiO_3$, $NaTaO_3$, $CaTiO_3$, $NaNbO_3$ show multiple unit cells which are $2\times2\times2$ times the cubic cell when referred to the original cube axes while $NaNbO_3$ shows a $4\times2\times2$ unit cell, and $PbZrO_3$ shows a $4\times4\times2$ unit cell.[38]

All of the unstable normal modes are rotations of groups of the oxygen ions. In models I and V octahedra rotate around the titanium ion while in model III squares of oxygens rotate about the points $(\frac{1}{2},0,0)$, $(0,\frac{1}{2},0)$ and $(0,0,\frac{1}{2})$. A further feature of these unstable normal modes is that their frequencies are very dependent upon the details of the models. For example, the normal mode Γ_{25}' are unstable for models I and V but for model III have a frequency of 2.6 and for model IV of 3.5.

The transitions to the multiple unit cell perovskites may well be instabilities against these normal modes as suggested by Cochran.[2] Unfortunately the displacements of the ions in real distorted perovskite structures are far more complex than mere oxygen octahedra rotations. However, in several of these materials, the rotations of the oxygen octahedra are the predominant displacements.[39] The displacements of the other ions are not, however, negligible and a detailed treatment would be very complicated. The unstable normal mode must be strongly coupled both to the macroscopic strain parameters and to some of the other normal modes in the crystal.

5. The Models of Other Authors

Several authors have previously used models for the lattice dynamics of perovskite ferroelectrics. Devonshire[32] used a rigid-ion model with Fowler's[31] short-range forces to attempt to relate the parameters of his thermodynamic theory to the microscopic interactions. Recently Dvorak and Janovec[34] have calculated the frequencies of the transverse optic modes of this model, and have found the structure unstable unless the formal ionic charges are multiplied by a factor 0.16. The frequencies are not then in agreement with the results of neutron or infrared spectrometry.

Kinase[33] has used this model, and included the electrical polarizabilities of the ions, but the results were no more satisfactory.

Last[18] suggested that the infrared spectra could be explained by assuming that the titanium-oxygen octahedra was a strongly bound complex which was weakly coupled to the other anion. As the lowest frequency optic mode is a vibration of the titanium against the rest of the structure this model is unsatisfactory. Rajopal and Srinivasan[40] studied the frequencies of vibration at $\mathbf{q}=0$ when all the Coulomb forces are neglected. The high- and low-frequency dielectric constants of this model are then equal (to unity!) and the frequencies do not agree with the experimental results. A similar model has been used by Silverman and Joseph[41] for the transverse optic modes with $\mathbf{q}=0$.

VII. CONCLUSIONS

The frequency versus wave-vector dispersion curves of strontium titanate for several normal modes propagating in the [0,0,1] direction have been measured experimentally by using neutron spectrometry. These results have been used to find the parameters of several models of the crystal within the harmonic approximation. It was found that quite reasonable agreement with experiment could be obtained by using shell models in which the ions interact with one another both through short-range forces between neighboring ions, and through long-range electrostatic forces, determined by the ionic charges. The effects of the polarizabilities of the ions are also included. The principal features of the more successful models are that the titanium-oxygen short-range forces are very large, while the ionic charges on the ions are also large and very nearly the formal charges.

Of particular interest in strontium titanate is the temperature dependence of the transverse optic mode with lowest frequency. This was measured experimentally and for the $\mathbf{q}=0$ mode the square of the frequency was found to be proportional to temperature above 90°K, in agreement with the temperature dependence of the static dielectric constant as predicted by Cochran.[2] This result shows that it is a valid approach to treat the problem of ferroelectricity as an instability of the crystal against one of the normal modes. The motion of the ions in this normal mode was obtained for several of the models used, and was found to be predominantly a vibration of the titanium ion against the oxygen octahedron. The displacements of the ions at the ferroelectric transition in barium titanate are very similar to this.

It was found that the experimentally observed changes in the frequencies of this normal mode could be obtained by changing the parameters of the shell models only slightly. The fractional changes were very similar to those needed to reproduce the temperature dependence of the normal modes in the alkali halides. This result suggests that it is unnecessary to introduce any mechanism to explain the temperature dependence of this normal mode, other than those which occur in the alkali halides. The indications are then that the temperature dependence of this normal mode can be explained

in terms of the anharmonic interactions between the normal modes of vibration.

The dispersion curves along the (1,1,0) and (1,1,1) directions of the models have been calculated and some of these show normal modes against which the crystal would be unstable. Although it is unlikely that these instabilities occur in strontium titanate, they may well be associated with the transitions in other perovskite materials.

The transition in strontium titanate at 110°K has been discussed in terms of an accidental degeneracy of two branches of the dispersion curves. The experimental results from neutron spectrometry show that this degeneracy occurs very near 110°K. The anomalous elastic properties near 110°K and the smooth behavior of the static dielectric constant can be easily obtained with this theory. It is suggested that the conflicting experimental results on the low-temperature dielectric properties, and the temperature dependence of the distortion of the crystal can also be explained by this approach.

It is clearly of interest to try to obtain more satisfactory models of strontium titanate, in the hope of obtaining a better understanding of both the temperature dependence of the static dielectric constant and of the 110°K transition. Experimental measurements of the dispersion curves in the (1,1,0) and (1,1,1) directions would enable the parameters of the models to be fitted more accurately. The models could then be extended by including anisotropic oxygen polarizabilities, more short-range forces, and abandoning the assumption that $\mathbf{R}=\mathbf{T}=\mathbf{S}$.

The difficulties in describing the results in terms of a harmonic model might then become more serious, and it might well prove necessary to use a complete anharmonic theory to describe the lattice vibrations.

ACKNOWLEDGMENTS

The author is grateful for helpful discussions on the experimental measurements with Professor B. N. Brockhouse, on group theory with Dr. V. Heine, and on distorted perovskite structures with Dr. H. D. Megaw and Dr. I. Lefkowitz. Above all, however, he is indebted to Dr. W. Cochran, F.R.S., who suggested the study of strontium titanate and who has continually given helpful advice and criticism.

The author is grateful for the award of a NATO studentship from the Department of Scientific and Industrial Research and to Atomic Energy of Canada Ltd. for allowing him to use experimental facilities. Permission to use the EDSAC II computer at the Cambridge University Mathematical Laboratory was given by Dr. M. V. Wilkes, F.R.S., for which the author is grateful. The excellent single crystal of strontium titanate was provided by the Titanium Division of the National Lead Company, for which the author is grateful.

APPENDIX I

A. The Characters of the Symmetry Operations

The representation chosen for the normal modes is obtained by displacing each ion in turn along the coordinate axes by a unit distance. The characters of the different symmetry elements are:

identity operator

$$\chi(E)=15,$$

triad axis

$$\chi(C_3)=0,$$

tetrad axis along the z axis

$$\chi(C_{4z})=1+2\exp(i2q_xr),$$

diad axis along the z axis

$$\chi(C_{2z})=-1-\exp(i2q_xr)-\exp(i2q_yr)-2\exp(i2(q_x+q_y)r),$$

diad axis at 45° to both x and y axes

$$\chi(C_{2xy}')=-2-\exp(i2q_zr),$$

inversion operator

$$\chi(I)=-3[1+\exp(i2(q_x+q_y+q_z)r)+\exp(i2(q_x+q_y)r)+\exp(i2(q_y+q_z)r)+\exp(i2(q_x+q_z)r)],$$

plane of symmetry perpendicular to the z axis

$$\chi(\sigma_{xy})=2+3\exp(i2q_zr),$$

plane of symmetry at 45° to x and y axes and including z axis

APPENDIX II: THE CONTRIBUTION OF THE SHORT-RANGE FORCES TO THE MATRIX $R(KK')$

The complete (15×15) matrix can be split up into the (5×5) matrices for the (xx), $(yy)\cdots$ components. In this appendix the (xx) and (xy) components are tabulated, in terms of the force constants introduced in Sec. II.2. C_x, C_y, C_z are the cosines of q_xr, q_yr, q_zr, while S_x, S_y, S_z are the analogous sines, and $2r$ is the lattice parameter.

The matrix $\mathbf{R}_{xx}$ in units of e^2/v is

	Ti	Sr	O_I	O_{II}	O_{III}
Ti	A_2+2B_2	0	$-B_2C_z$	$-B_2C_y$	$-A_2C_x$
Sr	0	$2A_1+4B_1$	$-(A_1+B_1)C_xC_y$	$-(A_1+B_1)C_xC_z$	$-2B_1C_yC_z$
O_I	$-B_2C_z$	$-(A_1+B_1)C_xC_y$	$A_1+B_1+B_2+A_3+3B_3$	$-2B_3C_yC_z$	$-(A_3+B_3)C_xC_z$
O_{II}	$-B_2C_y$	$-(A_1+B_1)C_xC_z$	$-2B_3C_yC_z$	$A_1+B_1+B_2+A_3+3B_3$	$-(A_3+B_3)C_xC_y$
O_{III}	$-A_2C_x$	$-2B_1C_yC_z$	$-(A_3+B_3)C_xC_z$	$-(A_3+B_3)C_xC_y$	$2B_1+A_2+2A_3+2B_3$

The matrix $\mathbf{R}_{xy}$ is, in units e^2/v:

	Ti	Sr	O_I	O_{II}	O_{III}
Ti	0	0	0	0	0
Sr	0	0	$(A_1-B_1)S_xS_y$	0	0
O_I	0	$(A_1-B_1)S_xS_y$	0	0	0
O_{II}	0	0	0	0	$(A_3-B_3)S_xS_y$
O_{III}	0	0	0	$(A_3-B_3)S_xS_y$	0

[a] The dimensionless Coulomb coefficients are defined in Ref. 16. If these numbers are multiplied by $(e^2/v)Z_KZ_{K'}$ they give the Coulomb contributions to the dynamical matrix.

Optical Absorption in an Electric Field

JOSEPH CALLAWAY*
Aeronutronic Division of Philco Corporation, Newport Beach, California
(Received 26 December 1963)

A previous calculation of the effect of an external, uniform electric field on the optical absorption associated with a direct transition between bands is extended. The absorption is shown to consist of a series of steps whose width is determined by the separation of the discrete levels produced by the field.

IN a previous calculation[1] (which will be referred to as I), it was shown that the discrete levels which are formed when a uniform electric field is present in an insulating crystal[2] produce a periodic structure in the energy dependence of the absorption due to interband transitions. The expression for the absorption coefficient which was given in that paper is a slowly convergent Fourier series which cannot easily be interpreted. It is the object of the present work to transform this series in such a way that the energy dependence of the optical absorption is evident. I hope that this work will help to stimulate experimental investigation of the discrete levels.

An infinite crystal containing a uniform electric field $\mathcal{E}$, in the x direction is considered. From Eqs. (14) and (21) of I, the following expression is obtained for the absorption coefficient α, produced by a direct transition between bands n' and n (the notation conforms to I as far as possible):

$$\alpha=\frac{2\kappa^2}{F\pi\omega n\epsilon_0 c\mathfrak{A}_0^2}\left[\int\frac{d\mathbf{k}_\perp}{(2\pi)^2}|M_{nn'}(x_0)|^2+2\sum_{l=1}^{\infty}\int\frac{d\mathbf{k}_\perp}{(2\pi)^2}|M_{nn'}(x_0)|^2\cos 2\pi l x_0\right], \quad (1)$$

in which κ is the width of the Brillouin zone in the x direction (which coincides with a reciprocal lattice vector); $\mathbf{k}_\perp$ represents components of the wave vector perpendicular to the field; $\mathfrak{A}_0$ is the magnitude of the vector potential of the radiation field (which has circular frequency ω); n is the index of refraction, and ϵ_0 is the permittivity of free space. In addition, $F=e\mathcal{E}$, and

$$x_0=\frac{\kappa}{2\pi F}(\Delta_{nn'}-\hbar\omega), \quad (2a)$$

where

$$\Delta_{nn'}(\mathbf{k}_\perp)=\kappa^{-1}\int_{-\kappa/2}^{\kappa/2}[E_n(k_x,\mathbf{k}_\perp)-E_{n'}(k_x,\mathbf{k}_\perp)]dk_x. \quad (2b)$$

The matrix element $M_{nn'}$ is given by

$$M_{nn'}=\frac{2\pi e\mathfrak{A}_0\beta^{1/3}}{m\kappa}(\boldsymbol{\varepsilon}\cdot\mathbf{p}_{nn'})\,\mathrm{Ai}(\sigma\beta^{1/3}), \quad (3)$$

where $\mathbf{p}_{nn'}$ is the usual interband matrix element of the momentum and $\boldsymbol{\varepsilon}$ is the polarization vector of the radiation. Both bands are treated in the effective mass approximation, so that the energy difference between bands is

$$E_n-E_{n'}=E_g+(\hbar^2k^2/2\mu). \quad (4)$$

In this equation, E_g is the energy gap at $k=0$, and μ is the reduced mass for the two bands: $\mu^{-1}=m_n^{-1}+m_{n'}^{-1}$. We also have

$$\beta=2\mu F/\hbar^2;\quad \sigma=F^{-1}(E_g-\hbar\omega+\hbar^2k_\perp^2/2\mu),$$

and Ai is the Airy integral, which is defined by

$$\mathrm{Ai}(z)=\frac{1}{\pi}\int_0^\infty\cos(sz+s^3/3)ds.$$

Other quantities which are not explicitly defined above have their usual significance.

In I, approximate expressions were worked out for the terms of the series, Eq. (1). It is, however, evident from Eqs. (1) and (2) without approximation that whenever the photon energy $\hbar\omega$ increases by $\Delta(\hbar\omega)$ with

$$\Delta(\hbar\omega)=2\pi F/\kappa, \quad (5)$$

all the cosines return to their original values. This energy change is just the separation between the discrete levels so that the absorption must contain some structure with this period. In order to investigate this structure, we proceed as follows. The sum of trigonometric functions is evaluated using the identity[3]

$$1+2\sum_{l=1}^{\infty}\cos ly=2\pi\sum_{m=-\infty}^{\infty}\delta(y-2m\pi). \quad (6)$$

Then with the use of (3)

$$\alpha=K\frac{2\mu}{\omega\beta^{1/3}}\int d\mathbf{k}_\perp\,\mathrm{Ai}^2(\sigma\beta^{1/3})\left[1+2\sum_{l=1}^{\infty}\cos 2\pi l x_0\right]$$

$$=(4\pi K\mu/\beta^{1/3}\omega)\sum_{j=-\infty}^{\infty}\int d\mathbf{k}_\perp\,\mathrm{Ai}^2(\sigma\beta^{1/3})\delta(2\pi x_0-2\pi j), \quad (7)$$

---

in which

$$K=2e^2|\boldsymbol{\varepsilon}\cdot\mathbf{p}_{nn'}|^2/\pi\hbar^2m^2n\epsilon_0c. \tag{8}$$

From Eqs. (2) and (4), we obtain for x_0

$$2\pi x_0=\kappa(\sigma+\chi\beta^{-1/3}), \tag{9}$$

in which

$$\chi=\kappa^2/12\beta^{2/3}.$$

Then we change the variable of integration in (7) to $y=\sigma\beta^{1/3}$ and obtain

$$\alpha=\frac{4\pi^2K\mu\beta^{2/3}}{\omega\kappa}\sum_{j=-\infty}^{\infty}\int dy\,\mathrm{Ai}^2(y)$$

$$\times\delta[y+\chi-(2\pi j\beta^{1/3}/\kappa)]. \tag{10}$$

If we allow k_1 to vary between 0 and ∞, then y varies from a lower value

$$y_0=R^2\beta^{-2/3};\quad R^2=(2\mu/\hbar^2)(E_g-\hbar\omega) \tag{11}$$

to ∞. Note that R^2 may be either positive or negative. We then find that the absorption coefficient is

$$\alpha=\frac{4\pi^2K\mu\beta^{2/3}}{\omega\kappa}\sum_{j=j_0}^{\infty}\mathrm{Ai}^2\left(\frac{2\pi j\beta^{1/3}}{\kappa}-\chi\right), \tag{12}$$

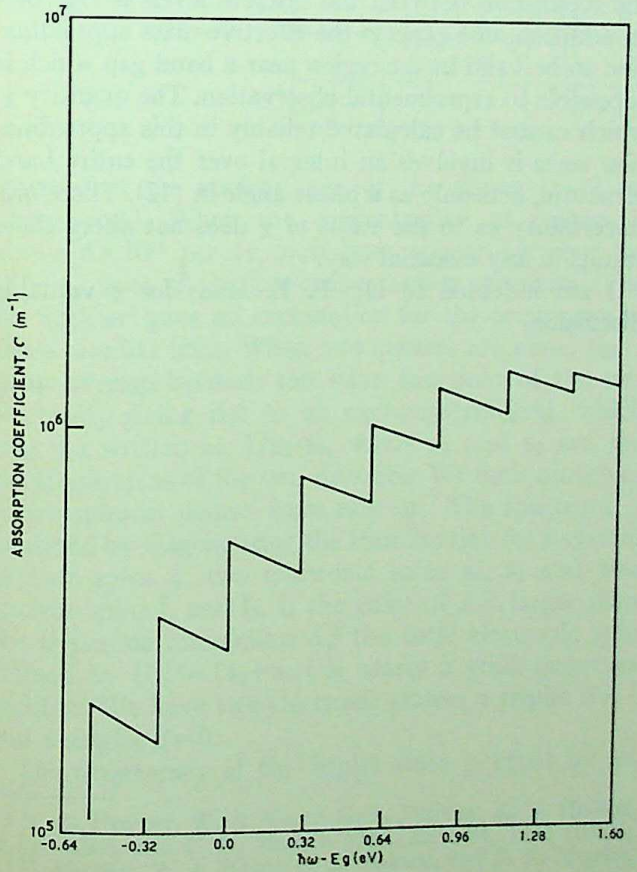

FIG. 1. The optical absorption coefficient α is shown as a function of $\hbar\omega-E_g$ as calculated from Eq. (12) using numbers appropriate to the transition between the heavy-hole band and the conduction band in gallium arsenide. For the purpose of illustration, a very large field, 10^9 eV/m has been chosen.

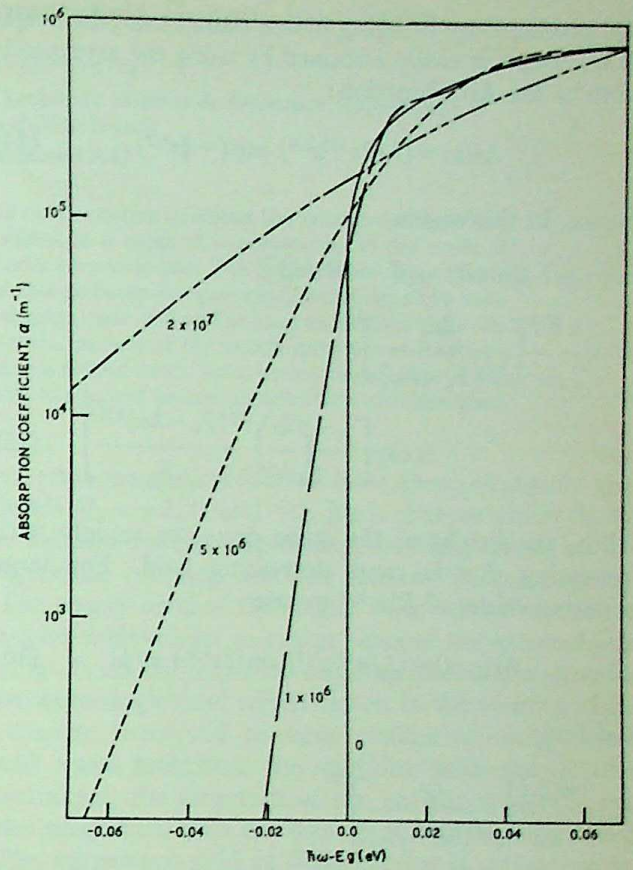

FIG. 2. The optical absorption coefficient is shown as a function of energy in the weak-field limit, Eq. (18), neglecting the discrete levels. Numbers appropriate to gallium arsenide, including both light and heavy holes, have been considered. Each curve is marked by the value of the field F in electron volts per meter which has been used in the calculation. The field is oriented along the [100] crystal axis.

in which the lower limit of the summation j_0 is determined by the condition that j_0 be the next integer larger than q_0, where

$$(2\pi q_0\beta^{1/3}/\kappa)-\chi=R^2/\beta^{2/3}. \tag{13}$$

Let us interpret this result. Observe that the argument of the Airy functions in (12) is independent of energy. The energy dependence of the absorption coefficient is contained in the external factor ω^{-1} and implicitly in the lower limit of the summation. As the photon energy $\hbar\omega$ increases, R^2 decreases, and consequently y_0 and j_0 decrease. For each decrease in j_0, a new term appears in the sum in Eq. (12). Consequently, a graph of the absorption coefficient α as a function of energy resembles a staircase with slanted steps. The width of each step is the energy required to produce a unit change in j_0. This is easily seen to be given by Eq. (5). Hence, the width of a step is just the separation of the discrete levels. The height of a step is proportional to $\mathrm{Ai}^2(R^2\beta^{-2/3})$, evaluated at the energy at which the jump occurs. The downward slant of each step is determined by the factor ω^{-1}.

For large positive values of $R^2\beta^{-2/3}$, the change in α,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$\Delta\alpha$, produced by bringing in one more term (the height of the step), is easily obtained by using the asymptotic form of the Airy function:

$$\mathrm{Ai}(z)=(1/2\pi^{1/2}z^{1/4})\exp(-\tfrac{2}{3}z^{3/2}). \tag{14}$$

Hence, in this region

$$\Delta\alpha\approx(\pi K\beta/\omega\kappa R)\exp[-4R^3/3\beta]$$

$$=\frac{\pi KF}{\kappa\omega}\left[\frac{2\mu}{\hbar^2(E_0-\hbar\omega)}\right]^{1/2}$$

$$\times\exp\left[-\frac{4}{3}\left(\frac{2\mu}{\hbar^2}\right)^{1/2}\frac{(E_0-\hbar\omega)^{3/2}}{F}\right]. \tag{15}$$

Thus, the height of the steps decreases rapidly with increasing $E_0-\hbar\omega$ and decreasing field. For large negative values of $R^2\beta^{-2/3}$ we use

$$\mathrm{Ai}(-z)=(1/\pi^{1/2}z^{1/4})\sin(\tfrac{2}{3}z^{3/2}+\pi/4) \tag{16}$$

and find

$$\Delta\alpha\approx\frac{4\pi KF}{\kappa\omega}\left[\frac{2\mu}{\hbar^2(\hbar\omega-E_0)}\right]^{1/2}$$

$$\times\sin^2\left[\frac{2}{3}\left(\frac{2\mu}{\hbar^2}\right)^{1/2}\frac{(\hbar\omega-E_0)^{3/2}}{F}+\frac{\pi}{4}\right]. \tag{17}$$

These results are illustrated in Fig. 1.

The mathematical argument may be concluded by observing that the weak-field limit of the absorption is obtained by replacing the sum in (12) by an integral. Put

$$z=2\pi j\beta^{1/3}/\kappa-\chi,$$

and let z be continuous. Then we obtain in place of (12)

$$\alpha=2\pi\omega^{-1}K\mu\beta^{1/3}\int_{y_0}^{\infty}\mathrm{Ai}^2(z)dz$$

$$=2\pi\omega^{-1}K\mu\beta^{1/3}\left[\left(\frac{d\,\mathrm{Ai}(y)}{dy}\right)_{y_0}^2-y_0\,\mathrm{Ai}^2(y_0)\right], \tag{18}$$

where y_0 is given in Eq. (11). This is equivalent to an expression given by Tharmalingam,[1] and may also be obtained by discarding all but the constant term in Eq. (1). Expressions valid in the limit of large positive or negative values of y_0 may be obtained by inserting the asymptotic expansions of the Airy functions Eqs. (14) and (16) into (18). The results of this can be obtained in an obvious way from Eqs. (23), (29), and (31) of I, and also from Tharmalingam's paper, so they will not be repeated here. However, since the weak-field absorption coefficient has not been exhibited in the region near the band gap in which asymptotic forms cannot be used, we present in Fig. 2 the absorption coefficient as calculated in this approximation using numbers appropriate to gallium arsenide.

Finally, we should note that although the detailed results of this calculation depend on the use of the effective-mass approximation, Eq. (4), the existence of structure in the absorption constant with the period of the separation between the discrete levels is rigorous. In addition, one expects the effective-mass approximation to be valid in the region near a band gap which is accessible to experimental observation. The quantity χ, which cannot be calculated reliably in this approximation since it involves an integral over the entire band structure, acts only as a phase angle in (12). Therefore, uncertainty as to the value of χ does not affect these results in any essential way.

I am indebted to Dr. P. E. Kaus for a valuable discussion.

Electron Spin Resonance on Interacting Donors in Silicon

D. JÉROME AND J. M. WINTER
Centre d'Etudes Nucléaires de Saclay, Service de Physique du Solide et de Résonance Magnétique, Gif-sur-Yvette, Seine-et-Oise, France

(Received 14 November 1963)

The value of the exchange integral J between pairs of donor centers in silicon has been investigated by looking at the ENDOR spectrum of phosphorus-doped silicon in a range of concentration of the order of 8×10^{16} per cc. The microwave field is saturating the cluster electronic line. The line shape of these ENDOR lines gives an unambiguous determination of the sign of this exchange integral which turns out to be antiferromagnetic. It is also possible to determine an order of magnitude of J and to have an idea about its distribution for two samples. We are able to understand all the features of the ENDOR spectrum at least in a qualitative way by calculating all the energy levels using a second-order perturbation calculation. A line coming from an ionized phosphorus center, weakly coupled to a pair of neutral phosphorus is also identified.

I. INTRODUCTION

THE substitutional donors like phosphorus or arsenic at low concentration in silicon give rise to a paramagnetic resonance spectrum[1,2] of $2I+1$ lines,

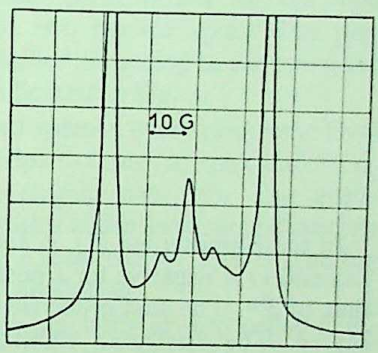

FIG. 1. Electron-resonance spectrum of phosphorus-doped silicon; 8×10^{16} P/cm³ at 1.3°K.

where I is the nuclear spin of the donor ($I=\frac{1}{2}$ for phosphorus). When the concentration of centers is above 6×10^{16} per cc, new lines appear between the $(2I+1)$ lines of the low-concentration spectrum (Fig. 1). Slichter[3] gave an explanation for the occurrence of these satellite lines. When two centers are close, there is an overlap between the wave functions of the two electrons, giving rise to an exchange integral, which may be written as $hJ\mathbf{s}_1\cdot\mathbf{s}_2$, where $\mathbf{s}_1$ and $\mathbf{s}_2$ are the electronic spins of the two electrons. We limit ourselves to phosphorus donors from now on. The spectrum is analyzed by diagonalizing the Hamiltonian for a system of four spins $\frac{1}{2}$, two electronic spins $\mathbf{s}_1$, $\mathbf{s}_2$ and two nuclear spins $\mathbf{I}_1$ and $\mathbf{I}_2$. If the value of J is larger than the hyperfine interaction A,[4] the total electronic spin defined by $|\mathbf{S}|^2=|\mathbf{s}_1+\mathbf{s}_2|^2$ is nearly a good quantum number. We have two electronic states; a triplet $S=1$ and a singlet $S=0$.

The degeneracy of the triplet state is lifted by an external magnetic field; we have three electronic sublevels $M_s=+1$, 0, and -1. Each of these sublevels has a fourfold nuclear degeneracy, partially lifted by the hyperfine coupling and the nuclear Zeeman energy. The energy level of the singlet state crosses one of the triplet sublevels for a certain value of the external field (Fig. 2). As the hyperfine coupling has matrix elements between singlet and triplet states, in the vicinity of the crossing, there will be large change of energy levels and wave functions. By studying with the ENDOR technique, the structure of the nuclear sublevels, and the magnitude and the sign of J will be determined. The microwave field at 9206 Mc/sec is saturating the cluster electronic line, therefore we select nuclear spins of pairs of exchange-coupled phosphorus nuclei (Fig. 1). In a given sample, there is a distribution of values of J due to the random distribution of phosphorus centers. We have been able to determine the value of J which has the largest probability for two samples with different phosphorus concentrations.

II. THEORY

1. First-Order Perturbation Theory of Energy Levels

We assume that the overlap of the wave functions belonging to two neighboring phosphorus atoms, leads

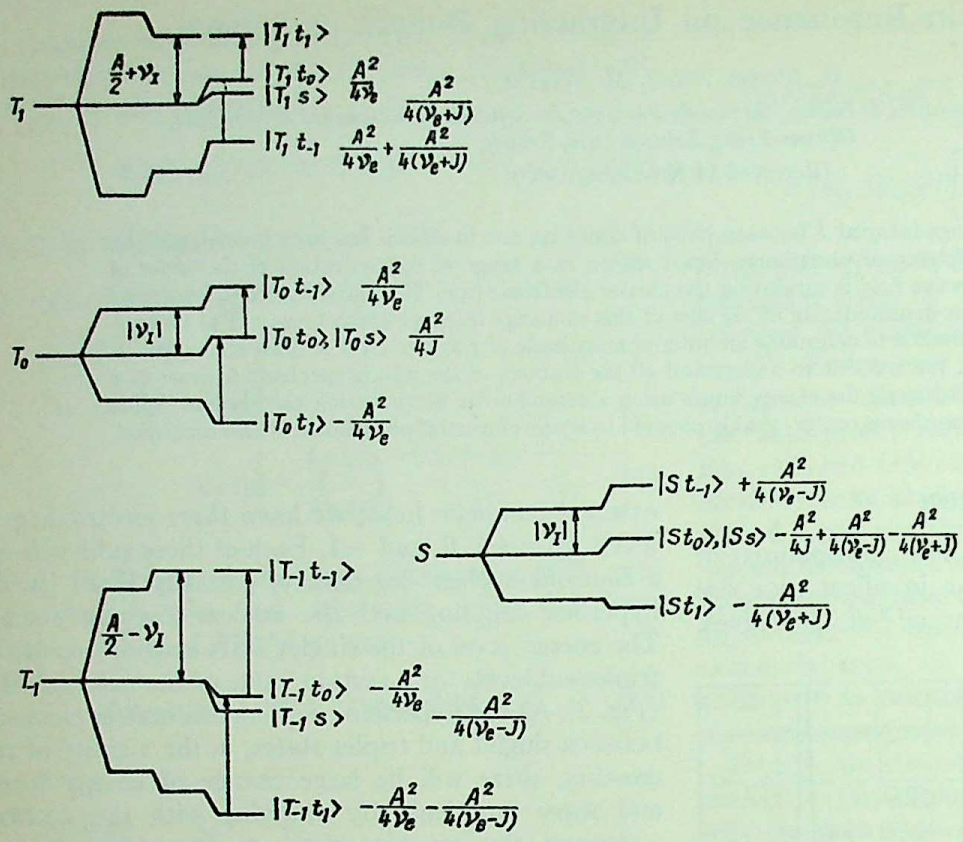

FIG. 3. Second-order shift of energy nuclear sublevels in the different triplet and singlet electronic states (not to scale). The good wave functions in zero-order approximation are noted beside each level. We assume an antiferromagnetic coupling lower than ν_e.

to a coupling between their spins $hJ\mathbf{s}_1\cdot\mathbf{s}_2$. The total Hamiltonian will be written in frequency units.[4]

$$\mathcal{H}=\nu_e(s_{1z}+s_{2z})+J\mathbf{s}_1\cdot\mathbf{s}_2+A(\mathbf{s}_1\cdot\mathbf{I}_1+\mathbf{s}_2\cdot\mathbf{I}_2)+\nu_I(I_{1z}+I_{2z}), \quad (1)$$

where ν_e and ν_I are the electronic and nuclear Larmor frequencies, respectively. J is the exchange coupling value which has been measured in cycles per second.[5]

To a first approximation, taking into consideration only the first two terms of the Hamiltonian (1), the total electronic spin is a good quantum number:

$$|\mathbf{S}|^2=|\mathbf{s}_1+\mathbf{s}_2|^2 \quad \text{and} \quad S_z=s_{1z}+s_{2z}$$

define good quantum numbers.

The Zeeman electronic Hamiltonian removes the degeneracy of the triplet state $S=1$ and gives the three following electronic states:

$$|T_1\rangle, \quad M_s=+1; \quad |T_0\rangle, \quad M_s=0; \quad |T_{-1}\rangle, \quad M_s=-1.$$

The singlet state $|S\rangle$, $S=0$ is diamagnetic. In the spin multiplicity $S=1$, $\mathbf{s}_1$ and $\mathbf{s}_2$ may be replaced by $\mathbf{S}/2$. This gives for the Hamiltonian of the whole system:

$$\mathcal{H}=\nu_e S_z+\tfrac{1}{4}J+\tfrac{1}{2}A\mathbf{S}\cdot(\mathbf{I}_1+\mathbf{I}_2)+\nu_I(I_{1z}+I_{2z}). \quad (2)$$

In lowest order, the energy of (2) will be given by

$$E_{M_s m_1 m_2}=\tfrac{1}{4}J+\nu_e M_s+\tfrac{1}{2}AM_s(m_1+m_2)+\nu_I(m_1+m_2).$$

[5] From now on, we assume a positive value for J. We shall see further that this hypothesis will be verified.

In the Hamiltonian (1), ν_e and A are positive quantities and ν_I is negative for a positive nuclear moment as that of P^{31}. The first-order energy levels are shown in Fig. 3. The electronic transition frequencies $\Delta S=0$, $\Delta M_s=\pm1$, $\Delta m_1=\Delta m_2=0$ are the following:

$$\nu=\nu_e+\tfrac{1}{2}A(m_1+m_2).$$

The electronic resonance spectra exhibit two lines at frequencies $\nu_e\pm\frac{1}{2}A$ which are not observable, due to the lines of the isolated donors and a line at the frequency ν_e twice as intense corresponding to $m_1+m_2=0$.[2,4]

We use the same considerations for clusters of three phosphorus atoms in the spin multiplicity $S=\frac{3}{2}$ which is completely symmetric with respect to the three spins $\mathbf{s}_1$, $\mathbf{s}_2$, and $\mathbf{s}_3$. We obtain for this case $\mathbf{s}_1=\mathbf{s}_2=\mathbf{s}_3=\frac{1}{3}\mathbf{S}$. The only electronic frequencies are $\nu_e\pm\frac{1}{2}A$ and $\nu_e\pm\frac{1}{6}A$.

The two eigenstates of spin $S=\frac{1}{2}$ give electronic resonance frequencies which vary from one cluster to another giving rise to a continuous background as has been shown by Abragam.[4]

The only discrete lines for four-atom clusters are ν_e, $\nu_e\pm\frac{1}{2}A$, $\nu_e\pm\frac{1}{4}A$. A line at frequency ν_e broadened by hyperfine interaction with Si^{29} spins appears only for clusters of an even number of phosphorus atoms.

At a temperature of 1.3°K the electronic resonance spectrum shows lines at frequencies $\nu_e\pm\frac{1}{4}A$ which merge almost completely in the background line. We conclude that the number of four-atom clusters is negligible in the samples (Fig. 1).

TABLE I. Allowed nuclear transitions and ENDOR frequencies.

$\lvert T_{-1},t_0\rangle \rightarrow \lvert T_{-1},t_{-1}\rangle$	$\frac{A}{2}-\nu_I+\frac{A^2}{4\nu_e}$	$\lvert T_1,t_0\rangle \rightarrow \lvert T_1,t_1\rangle$	$\frac{A}{2}+\nu_I-\frac{A^2}{4\nu_e}$	$\lvert T_0,t_1\rangle \rightarrow \lvert T_0,t_0\rangle$	$\lvert\nu_I\rvert+\frac{A^2}{4\nu_e}+\frac{A^2}{4J}$
$\lvert T_{-1},t_1\rangle \rightarrow \lvert T_{-1},t_0\rangle$	$\frac{A}{2}-\nu_I+\frac{A^2}{4(\nu_e-J)}$	$\lvert T_1,t_{-1}\rangle \rightarrow \lvert T_1,t_0\rangle$	$\frac{A}{2}+\nu_I-\frac{A^2}{4(\nu_e+J)}$	$\lvert T_0,t_0\rangle \rightarrow \lvert T_0,t_{-1}\rangle$	$\lvert\nu_I\rvert+\frac{A^2}{4\nu_e}-\frac{A^2}{4J}$

2. Second-Order Perturbation Theory of Energy Levels

There are nondiagonal matrix elements of the hyperfine structure Hamiltonian $\mathcal{H}_P=A(\mathbf{I}_1\cdot\mathbf{s}_1+\mathbf{I}_2\cdot\mathbf{s}_2)$ between different triplet states and between singlet and triplet states. The Oz component of the total spin $F_z=S_z+I_{1z}+I_{2z}$ and the total symmetry of wave functions with respect to interchange of two atoms are good quantum numbers. We defined a total parity number P as negative when the sign of the wave function changes by simultaneous permutation of the two electronic spins and the two nuclear spins. The perturbed states will be classified according to the two good quantum numbers as indicated in Fig. 3.

The coupling of nuclear spins in every electronic level gives three symmetric triplet states $\lvert t_1\rangle$, $\lvert t_0\rangle$, and $\lvert t_{-1}\rangle$, and an antisymmetric singlet state $\lvert s\rangle$. The even-interaction $\mathcal{H}_P$ couples states which have same quantum numbers F_z and the same total parity. This is true for any order perturbation calculation.

Starting with the eigenfunctions of zero order (Fig. 3), we obtain immediately the nondiagonal matrix elements from which one can obtain the shift of energy levels.

We present the calculation of the shift for triplet states $\lvert T_1\rangle$ and $\lvert T_0\rangle$. We deduce shifts of $\lvert T_{-1}\rangle$ levels by exchanging ν_e in $-\nu_e$ in the formula.

(a) $\lvert T_1,t_1\rangle$. This state is not coupled with any other state triplet or singlet because $\lvert T_1,t_1\rangle$ is the only state with $F_z=2$ and there is no change in its energy beyond the first-order value.

(b) $\lvert T_1,t_0\rangle$ *and* $\lvert T_1,s\rangle$. $\lvert T_1,t_0\rangle$ is coupled to $\lvert T_0,t_0\rangle$ and $\lvert T_1,s\rangle$ to $\lvert S,t_1\rangle$ by the nondiagonal matrix elements. There are no diagonal matrix elements for any of these states,

$$\langle T_1,t_0\lvert\mathcal{H}_p\rvert T_0,t_1\rangle=A/2,$$
$$\langle T_1,s\lvert\mathcal{H}_p\rvert S,t_1\rangle=-A/2.$$

The second-order shift of the state $\lvert T_1,s\rangle$ is

$$E=A^2/4(\nu_e+J),$$

and that of state $\lvert T_1,t_0\rangle$ is

$$E=A^2/4\nu_e.$$

(c) $\lvert T_1,t_{-1}\rangle$. This state is coupled to $\lvert T_0,t_0\rangle$ and $\lvert S,s\rangle$. Its shift is

$$A^2/4\nu_e+A^2/4(\nu_e+J).$$

(d) $\lvert T_0,t_0\rangle$ *and* $\lvert T_0,s\rangle$. The same method as that of Sec. 2(b) does not remove the degeneracy between the two states in second order. To that order both states are shifted by the same amount,

$$E=A^2/4J.$$

(e) $\lvert T_0,t_1\rangle$ *and* $\lvert T_0,t_{-1}\rangle$. The shifts are respectively $A^2/4\nu_e$ and $-A^2/4\nu_e$. This computation is only valid under conditions: $A\ll\nu_e$, J, ν_e-J, ν_e+J. It is not valid at the crossing of energy levels. This restriction is important as we shall see further.

3. Line Shapes and Frequencies of Nuclear Transitions

(a) The coupling with the rf field inducing an electronic or nuclear transition is an operator proportional to

$$\alpha(s_{1z}+s_{2z})+\beta(I_{1z}+I_{2z}).$$

The selection rules for electronic or nuclear transitions are thus $\Delta F_z=\pm1$, $\Delta P=0$. With a perturbation like $s_{1z}+s_{2z}$ or $I_{1z}+I_{2z}$ the total parity is preserved. The allowed transitions are shown in Table I and Fig. 3.

(b) From Table I, it appears that nuclear lines are

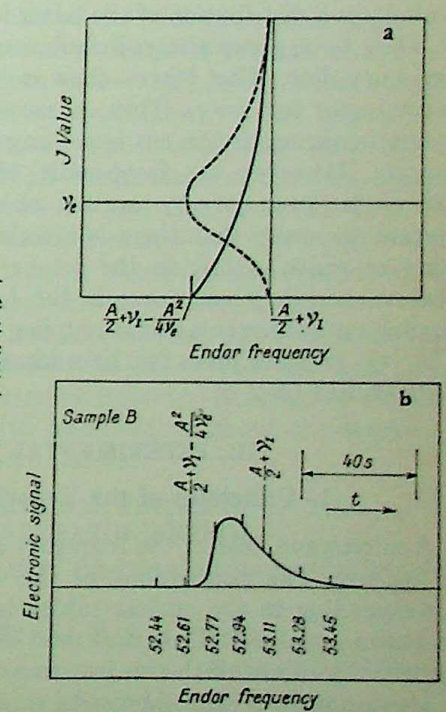

FIG. 4. (a)–Theoretical dependence on J of the ENDOR frequency in the group $\frac{1}{2}A+\nu_I$ and estimate of J distribution in dashed line. (b)–Experimental line shape for sample B.

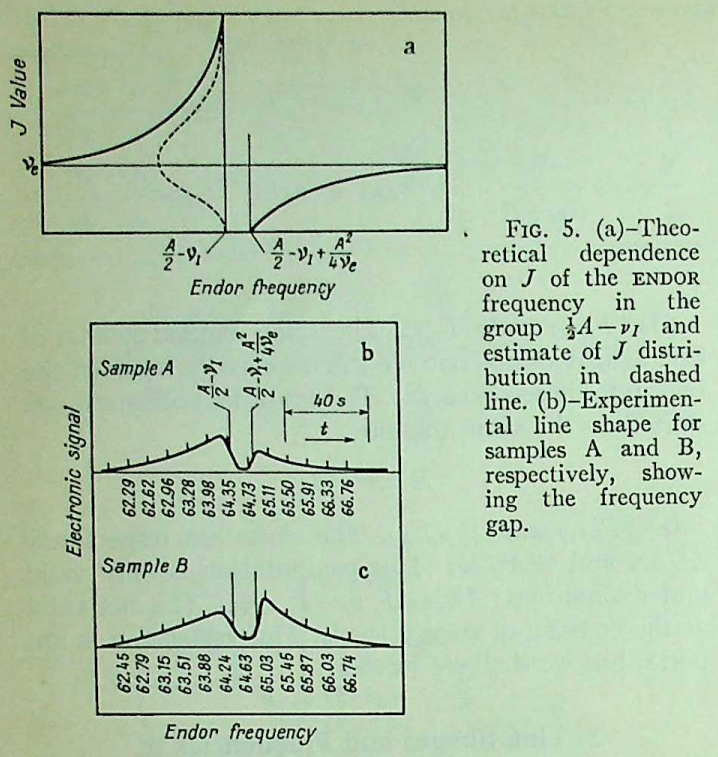

FIG. 5. (a)–Theoretical dependence on J of the ENDOR frequency in the group $\frac{1}{2}A-\nu_I$ and estimate of J distribution in dashed line. (b)–Experimental line shape for samples A and B, respectively, showing the frequency gap.

split into three groups, two whose frequencies in first order are $\frac{1}{2}A-\nu_I$ and $\frac{1}{2}A+\nu_I$, and one whose mean frequency is near the Larmor frequency of a bare phosphorus atom. We assume now $J>0$. The values of the coupling constant are distributed in the clusters with a distribution function $P(J)$ normalized to unity when J is varied from zero to infinity. It is assumed to have a maximum for a value $J=J_P$.

The $\frac{1}{2}A+\nu_I$ group includes two frequencies. One is J-independent $\frac{1}{2}A+\nu_I-(A^2/4\nu_e)$, the other is J-dependent $\frac{1}{2}A+\nu_I-[A^2/4(\nu_e+J)]$. The distribution of J produces a distribution of the latter frequencies (Fig. 4). The $\frac{1}{2}A-\nu_I$ group always includes one J-independent frequency line. The others show a singular energy denominator for $J=\nu_e$. Thus, a second-order perturbation-frequency treatment is no longer valid for such clusters. However the frequencies of these clusters ($J\simeq\nu_e$) far from $\frac{1}{2}A-\nu_I$, are not observed. It is important to notice that there is a forbidden frequency band of width $A^2/4\nu_e$ in the $\frac{1}{2}A-\nu_I$ group. Such a phenomenon does not occur in the $\frac{1}{2}A+\nu_I$ group assuming an antiferromagnetic coupling (Figs. 4 and 5). The $|\nu_I|$ group includes two lines whose frequencies are J-dependent (Fig. 6).

III. EXPERIMENTAL

1. Principles of the Experiment

A microwave field at the frequency $\nu_e=9206$ Mc/sec is applied. The populations of the electronic levels corresponding to the nuclear sublevels $m_1+m_2=0$ are therefore equalized. Then a rf field of frequency ν in the vicinity of one of the nuclear-transition frequencies is also applied. This field produces a change in the population of one of the states with $m_1+m_2=0$ and the electronic signal varies. By sweeping the radio-frequency ν we reach all the nuclear frequencies possible.[6] For a given ν the change of the electronic signal is very likely proportional to the number of clusters having the nuclear frequency transition ν. For instance, if we look at the ENDOR frequencies $\nu_I+(A^2/4\nu_e)\pm(A^2/4J)$, the spectrum reproduces the distribution of the values of $A^2/4J$ in our sample.

2. Experimental Technique

The frequency of the electronic spectrometer is stabilized by a Pound discriminator on an external cavity. We use a constant-level symmetric detection.[7] All these experiments have been done at 1.3°K and because of the length of the electronic relaxation time, the dispersion mode is observed.[6] The signal-to-noise ratio for the ENDOR signal on clusters varies between 3 and 5. We use two samples of phosphorus-doped silicon from Merck;

Sample A: $N=8\times10^{16}\,P/\text{cc}$ $\rho=0.11\Omega$-cm,

Sample B: $N=6\times10^{16}\,P/\text{cc}$ $\rho=0.13\Omega$-cm.

3. Experimental Results

Taking for the phosphorus nuclear Larmor frequency the value $|\nu_I|=5.67$ Mc/sec and for the hyperfine constant the value[6] $A=117.53$ Mc/sec, the nuclear-frequency transition calculated in a first-order approximation is given by $\frac{1}{2}A-\nu_I=64.11$ Mc/sec, $\frac{1}{2}A+\nu_I=53.09$ Mc/sec, and $|\nu_I|$. A typical second-order correction is given by $A^2/4\nu_e=0.375$ Mc/sec.

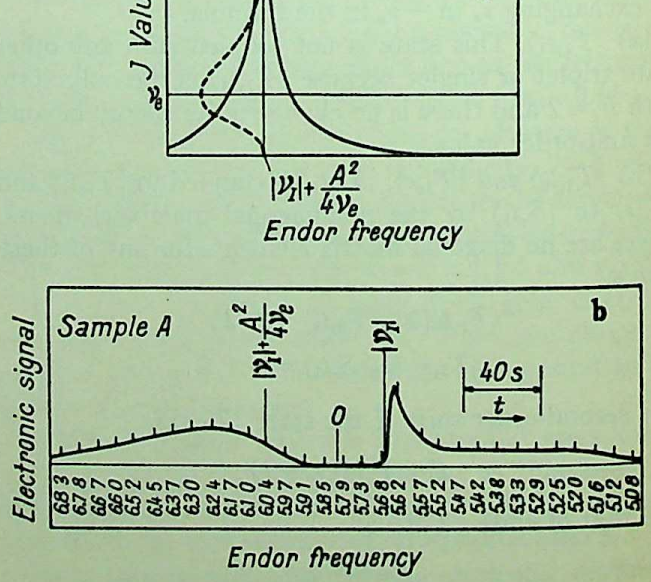

FIG. 6. (a)–Theoretical dependence on J of the ENDOR frequency in the group $|\nu_I|$. (b)–Experimental line shape for sample A.

The ENDOR line in the vicinity of $\nu=\frac{1}{2}A-\nu_I$ shows two peaks separated by a frequency gap of the order of $A^2/4\nu_e$. This fact shows without any ambiguity that the singlet level crosses the group of $M_s=-1$ sublevels and the coupling is antiferromagnetic (Fig. 5).

The line for $M_s=1$ sublevels shows only a broadening (Fig. 4) coming from the different possible value of the second-order shift $A^2/4(\nu_e+J)$.

The ENDOR line for the $M_s=0$ group of levels (Fig. 6) occurs at the frequencies ν given by $\nu=|\nu_I|+(A^2/4\nu_e)\pm(A^2/4J)$.

As stated above, the shape of the line reproduces the distribution of $A^2/4J$. If we call J_F the value of J which gives the maximum probability for $A^2/4J$, we deduce $A^2/2J_F$ by measuring the distance between the maximum of the two peaks. For the sample A we find

$$A^2/2J_F=0.94 \text{ Mc/sec}.$$

Knowing the distribution for $A^2/4J$, it is possible to deduce the function $P(J)$, giving the probability of finding a given J and in particular, the value J_P giving the maximum value for $P(J)$. The results are

$$\text{Sample A:}\quad J_P=15\,000\pm3\,000 \text{ Mc/sec},$$

$$\text{Sample B:}\quad J_P=13\,500\pm3\,000 \text{ Mc/sec}.$$

The shape of the two other lines can be discussed in a qualitative way. Figure 5 shows the lines $\frac{1}{2}A-\nu_I$ for the two samples; for the sample A the low-frequency peak is more intense than the high-frequency peak. The result is opposite for sample B.

Since the low-frequency peak corresponds to values of J larger than ν_e and the other peak to values of J smaller than ν_e, this result is consistent with the fact that J_P is smaller in sample B than in sample A (Fig. 5).

The width of the experimental frequency gap is smaller than $A^2/4\nu_e$; the time constant due to electronic saturation is probably reducing the experimental gap.

Coming back to the line at ν_I we notice (Fig. 6) the two broad lines. The intensity of these lines is very small in sample B. The width of the line, being of the order of $A^2/4J_P$, is larger for sample B and is responsible for the small signal.

IV. INFLUENCE OF IONIZED CENTERS

A very narrow line (10 kc/sec) occurring exactly at the frequency $|\nu_I|$ is observed in the ENDOR spectrum of both samples (Fig. 6). Feher[6] already noticed the occurrence of this line in the ordinary ENDOR spectrum of a compensated sample and attributed it to an ionized phosphorus center.

Assuming that there is an ionized phosphorus in the vicinity of a cluster of two neutral phosphorus, there always will be a small scalar coupling between the two electronic spins and the ionized phosphorus nuclear spin $\mathbf{I}'$. We therefore add, to our Hamiltonian (1), the term

$$a_1\mathbf{I}'\cdot\mathbf{s}_1+a_2\mathbf{I}'\cdot\mathbf{s}_2+\nu_I I_z'.$$

This coupling comes because the wave function for the two electrons localized around phosphorus 1 and 2, has a small admixture of a wave function for an electron bound to the phosphorus I'. This is an extension to a system of three phosphorus and two electrons of the calculation performed by Miller and Abrahams[8] for explaining the conduction of compensated sample. Because the admixture is very small a_1 and a_2 are much smaller than A. This new term gives a contribution to the energy spectrum, which is for a state M_s (of the triplet):

$$\nu_I m'+\tfrac{1}{2}(a_1+a_2)m'M_s,$$

m' being the value of I_z'.

As a_1 and a_2 are small this term does not influence the electronic spectrum. But there are now ENDOR lines corresponding to the selection rule $\Delta m'=\pm1$, and occurring at frequencies given by

$$\nu=|\nu_I|+\tfrac{1}{2}(a_1+a_2)M_s$$

(we neglect second-order corrections). For $M_s=0$ a line appears exactly at $\nu=|\nu_I|$.

There are also ENDOR lines corresponding to value of $M_s=\pm1$, but they are not observed because there is a distribution of a_1 and a_2 values.

The important point is to notice that only lines corresponding to the $M_s=0$ level of clusters are observed. There is undoubtedly phosphorus ionized near isolated neutral phosphorus, but their ENDOR frequencies are given by $\nu=|\nu_I|+\frac{1}{2}aM_s$, $M_s=\pm\frac{1}{2}$ and are not observed. We observe only ionized phosphorus coupled to clusters of two neutral phosphorus, this point is also proved by the following experimental fact.

Now we saturate the electronic line $\nu=\nu_e\pm\frac{1}{2}A$ (Fig. 1) and look at the ENDOR spectrum. The narrow line at $|\nu_I|$ appears but its intensity is half the intensity of the $|\nu_I|$ line observed when we saturate the $\nu=\nu_e$ line. It is known that a cluster of two has an electron spectrum with lines at $\nu=\nu_e\pm\frac{1}{2}A$ which are not observed because they are masked by the large signal coming from isolated phosphorus, the intensity of these lines is one-half the intensity of the $\nu=\nu_e$ central line. So the narrow $\nu=|\nu_I|$ line observed when we saturate the electronic lines at $\nu=\nu_e\pm\frac{1}{2}A$ is not due to the ENDOR spectrum of isolated phosphorus but to the ENDOR spectrum of clusters of phosphorus.

By comparing the intensity of the narrow $\nu=|\nu_I|$ line and the intensity of the broad line near $|\nu_I|$ (coming from neutral phosphorus) it should be possible to get quantitative informations about the degree of compensation of the samples.

V. THEORETICAL ESTIMATE OF THE EXCHANGE ENERGY

The Hamiltonian of the two-electron system is given by

$$\mathcal{H}(1,2)=T(\mathbf{r}_1)+T(\mathbf{r}_2)+V_i(\mathbf{r}_1)+V_j(\mathbf{r}_1)+V_i(\mathbf{r}_2)+V_j(\mathbf{r}_2)+V(\mathbf{r}_1,\mathbf{r}_2),$$

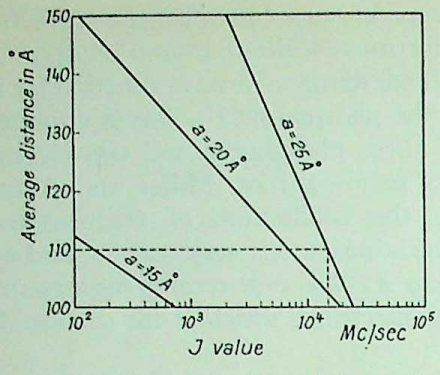

FIG. 7. Results of the computation of J as a function of the average distance between two neighboring donors. The experimental value of J for sample A corresponds to an average distance of 110 Å, assuming $a=25$ Å.

where $\mathbf{r}_1$ and $\mathbf{r}_2$ are the coordinates of the two electrons, $T(\mathbf{r})$ is the kinetic-energy operator, $V_i(\mathbf{r})$ and $V_j(\mathbf{r})$ are the attractive potentials due to phosphorus nuclei at sites i and j. In our spin Hamiltonian (1), J is defined as the energy difference between triplet and singlet spin states[9,10]

$$J=\langle T|\mathcal{H}(1,2)|T\rangle-\langle S|\mathcal{H}(1,2)|S\rangle,$$

where $|T\rangle$ is the total wave function for the system, antisymmetric with respect to the orbital variables, symmetric with respect to the spin variables in the triplet spin state. The opposite is true for $|S\rangle$.

The orbital part of the one-electron wave function, taken from the effective-mass theory[11] may be written at a site i:

$$\psi_i(\mathbf{r})=\sum_{p=1}^{6}(6)^{-1/2}F_p(\mathbf{r})\phi_p(\mathbf{r}),$$

where $\phi_p(\mathbf{r})$ is a Bloch function corresponding to the wave vector of the p valley, and $F_p(\mathbf{r})$ is an envelope function satisfying the wave equation in the effective-mass approximation:

$$F_p(\mathbf{r})=(\pi a^2 b)^{-1/2}\exp-\left[\frac{x^2+y^2}{a^2}+\frac{z^2}{b^2}\right]^{1/2},$$

the z axis being parallel to the wave vector corresponding to the value p. In silicon a and b are[12]

$$a=25\text{ Å},\quad b=14.2\text{ Å}.$$

According to our definition of the exchange energy, J takes the following form[9]:

$$J=-2\int\psi_i^*(\mathbf{r}_1)\psi_j(\mathbf{r}_1)\int\psi_j^*(\mathbf{r}_2)V(\mathbf{r}_2)\psi_i(\mathbf{r}_2)d\mathbf{r}_1 d\mathbf{r}_2$$
$$-\int\psi_i^*(\mathbf{r}_1)\psi_j(\mathbf{r}_1)\frac{e^2}{\kappa_0}|\mathbf{r}_1-\mathbf{r}_2|^{-1}\psi_j^*(\mathbf{r}_2)\psi_i(\mathbf{r}_2)d\mathbf{r}_1 d\mathbf{r}_2.$$

Since $V(\mathbf{r}_2)$ is an attractive potential the first term is a positive one, the second is negative. If one neglects the anisotropy of the envelope function within a given valley, the estimate of J is simple. But one should notice that each term of the latter expression is smaller than the one obtained by using a pure hydrogenic wave function because there is destructive interference between parts of the wave functions coming from different valleys.

Utilizing Eq. (II 17), Eq. (II 18), and (paragraph) IV of Ref. 8, we evaluated J (as function of the distance between phosphorus centers) assuming an isotropic envelope function and taking for the radius $a=25$, 20, or 15 Å (Fig. 7). We find that the positive theoretical value of J agrees with the experimental results. The average distance between centers is easily deduced from the concentration of centers, and we find that the experimental value of J is larger than the theoretical prediction, even if we use $a=25$ Å for the radius. If we believe in the impurity concentration measurements by conductivity at room temperature, this fact seems to indicate that the average distance between donors is smaller than the average distance deduced from the concentration, by about 20%. This may be due to a nonuniform concentration of phosphorus donors. It has been suggested that impurities tend to concentrate along dislocation lines.[13]

VI. CONCLUSION

The method we described can only give information if the exchange integral is larger than the hyperfine coupling A, otherwise no electronic line at the frequency ν_e appears in the spectrum. There is also an upper limit because when J becomes larger than kT and $h\nu_e$; there are very few electrons in the triplet states. If we remark that J varies very rapidly with the distance, our method is only valid in a narrow range of concentration. At high concentration, another limit appears. The electronic relaxation time becomes shorter, and the line difficult to saturate.

The possibility of measuring J is directly related to the presence of the hyperfine coupling term; without it, the exchange term and the Zeeman term commute and the frequencies are not affected by the exchange term. It is the small coupling by the hyperfine energy of the triplet and singlet levels which allows measurement of J. The effect of exchange on the energy spectrum is very small except when the crossing occurs. By a second-order perturbation calculation we are able to explain the shape of the experimental ENDOR spectrum and to determine the sign and the magnitude of J.

We have explained the occurrence of an ENDOR line

Peierls Stress and Creep of a Linear Chain*

J. H. WEINER AND W. T. SANDERS
Department of Mechanical Engineering, Columbia University, New York, New York
(Received 19 December 1963; revised manuscript received 23 January 1964)

The Frenkel-Kontorova dislocation model is modified by replacing the sinusoidal substrate force by one which is piecewise linear. Exact solutions are found for the static configuration and for the Peierls stress, σ_P. Good agreement is found between these values of σ_P and those obtained previously for a two-dimensional Rosenstock–Newell model. The atoms of the linear chain are then considered in random motion corresponding to thermal equilibrium and under an applied stress $\sigma<\sigma_P$. The time required for motion of the dislocation from one position of stable equilibrium to an adjacent one is computed by means of a rate-theory formulation adapted to the present type of problem in which the positions of all the atoms in the chain are required to vary in passing over the potential barrier. The theoretical transition times for an infinite chain are compared with analog computer results for a six-atom chain and reasonably good agreement is found.

1. INTRODUCTION

THE rate of dislocation creep over the Peierls barrier has been studied in connection both with low-temperature creep[1] and the Bordoni peak.[2] Because of the complexity of the phenomenon, it is necessary to make various assumptions of a mathematical and physical nature when treating a realistic model of the process.

The purpose of the present work has been to construct a simple dislocation model which is amenable to analysis with few additional assumptions. It is hoped that the results of this idealized analysis may provide insight into the nature of the real process, and that the mathematical techniques employed may be applied to more realistic models.

The dislocation model considered here is a modification of the Frenkel-Kontorova one-dimensional model[3] with the sinusoidal substrate force replaced by one which is piecewise linear as in the two-dimensional treatment of Sanders.[4] For this model it is possible to obtain exact solutions to the difference equation describing the static configuration under applied stress and to derive an exact expression for the Peierls stress, σ_P (Sec. 2). The values of σ_P computed here agree surprisingly well with the results of the two-dimensional calculations.[4]

In order to study the dislocation creep rate, the atoms of the model are then considered in random motion corresponding to thermal equilibrium and under an applied stress $\sigma<\sigma_P$. The problem of determining the rate at which the dislocation passes from one stable equilibrium position to an adjacent one is in the general class of problems considered in rate theory.[5] We present here (Sec. 3) a derivation of the pertinent rate formula *ab initio* which is somewhat different from the usual one and is particularly adapted to the present type of problem in which the positions of all the atoms in the chain are required to vary in passing over the potential barrier.

For the infinite chain dislocation model it is possible (Sec. 4) to calculate explicitly all the quantities entering into this rate formula. The theoretically predicted values of the frequency of transition of the dislocation from one equilibrium position to an adjacent one are found to be in order-of-magnitude agreement with analog

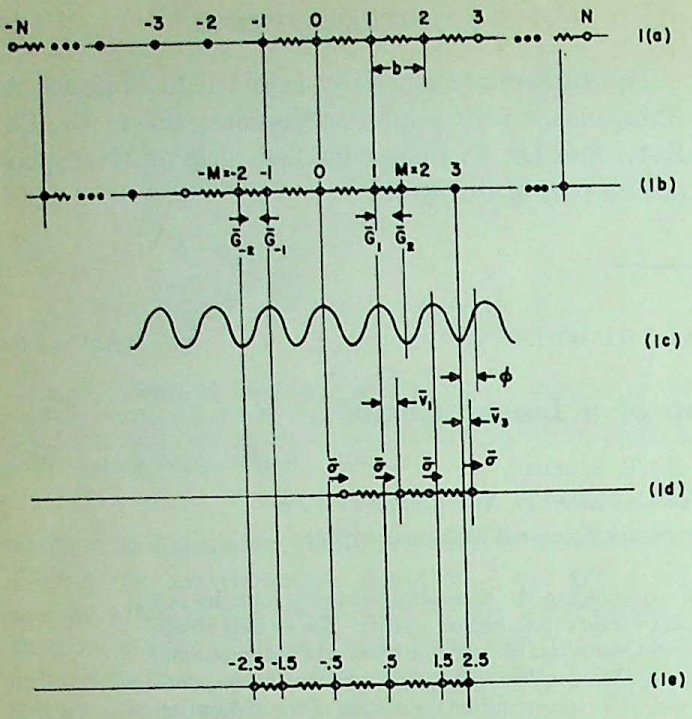

FIG. 1. Linear chain dislocation model.

computer results for a 6-atom chain. Finally, a summary and conclusions are presented in Sec. 5.

2. STATIC SOLUTION

Model Description

As a simplified crystal model, we consider a linear chain of mass points (hereafter referred to as atoms) interconnected by linear springs with spring constant k_1 and equilibrium spacing b (corresponding to the lattice parameter) and subjected also to a periodic (with period b) substrate potential. This substrate potential, as in the original Frenkel-Kontorova model, represents the net effect of the remaining atoms in the (3-dimensional) crystal. We assume a piecewise quadratic, continuous potential $U(x)$, namely,

$$\begin{aligned} U(x)&=\tfrac{1}{2}k_2x^2, && |x|\leq\phi,\\ &=\tfrac{1}{4}k_2\phi b-\frac{k_2\phi}{b-2\phi}\left(\frac{b}{2}-x\right)^2, && \phi\leq|x|\leq\frac{b}{2}, \end{aligned} \tag{2.1}$$

where x is the distance from a potential minimum. This replacement of the trigonometric potential of Frenkel and Kontorova by the piecewise quadratic potential of Eq. (2.2a) simplifies the analysis and introduces the additional parameter ϕ, the distance from a potential minimum to the nearest point at which the potential curvature is discontinuous and becomes negative; ϕ is thus a measure of the hardness of the crystal. The parameter k_2 in Eq. (2.1) is a measure of the shear modulus of the crystal while the parameter k_1 is a measure of the Young's modulus of the crystal.

In order to introduce a dislocation into this model, we start with the linear chain as in Fig. 1(a) and subject the jth atom to a longitudinal force $\bar{G}_j$, where

$$\bar{G}_M=\bar{G}_{-M+1}=-\tfrac{1}{2}k_1b;\quad \bar{G}_{M-1}=\bar{G}_{-M}=\tfrac{1}{2}k_1b;$$
$$\bar{G}_j=0 \quad \text{all other } j. \tag{2.2a}$$

From this, the following equilibrium configuration will result: All atoms $j\geq M$ are displaced $b/2$ to the left, all atoms $j\leq -M$ are displaced $b/2$ to the right, and those for which $-M<j<M$ are undisturbed.[6] To verify that this is indeed an equilibrium configuration, observe that the sum of the forces acting on each atom vanishes. For the special case $M=2$, this new equilibrium configuration is shown in Fig. 1(b). This configuration provides a model for a dislocation because five atoms, viz., -2, -1, 0, 1, and 2, now occupy a region ordinarily occupied by only four atoms.

Now with these forces still applied, the atoms are subjected to the periodic substrate potential defined in Eq. (2.1) and sketched in Fig. 1(c), and which is positioned relative to the configuration of Fig. 1(b) with either a maximum or minimum at the position of all atoms so that it exerts no forces on them in this configuration.

We next apply forces $-\bar{G}_j$ to the configuration of 1(b) and (c), annulling those originally applied, and also apply a constant force $\bar{\sigma}$ (which represents externally applied shear stress) to each atom. Let the resulting displacement of the jth atom from the configuration of 1(b) be $\bar{v}_j$. With the substrate potential of Eq. (2.1), the substrate force on the jth atom is

$$\begin{aligned} &F_j=-k_2\bar{v}_j \quad \text{for} \quad |j|\geq M, \quad \text{providing} \quad |\bar{v}_j|\leq\phi,\\ &F_j=\frac{2k_2\phi}{b-2\phi}\bar{v}_j \quad \text{for} \quad |j|<M,\\ &\qquad\qquad \text{providing} \quad |\bar{v}_j|\leq\left(\frac{b}{2}-\phi\right). \end{aligned} \tag{2.2b}$$

Note that in the first of Eqs. (2.2b) $\bar{v}_j$ is measured from a potential minimum, while in the second of these equations $\bar{v}_j$ is measured from a potential peak. As will be seen subsequently, the value of M is determined for a given set of parameters so that the inequalities on the atom displacements associated with Eq. (2.2b) are satisfied. The final configuration, after forces $-\bar{G}_j$ and $\bar{\sigma}$ are applied is then as shown in Fig. 1(d). The atoms in the range $|j|<M$ will be termed subject to weak bonds to the substrate potential while the others will be referred to as strong bonds. The number of weak bonds, $n_w=2M-1$, may be odd or even. In the latter case, the atoms will be indexed as shown in Fig. 1(e); that is, j is understood to take on the values $\cdots, -1\tfrac{1}{2}, -\tfrac{1}{2}, +\tfrac{1}{2},$

[6] Only the infinite chain will be considered in detail and therefore the location of the origin may always be taken as the midpoint of the dislocation. The indices j and M in Eq. (2.2a) may be either integers or half-odd integers; see discussion following Eq. (2.2b).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$1\frac{1}{2}, \cdots$ when $2M$ is odd. Therefore in both cases the weak-bond atoms may be taken to correspond to $-M<j<M$ and both cases may be treated together. The equations of equilibrium for the configuration of 1(d) are

$$k_1(\bar{v}_{j+1}+\bar{v}_{j-1}-2\bar{v}_j)-k_2\bar{v}_j-\bar{G}_j+\bar{\sigma}=0\,,\quad |j|\geq M\,,$$

$$k_1(\bar{v}_{j+1}+\bar{v}_{j-1}-2\bar{v}_j)+\frac{2k_2\phi}{b-2\phi}\bar{v}_j-\bar{G}_j+\bar{\sigma}=0\,, \tag{2.3}$$

$$-M<j<M\,.$$

With the introduction of the dimensionless variables

$$\begin{aligned} &v_j=\bar{v}_j/b\,, && G_j=\bar{G}_j/(k_1b);\\ &\sigma=\bar{\sigma}/(k_2b)\,, && P=k_2/k_1;\\ &\gamma=\phi/b\,, && Q=\frac{2\gamma P}{1-2\gamma}; \end{aligned} \tag{2.4a}$$

and the reduced displacements

$$u_j=v_j-\sigma\,, \tag{2.4b}$$

these equations may be written

$$u_{j+1}-(2+P)u_j+u_{j-1}=G_j\,,\qquad |j|\geq M; \tag{2.5a}$$

$$u_{j+1}-(2-Q)u_j+u_{j-1}=G_j-\frac{\sigma P}{(1-2\gamma)},$$

$$-M<j<M\,. \tag{2.5b}$$

Displacement Solution

We treat here only the infinite chain, $N\to\infty$; the solutions to Eq. (2.5) which decay at infinity are

$$\begin{aligned} &u_j=A\beta^{-j}, && j\leq -M;\\ &u_j=B\beta^{j}, && j\geq +M;\\ &u_{M-1}=B\beta^{M-1}-\tfrac{1}{2}, && u_{-M+1}=A\beta^{M-1}+\tfrac{1}{2};\\ &u_j=C\cos j\theta+D\sin j\theta-\frac{\sigma}{2\gamma}, && -M<j<M;\\ &u_M=C\cos M\theta+D\sin M\theta-\frac{\sigma}{2\gamma}+\tfrac{1}{2};\\ &u_{-M}=C\cos M\theta-D\sin M\theta-\frac{\sigma}{2\gamma}-\tfrac{1}{2}; \end{aligned} \tag{2.6a}$$

where

$$\beta=\tfrac{1}{2}[P+2-(P^2+4P)^{1/2}], \tag{2.7}$$

$$\cos\theta=1-Q/2\,.$$

Equations (2.6a) and (2.6b) satisfy (2.5a) and (2.5b), respectively. The four constants A, B, C, and D may then be determined by the requirement that Eqs. (2.6a) and (2.6b) agree for the four atoms, $-M$, $-M+1$, $M-1$, M for which the expressions overlap. The resulting expressions for the displacements are

$$\begin{aligned} u_j(\sigma;M)&=(\sigma F_M+G_M)\beta^{-j}; && j\leq -M;\\ &=(\sigma F_M-G_M)\beta^{j}, && j\geq M; \end{aligned} \tag{2.8a}$$

$$u_j=\frac{\sigma(\beta-1)\cos j\theta}{2\gamma[\beta\cos(M-1)\theta-\cos M\theta]}$$

$$+\frac{(\beta-1)\sin j\theta}{2[\sin M\theta-\beta\sin(M-1)\theta]}-\frac{\sigma}{2\gamma},\quad -M<j<M;$$

where

$$F_M=\frac{\cos M\theta-\cos(M-1)\theta}{2\gamma[\beta^M\cos(M-1)\theta-\beta^{M-1}\cos M\theta]},$$

$$G_M=\frac{\sin M\theta-\sin(M-1)\theta}{2[\beta^M\sin(M-1)\theta-\beta^{M-1}\sin M\theta]}. \tag{2.8b}$$

In order to complete the solution for the displacements, it is necessary to determine the value of M, characterizing the number of weak bonds, which corresponds to given values of P, the force constant ratio, $\gamma=\phi/b$, and the applied stress, σ. We proceed in an inverse fashion, regarding M as well as P as prescribed, and determine the range of γ for which a solution with $n_w=2M-1$ weak bonds is (1) compatible with the assumed force law (2.2b) and (2) is mechanically stable.

For compatibility, the following conditions are necessary [see Eq. (2.2b)]:

$$\begin{aligned} &\bar{v}_M\leq\phi, && \bar{v}_{-M}\geq-\phi,\\ &\bar{v}_{M-1}\geq-\left(\frac{b}{2}-\phi\right), && \bar{v}_{-M+1}\leq\left(\frac{b}{2}-\phi\right); \end{aligned} \tag{2.9a}$$

these will later be shown to lead to sufficient conditions. With the use of Eqs. (2.4) and (2.8) these inequalities become

$$\gamma\geq-\beta^MG_M+\sigma(1+\beta^MF_M)\,,\gamma\geq-\beta^MG_M-\sigma(1+\beta^MF_M);$$

and (2.9b)

$$\begin{aligned} &\gamma\leq-\beta^{M-1}G_M+\sigma(1+\beta^{M-1}F_M)\,,\\ &\gamma\leq-\beta^{M-1}G_M-\sigma(1+\beta^{M-1}F_M)\,. \end{aligned}$$

Clearly, if a given bond configuration is not compatible without stress it is not compatible under stress. The stress-free compatibility range is

$$-\beta^MG_M\leq\gamma\leq-\beta^{M-1}G_M\,. \tag{2.9c}$$

Through the use of Eqs. (2.7) and (2.8b) together with some trigonometric manipulation, the following implicit

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

equation for the lower limit on γ is obtained:

$$\tan M\theta=\frac{1-\beta}{1+\beta}\operatorname{ctn}\frac{\theta}{2}. \tag{2.9d}$$

Let the value of γ^{-1} that satisfies this equation be denoted by C_M. The corresponding equation for the upper limit on γ is

$$\tan(M-1)\theta=\frac{1-\beta}{1+\beta}\operatorname{ctn}\frac{\theta}{2} \tag{2.9e}$$

so that the range corresponding to that of Eq. (2.9c) is

$$C_{M-1}\leq\gamma^{-1}\leq C_M. \tag{2.9f}$$

A detailed investigation shows that some of the inequalities (2.2b) other than those of (2.9a) will be violated unless the lowest values of θ satisfying Eqs. (2.9d) and (2.9e) are chosen. If this is done, then the maximum value of θ in the range (2.9f) satisfies the inequality $(M-1)\theta<\pi/2$, and this can be used together with Eqs. (2.8) to show that for $0<j<M$ u_j is negative and $u_{j+1}<u_j$ and that for $j\geq M$ u_j is positive and $u_{j+1}<u_j$ (only positive j, because of symmetry, need be considered). Then all of the inequalities (2.2) are satisfied.

For the examination of the stability of the equilibrium configuration defined by the displacements u_j it is convenient to return first to the consideration of a finite chain, $-(N+1)\leq j\leq N+1$ [where N may be a half-odd-integer; see Fig. 1(e)] and then to let $N\rightarrow\infty$. Let q_j be a small displacement of the jth atom from the equilibrium position being examined, with $q_{-N-1}=q_{N+1}=0$, $V(q_{-N},\cdots,q_N)$ the resulting change in potential energy, and $S_{ij}=(1/k_1)(\partial^2V/\partial q_i\partial q_j)$, $-N\leq i,\ j\leq N$, evaluated at $q_j\equiv 0$. Then

$$\begin{aligned}
&S_{jj}=(2+P);\quad -N\leq j\leq -M;\quad M\leq j\leq N;\\
&S_{jj}=(2-Q);\quad -M<j<M;\\
&S_{j,j+1}=S_{j+1,j}=-1;\quad -N+1\leq j\leq N-1;\\
&S_{ij}=0\quad\text{for}\quad |i-j|>1.
\end{aligned} \tag{2.10}$$

Let $q(\lambda)=(q_{-N}(\lambda),q_{-N+1}(\lambda),\cdots,q_N(\lambda))$ be an eigenvector of S_{ij} corresponding to the eigenvalue of λ. Then $q_j(\lambda)$ are the solutions to the difference equations

$$\begin{aligned}
&q_{j-1}-(2+P-\lambda)q_j+q_{j+1}=0;\\
&\qquad -N\leq j\leq -M;\quad M\leq j\leq N;\\
&q_{j-1}-(2-Q-\lambda)q_j+q_{j+1}=0;\\
&\qquad -M<j<M;\quad q_{-N-1}=q_{N+1}=0.
\end{aligned} \tag{2.11}$$

In the terminology of Gantmacher[7] S_{ij} is a normal Jacobi matrix. The eigenvalues λ are then real and simple and are denoted by $\lambda_0<\lambda_1<\cdots\lambda_{2N+1}$. A second property of normal Jacobi matrices is that the sequence $q_{-N}(\lambda_p)$, $q_{-N+1}(\lambda_p)$, $\cdots$, $q_N(\lambda_p)$, $p=0,\cdots,2N+1$, has precisely p changes in sign. In order to determine criteria for the positive definiteness of S_{ij} and hence for the stability of a solution with $2M-1$ weak bonds, it is sufficient to consider λ_0 and we therefore seek a solution to Eqs. (2.11) with no changes in sign. This solution, for the case $N\rightarrow\infty$ may be written in the form, analogous to that of Eq. (2.6),

$$q_j=A\bar\beta^{-j},\quad j\leq -M+1; \tag{2.12a}$$

$$q_j=B\bar\beta^{j},\quad j\geq M-1;$$

$$q_j=C\cos j\bar\theta+D\sin j\bar\theta,\quad -M\leq j\leq M; \tag{2.12b}$$

where

$$\begin{aligned}
&\bar\beta=\tfrac{1}{2}[\bar P+2-(\bar P^2+4\bar P)^{1/2}];\\
&\cos\bar\theta=1-\bar Q/2;\\
&\bar P=P-\lambda,\quad \bar Q=Q+\lambda.
\end{aligned} \tag{2.13}$$

The four coefficients, A, B, C, and D are determined by the requirement that Eqs. (2.12a) and (2.12b) agree for the four atoms for which the expressions overlap. The resulting system of four homogeneous equations may be separated into two sets of two each for symmetric and antisymmetric eigenvectors, respectively. We consider only the former set of equations since λ_0 corresponds to a symmetric eigenvector (as noted above, there are no changes in sign in the sequence of its components). They are [with $F=\frac{1}{2}(A+B)$]

$$\begin{aligned}
&C\cos M\bar\theta-F\bar\beta^M=0,\\
&C\cos(M-1)\bar\theta-F\bar\beta^{M-1}=0,
\end{aligned} \tag{2.14}$$

and equating the determinant of the system to zero leads to the following implicit equation for λ_0,

$$\bar\beta=\frac{\cos M\bar\theta}{\cos(M-1)\bar\theta}, \tag{2.15a}$$

where λ_0 is that root for which $M\bar\theta<(\pi/2)$. We consider next the variation of $\lambda_0=\lambda_0(\gamma^{-1};M)$ with γ^{-1}, with P constant. The following sequence of inequalities may be determined from the equations cited:

$$\frac{d\bar\beta}{d\lambda_0}>0, \qquad \text{[Eq. (2.13)]}$$

$$\frac{d\bar\beta}{d(\cos\bar\theta)}>0. \qquad \text{[Eq. (2.15a)]}$$

Consequently $d(\cos\bar\theta)/d\lambda_0>0$, and from Eqs. (2.4a) and (2.13)

$$\frac{d\gamma^{-1}}{d\lambda_0}=\frac{d\gamma^{-1}}{dQ}\frac{dQ}{d\lambda_0}=-\frac{2P}{Q^2}\left(\frac{dQ}{d\lambda_0}-\frac{1}{2}\right)=\frac{2P}{Q^2}\left[\frac{d(\cos\bar\theta)}{d\lambda_0}+\frac{1}{2}\right]>0.$$

The same result, that a decrease in γ^{-1} decreases λ_0,

[7] F. R. Gantmacher and M. G. Krein, *Oszillationsmatrizen, Oszillationskerne und Kleine Schwingungen Mechanischer Systeme* (Akademie-Verlag, Berlin, 1960), p. 80.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

may also be seen directly from Rayleigh's theorems,[8] since, as appears from Eqs. (2.4a), a decrease in γ^{-1} corresponds to an algebraic decrease of the weak-bond spring constants. Therefore the solution corresponding to $2M-1$ weak bonds will be stable only for $\gamma^{-1}\geq S_M$ where S_M is that value of γ^{-1} for which $\lambda_0(S_M;M)=0$. Since for $\lambda_0=0$, $\bar{\beta}=\beta$ and $\bar{\theta}=\theta$, the transcendental equation for S_M is

$$\cos M\theta-\beta\cos(M-1)\theta=0, \quad M\theta<(\pi/2); \quad (2.15b)$$

or

$$\tan(M-\tfrac{1}{2})\theta=\frac{1-\beta}{1+\beta}\operatorname{ctn}\frac{\theta}{2}, \quad (2.15c)$$

where Eq. (2.15c) follows upon use of trigonometric identities. Consequently $S_M=C_{M-\frac{1}{2}}$.

Therefore, combining the discussions for compatibility and stability, we may conclude that for a value of γ^{-1} in the range $C_{M-\frac{1}{2}}\leq\gamma^{-1}\leq C_M$ a solution with $2M-1$ weak bonds is both compatible and stable, while the only other compatible solution for the same γ, that with one more weak bond, is unstable.

Peierls Stress

Consider next a linear chain with displacements corresponding to a compatible and stable solution with $2M-1$ weak bonds and apply to it a stress σ which is zero initially and increases slowly (so that inertia effects are negligible). Equations (2.9b) show that this bond configuration will remain compatible while

$$\sigma\leq\frac{\gamma+\beta^M G_M}{1+\beta^M F_M}, \quad \sigma\leq-\frac{\gamma+\beta^{M-1}G_M}{1+\beta^{M-1}F_M}. \quad (2.16a)$$

We define σ_P as the stress above which these inequalities are invalid; for $\sigma>\sigma_P$ the problem has no (statically) compatible solution, i.e., the chain could not support a stress $\sigma>\sigma_P$ in static equilibrium. Therefore σ_P corresponds to the Peierls stress for the model considered. The first of Eqs. (2.16a) may be shown to be controlling; this yields

$$\sigma_P=\gamma\left[\frac{\cos M\theta-\beta\cos(M-1)\theta}{\sin M\theta-\beta\sin(M-1)\theta}\right]\times\left[\frac{\sin M\theta-\delta\sin(M-1)\theta}{\cos M\theta-\delta\cos(M-1)\theta}\right], \quad (2.16b)$$

where $\delta=\beta(2\gamma-1)/(2\gamma-\beta)$. We note that $\sigma_P=0$ for $\gamma^{-1}=C_M$ [this follows from Eq. (2.9d)] and for $\gamma^{-1}=S_M$ [Eq. (2.15b)], that is at the limits of compatibility and stability of configurations with $2M-1$ weak bonds.

Numerical Results

Equation (2.16b) has been evaluated, for values of P (the ratio of noncentral to central forces) equal to 1, 0.5, and 0.2. For each value of P the parameter γ (the ratio of perfect crystal shear strength to shear modulus) was varied over a range wide enough to show the important details of the problem. The results are shown in Figs. 2 and 3; for purposes of comparison Sanders' results,[4] corresponding to $P=0.5$, are also shown in Fig. 2.

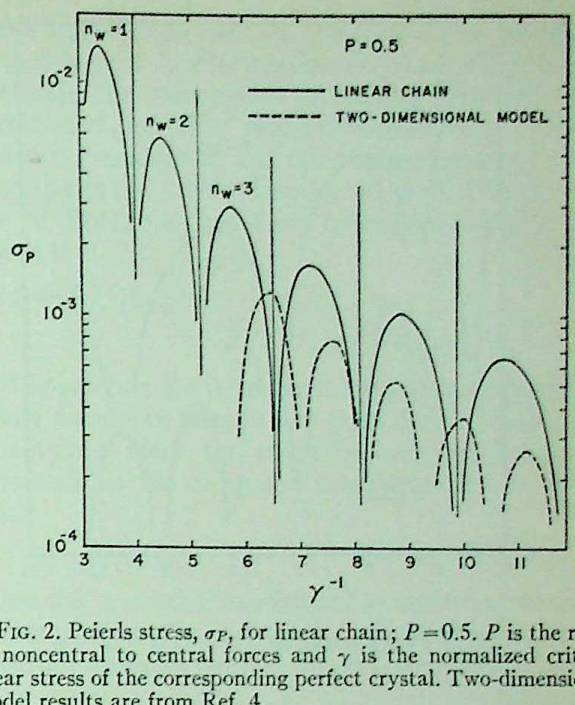

FIG. 2. Peierls stress, σ_P, for linear chain; $P=0.5$. P is the ratio of noncentral to central forces and γ is the normalized critical shear stress of the corresponding perfect crystal. Two-dimensional model results are from Ref. 4.

The agreement between these results and the earlier ones is quite good, in view of the expected sensitivity of the Peierls stress to the details of the model. Both sets have the quasicyclic pattern, and both have about the same exponential dependence on γ^{-1}, while the present results have peak values roughly twice those of the earlier ones.

A qualitative argument would indicate two opposite effects in passing from the one to the two-dimensional model: if the single chain treated here is considered as the first atom row above the slip plane, then the presence of the rows below it would tend to narrow the dislocation, increasing the Peierls stress, while the rows above it would increase the width and lower the stress. Apparently, the latter effect dominates.

The agreement between the one- and two-dimensional cases might serve to substantiate the superiority of the accurate calculation on a discrete model, even a relatively poor model, over the use of a continuum model for dislocation studies.[9]

3. STATISTICAL MECHANICAL CONSIDERATIONS

We wish to consider next the creep, due to thermal motion, of a linear chain, as described in Sec. 2, with a dislocation under an applied stress $\sigma<\sigma_P$. For this

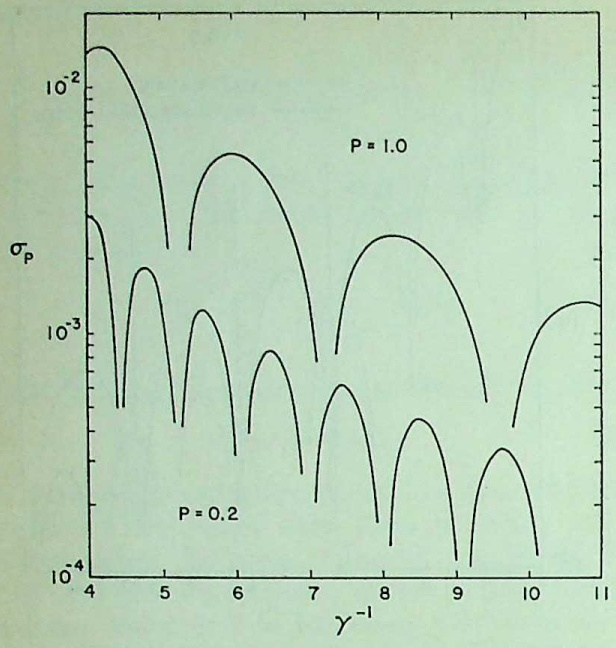

FIG. 3. Peierls stress, σ_P, for $P=1.0$, 0.2.

purpose an ensemble of such chains is assumed with distribution function $\rho(p_{-N},\cdots,p_N,q_{-N},\cdots,q_N)=\rho(p,q)$ where $q_j(t)$ is the displacement at time t of the jth atom from its equilibrium position under stress σ, and $p_j=m\dot{q}_j$ is the momentum of the jth particle with mass m. We treat a chain in thermal equilibrium with its surroundings at temperature T and accordingly set

$$\rho(p,q)=Ce^{-H/kT}, \tag{3.1}$$

where

$$H(p,q)=(1/2m)p_jp_j+V(q_{-N},\cdots,q_N), \tag{3.2}$$

$$C^{-1}=\int_\Omega e^{-H(p,q)/kT}\prod_i dp_i\,dq_i. \tag{3.3}$$

In these equations and in the remainder of this section latin subscripts assume the values $-N,\cdots,N$, where by the latter notation we signify zero included. Greek subscripts assume the values $-N,\cdots,-1,1,\cdots,N$, zero excluded. The symbol Ω denotes the full phase space, $-\infty<p_i<\infty$, $-\infty<q_i<\infty$, and the summation convention is employed.

The potential energy function $V(q)$ for the type of system under consideration admits of a number of positions of stable equilibrium with intermediate positions of unstable equilibrium. Let a typical stable equilibrium position have coordinates $q=(q_{-N},\cdots,q_N)=0$. In a neighborhood of $q=0$, the potential $V(q)$ may be approximated by

$$V(q)=(k_1/2)S_{ij}q_iq_j, \tag{3.4}$$

where the matrix $S=[S_{ij}]$, $S_{ij}=(1/k_1)(\partial^2V(0)/\partial q_i\partial q_j)$, is positive-definite. It is now assumed that the system spends most of the time in this neighborhood of $q=0$, so that $\rho(p,q)$ is very small elsewhere, and that therefore for the purpose of computing the normalization constant C, Eq. (3.3), the approximate expression for $V(q)$, Eq. (3.4), may be used. The result is

$$C=\frac{|S|^{1/2}k_1^{N+\frac{1}{2}}}{(2\pi kT)^{2N+1}m^{N+\frac{1}{2}}}, \tag{3.5}$$

where $|S|$ is the determinant of the matrix S.

Consider next the position of unstable equilibrium at $q=d=(d_{-N},\cdots,d_N)$ nearest to the stable equilibrium position at $q=0$. We confine attention to a neighborhood of the saddle point $q=d$ in which the potential $V(q)$ is adequately represented by its quadratic approximation

$$V(q)=V(d)+(k_1/2)U_{ij}(q_i-d_i)(q_j-d_j), \tag{3.6}$$

where

$$U_{ij}=(1/k_1)(\partial^2V(d)/\partial q_i\partial q_j) \tag{3.6a}$$

so that the equations of motion in that neighborhood take the form

$$m\ddot{q}_i=-k_1U_{ij}(q_j-d_j). \tag{3.7}$$

Let λ_i be the eigenvalues of the matrix $U=[U_{ij}]$ with associated unit eigenvectors a_{ij} and let $\lambda_0<0$ be the minimum eigenvalue with the sign of a_{0j} chosen so that $a_{0j}d_j>0$. It is assumed that λ_0 is the only negative eigenvalue.[10] With the orthogonal change in coordinates

$$Q_i=a_{ij}(q_j-d_j), \tag{3.8}$$

Eq. (3.7) assumes the form, for $Q_0(t)$,

$$\ddot{Q}_0=+s^2Q_0,\quad s^2=-k_1\lambda_0/m, \tag{3.9}$$

with the solution

$$Q_0(t)=\tfrac{1}{2}[Q_0(0)+s^{-1}\dot{Q}_0(0)]e^{st}+\tfrac{1}{2}[Q_0(0)-s^{-1}\dot{Q}_0(0)]e^{-st}. \tag{3.10}$$

Therefore, if at an arbitrary instant of time, $t=0$,

$$Q_0(0)=0\quad\text{and}\quad\dot{Q}_0(0)>0,$$

then $Q_0(t)$ will increase monotonically, at least as long as Eq. (3.5) applies. Since a_{0j} points away from the stable equilibrium position at $q=0$, this result implies that if the system, in its notion in phase space, reaches the hyperplane $Q_0=0$ with positive velocity, it will not return to its original equilibrium position but continue on towards the next equilibrium position.[11] This hyperplane corresponds therefore to the crest of the ridge between the two valleys. In order to compute the frequency, f, with which the system reaches the hyperplane $Q_0=0$ with $\dot{Q}_0>0$, we introduce, as new coordinates for phase space the Q_i as defined by Eq. (3.8) and the corresponding new momenta $P_i=a_{ij}p_j$. The distribution function in terms of these new variables will be denoted by $\rho(P_0,Q_0,P_\alpha,Q_\alpha)$ where the arguments are separated as shown for future convenience. The

[10] For the case of the linear chain described in Sec. 2, it can be proved that only one negative eigenvalue exists.

[11] This statement is, of course, intended only to apply to short times.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

frequency f may now be obtained directly by use of a formula derived by Rice.[12] This formula, which requires the assumption of the ergodic hypothesis for its validity, is in the present case,

$$f=\frac{1}{m}\int_0^\infty P_0 dP_0 \int_{\Omega'} \rho(P_0,0,P_\alpha,Q_\alpha)\prod_\alpha dP_\alpha dQ_\alpha, \quad (3.11)$$

where Ω' is the subspace, $-\infty<P_\alpha<\infty$, $-\infty<Q_\alpha<\infty$. This leads, after the integrations in P_i are performed, to

$$f=\frac{k_1{}^{N+\frac{1}{2}}|S|^{1/2}}{(2\pi)^{N+1}(kT)^N\sqrt{m}} \times\int_{\Omega''}\exp\left\{\frac{-V(0,Q_\alpha)}{kT}\right\}\prod_\alpha dQ_\alpha, \quad (3.12)$$

where Ω'' is the subspace $-\infty<Q_\alpha<\infty$ and $V(Q_0,Q_\alpha)$ is the function $V(q)$ expressed in terms of the new coordinates Q_i. The assumption is next made that, for the purpose of evaluating the integral in Eq. (3.12), $V(0,Q_\alpha)$ may be evaluated from Eq. (3.6), the expression valid in the neighborhood of the saddle point. Then

$$V(0,Q_\alpha)=V(d)+(k_1/2)\textstyle\sum_\alpha \lambda_\alpha Q_\alpha{}^2. \quad (3.13)$$

Substitution of this expression into Eq. (3.12) leads to the following expression for f:

$$f=f_0\nu e^{-V(d)/kT} \quad (3.14)$$

where

$$f_0=\frac{1}{2\pi}(k_2/m)^{1/2}; \quad \nu=\left(\frac{\lambda_0|S|}{P|U|}\right)^{1/2} \quad (3.14a)$$

and where $|U|=\prod_i\lambda_i$ is the determinant of the matrix U. The quotient of determinants may be written

$$|S||U|^{-1}=|I+S^{-1}D|^{-1}, \quad (3.15)$$

where S^{-1} is the matrix inverse to S, I is the unit matrix and $D=U-S$. In the type of problem considered here the difference matrix, D, will have only a few nonzero elements; in this case, the determinant $|I+S^{-1}D|$ may be expressed in terms of a correspondingly low-order determinant, as will be seen in Sec. 4.

4. CREEP OF LINEAR CHAIN

In this section, the rate formula of Eq. (3.14) is applied to the linear chain described in Sec. 2 under an applied stress $\sigma<\sigma_P$.

Saddle-Point Energy, $V(d)$

In Sec. 3, two approximate expressions for $V(q)$, Eqs. (3.4) and (3.6) were given, the first valid in the neighborhood of the stable equilibrium position, $q=0$, and the second valid in the neighborhood of the unstable equilibrium position, $q=d$. For the model described in Sec. 2, with a piecewise quadratic substrate potential, the two regions of validity (referred to as stable and unstable regions, respectively) have a common boundary B, and the displacements $q_i{}^P$ corresponding to the Peierls stress σ_P fall on B. Therefore, by use of Eqs. (3.4) and (3.6) to evaluate $V(q^P)$, it is found that

$$V(d)=(k_1/2)S_{ij}q_i{}^Pq_j{}^P -(k_1/2)U_{ij}(q_i{}^P-d_i)(q_j{}^P-d_j). \quad (4.1)$$

The position $q_i=0$ corresponds to stable equilibrium under an applied stress $\bar\sigma<\bar\sigma_P$ (bars denote dimensional quantities). Since the stress-displacement relation is linear within the stable and unstable region, it follows that

$$\partial V(q^P)/\partial q_i=k_1S_{ij}q_j{}^P=\bar\sigma_P-\bar\sigma, \quad \text{all } i. \quad (4.2)$$

when the position q^P is regarded as arrived at from the stable position. Similarly, if it is regarded as arrived at from the unstable position at $q=d$, we have

$$\partial V(q^P)/\partial q_i=k_1U_{ij}(q_j{}^P-d_j)=\bar\sigma_P-\bar\sigma, \quad \text{all } i. \quad (4.3)$$

Substitution from Eqs. (4.2) and (4.3) into Eq. (4.1) yields

$$V(d)=\tfrac{1}{2}(\bar\sigma_P-\bar\sigma)\textstyle\sum_i d_i. \quad (4.4)$$

Because of the linear behavior in both regions, $q_i{}^P(\bar\sigma)$, the displacements to the common B from the equilibrium positions corresponding to the applied stress, $\bar\sigma$, are given by

$$q_i{}^P(\bar\sigma)=[(\bar\sigma_P-\bar\sigma)/\bar\sigma_P]q_i{}^P(0),$$
$$d_i(\bar\sigma)-q_i{}^P(\bar\sigma)=[(\bar\sigma_P-\bar\sigma)/\bar\sigma_P][d_i(0)-q_i{}^P(0)],$$

so that

$$d_i(\bar\sigma)[(\bar\sigma_P-\bar\sigma)/\bar\sigma_P]d_i(0). \quad (4.5)$$

Therefore, the energy at the saddle point $d(\bar\sigma)$, corresponding to an applied stress, $\bar\sigma$, is

$$V(d(\bar\sigma))=[(\bar\sigma_P-\bar\sigma)^2/2\bar\sigma_P]\textstyle\sum_i d_i(0). \quad (4.6)$$

Consider $V(d(0))$. Let Δ_j be the displacement of the jth atom when the dislocation moves from the stable equilibrium position at $q=0$ to the next adjacent stable equilibrium position. Then $V(0)=V(\Delta)=0$, and $V(d(0))$ can be computed by considering either displacements from $q=0$ or $q=\Delta$. In both cases Eq. (4.6) applies (with oppositely signed $\bar\sigma_P$) so that

$$V(d(0))=\tfrac{1}{2}\bar\sigma_P\textstyle\sum_i d_i(0)=-\tfrac{1}{2}\bar\sigma_P\sum_i(d_i(0)-\Delta_i)$$

or

$$2\textstyle\sum_i d_i(0)=\sum_i\Delta_i=b, \quad (4.7)$$

where b is the Burger's vector of the dislocation. Substitution into Eq. (4.6) then yields the following formula for the saddle-point energy:

$$v(d(\bar\sigma))=\frac{(\bar\sigma_P-\bar\sigma)^2b}{4\bar\sigma_P}=\frac{(\sigma_P-\sigma)^2}{4\sigma_P}k_2b^2. \quad (4.8)$$

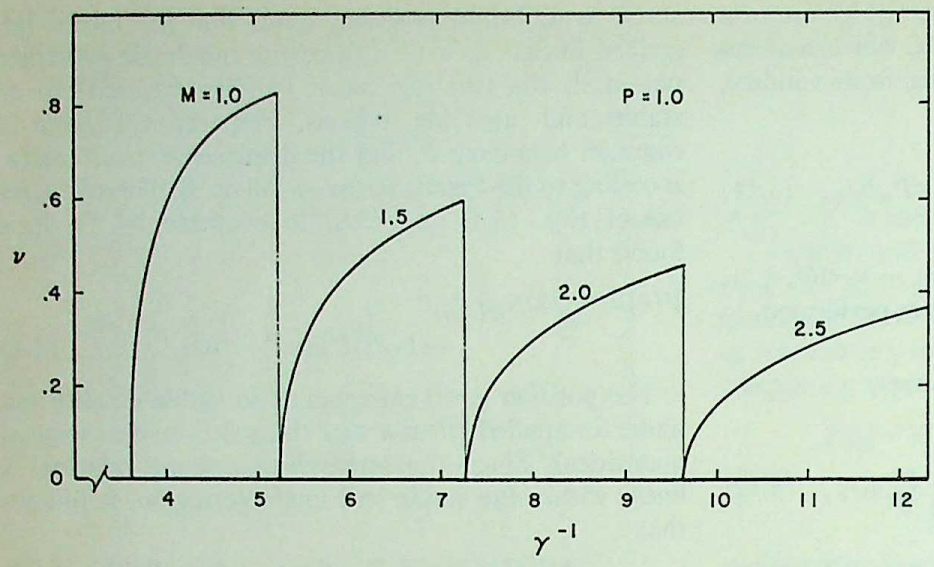

FIG. 4. Variation of the dimensionless frequency ν, Eq. (3.14), with the normalized critical shear stress γ.

Computation of ν

For the model of Sec. 2 which is stable with $2M-1$ weak bonds, only the elements of S and U corresponding to $i=j=M$ differ, so that the only nonzero element of $D=U-S$ is

$$D_{MM}=-(P+Q)=\frac{-P}{1-2\gamma}. \tag{4.9}$$

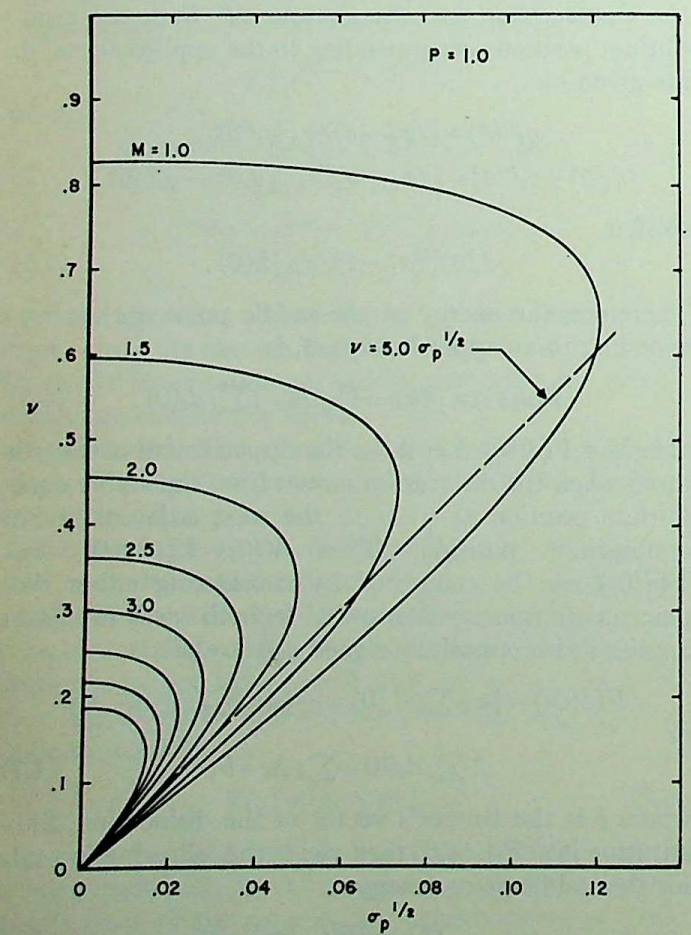

FIG. 5. Variation of the dimensionless frequency ν, Eq. (3.14), with Peierls stress, σ_P.

Substitution in Eq. (3.15) gives the result

$$|S||U|^{-1}=(1+S^{-1}{}_{MM}D_{MM})^{-1} \tag{4.10}$$

so that only the element $S^{-1}{}_{MM}$ of the matrix S^{-1} is needed. This is found (for the infinite chain) by solution of the difference equations $S_{ij}w_j=\delta_{iM}$ with the result

$$S^{-1}{}_{MM}=\frac{\beta}{2}\left[\frac{\cos M\theta}{\cos M\theta-\beta\cos(M-1)\theta}+\frac{\sin M\theta}{\sin M\theta-\beta\sin(M-1)\theta}\right]. \tag{4.11}$$

Finally it is necessary to calculate λ_0, the minimum eigenvalue of the matrix U. This is found from Eq. (2.15a) with M replaced by $M+\frac{1}{2}$. For the case in which stability corresponds to $M=1$, an explicit formula for λ_0 may be derived, namely,

$$\lambda_0=\left[\frac{(2-Q)(P+Q+2)-P-4}{P+Q+1}\right]. \tag{4.12}$$

For other values of M, numerical evaluation of Eq. (2.15a) was used. The resulting values of ν, the dimensionless frequency that appears in the rate equation, Eq. (3.14), are plotted in Fig. 4 for $P=1.0$ as a function of γ. It may be noted that $\nu=0$ for those values of γ which correspond to the limit of stability, S_M, for the given configuration, as does σ_P (Figs. 2 and 3). However, ν increases monotonically within the range $S_M\leq\gamma^{-1}<C_M$, whereas σ_P returns to zero at $\gamma^{-1}=C_M$. It is clear, therefore, that these calculations do not reveal a linear dependence of ν upon $\sqrt{\sigma_P}$ as might be expected from a model treating the dislocation as a single entity moving in a potential field corresponding to σ_P. A plot of ν as a function of $\sqrt{\sigma_P}$, given in Fig. 5, reveals, however, that if only the initial portion of each range of γ is considered, the two quantities are indeed linearly related. It may be that these deviations from

TABLE I. Comparison of theoretical and analog creep rates.

k_2b^2/kT		990	560	245
f/f_0	analog	0.157	0.22	0.46
	theoretical	0.456	0.53	0.595

linearity are due in part to the discontinuous substrate potential employed. If only the initial portions of each range of γ are considered, then the present calculations lead to the relationship $v \simeq a\sqrt{\sigma_P}$ with $a=5\pm0.5$ for $0.1 \leq P \leq 10$. This may be compared with the similar relationships found, for example, by Seeger,[13] Weertman,[14] and Lothe[1] in their treatments of a dislocation as a vibrating string, the latter two obtaining values of $a=5.6$ and 2.5 respectively.

Analog Computer Results

A REAC Model-400 analog computer was used in an attempt to check these rate calculations, at least in order of magnitude. Because of limitations in equipment only a six-atom model could be simulated; also it was not considered feasible to run through a random sequence of initial conditions, so initial conditions were chosen that would give a minimum frequency of jumps of the dislocation. This model, then, was run for $P=1$, $\gamma=0.2396$, and $\sigma=0.010$ ($\sigma_P=0.0146$), and for three values of temperature. Table I shows these results together with corresponding results based on Eq. (3.14).

The analog data do agree, within a factor of 3, with the theoretical results. The analog results show a lower frequency, as expected (because of initial conditions). They also exhibit a more sensitive dependence on temperature; this again was expected, because of the fact that only six atoms were simulated. In view of the limitations on the analog model, the agreement seems to be good, and appears to lend justification to the assumptions made in the theoretical derivation.

5. CONCLUSIONS

Some conclusions which may be drawn from this work are as follows:

(1) The one-dimensional dislocation model yields values for the Peierls stress σ_P in surprisingly good agreement with those for the two-dimensional model considered by Sanders.[4]

(2) In particular, the sensitivity of σ_P to small changes in γ, the critical shear stress, which was found in the two-dimensional calculations[4] is confirmed here.

(3) Detailed results could be obtained on rate of motion of the dislocation under various levels of applied stress less than the Peierls stress and for a range of values of the other parameters of the problem. The relation between these rates and the Peierls stress is in good agreement with that found earlier by treating the dislocation as a vibrating string, except for systematic deviations that are possibly due in part to the discontinuous substrate potential used here.

(4) The rate formula, Eq. (3.14), which has been applied here to a specific one-dimensional model has broader applicability. It allows explicit calculation of rates of transition, without consideration of the concept of entropy of activation, when the potential energy function of the system as a function of the microscopic coordinates is known.

Incoherent and Thermal Small-Angle X-Ray Scattering in Silicon

D. L. WEINBERG*
Corning Glass Works, Corning, New York
(Received 30 December 1963)

The intensity of small-angle x-ray scattering in single-crystal silicon has been measured with the scattering vector **K** oriented along each of the three symmetry directions. The scattering intensity extrapolates to zero angle in reasonable agreement with the thermal scattering, calculated from the velocity of sound in each direction. The thermal scattering is calculated from known phonon dispersion relations and subtracted from the total to obtain the incoherent, or Compton, scattering. The incoherent scattering is smaller than that calculated by Freeman from Hartree-Fock wave functions for the free atom. This conclusion agrees with previous approximate measurements at small K on other crystals. Theoretical ideas about the source of the deficiency, apparently a solid-state effect, and about small-angle thermal scattering are outlined. The incoherent scattering shows little anisotropy and no sharp rise with increasing angle, which would suggest the onset of excitation of electrons across the forbidden band.

I. INTRODUCTION AND THEORY

A. Incoherent Scattering

IN a perfect, rigid crystal all the diffuse single scattering is incoherent. From the semiclassical or quantum theory, it is[1]

$$I_{\rm inc}(\mathbf{K})=\sum_{m\neq 0}\left|\int\psi_m^*\psi_0\sum_j^N e^{i\mathbf{K}\cdot\mathbf{r}_j}d\tau\right|^2 \quad (1)$$

$$=\int|\psi_0|^2|\sum_j^N e^{i\mathbf{K}\cdot\mathbf{r}_j}|^2 d\tau - \left|\int|\psi_0|^2\sum_j^N e^{i\mathbf{K}\cdot\mathbf{r}_j}d\tau\right|^2 \quad (2)$$

in electron units (e.u.). $K=4\pi\sin\frac{1}{2}\theta/\lambda$, θ is the scattering angle, λ is the x-ray wavelength, ψ_m is the wave function in state m, $m=0$ is the ground state, N is the total number of electrons, $\mathbf{r}_j$ is the position of the jth electron, and the integrations are over all coordinates of the electrons. Then $I_{\rm inc}(0)=0$. The approximations that the x-ray frequency is small enough to avoid recoil and relativity corrections, but that it is much larger than the Bohr frequency ν_{0m} for any m which contributes appreciably to the sum in (1), are used. The former assumption holds in the present work. The latter assumption excludes anomalous dispersions, or Raman, terms which correspond to excited final electronic states. These terms are too small to have been observed in x-ray scattering, but are finite at $K=0$.

Thermal motion produces additional diffuse scattering $I_{\rm th}$. Walker[2] separated $I_{\rm inc}$ from $I_{\rm th}$ in Al experimentally, by their temperature dependences. $I_{\rm th}$ is almost unshifted in wavelength, but $I_{\rm inc}$ is known, from spectral measurements at large K, to peak near a wavelength shift $\Delta\lambda=(h/m_ec)(1-\cos\theta)$, the value for a slow, free electron. Thus Curien and Deroche[3] separated $I_{\rm inc}$ from $I_{\rm th}$ in Al with a dispersive filter. Laval[4] measured $I_{\rm inc}$ in Al, diamond, and KCl by subtracting estimated $I_{\rm th}$ from the total diffuse scattering. Measured phonon dispersion relations were not then available. Cribier[5] treated CaF_2 similarly. Measurements on pure, perfect crystals at small K have been difficult in the past. The weak scattering power requires an unusually strong x-ray source and low background. For convenient λ, θ is small, so that common diffraction equipment is not suitable.

If ψ_0 is a determinant of one-electron functions ψ_j, then from (2),

$$I_{\rm inc}=N-\sum_{jj'}^N\left|\int\psi_j^*(r)\psi_{j'}(r)e^{i\mathbf{K}\cdot\mathbf{r}}d\tau\right|^2. \quad (3)$$

The most careful calculations have used (3) with Hartree-Fock ψ_j for free atoms or ions. A recent review[6] lists the results. They lie above the measurements[4] at small K, but agree otherwise.[6,7] Coherent scattering in crystals (at large K) is also well described by free-atom orbitals.[8] Neglect of interatomic overlap in (3), which is emphasized at small K, presumably produces much of the overestimate of $I_{\rm inc}$. It may be that overlap contributions vanish when $e^{i\mathbf{K}\cdot\mathbf{r}}$ varies with large K, and that well within the atom, ψ_j is similar in free atom and crystal. Overlap effects might be estimated with simple approximate atomic orbitals. The solutions of the Hartree-Fock problem are Bloch functions, extend-

ing over the whole crystal, but the determinental ψ_0 is not changed if one takes each ψ_j as a linear combination of the Bloch functions which is localized on an atom. However, for metallic or covalent bonding, these ψ_j have greater overlap than the free atom orbitals. For example, the assumption of some free electrons,[2] instead of isolated atoms, reduces $I_{\rm inc}$ at small K (except very near $K=0$). In the absence of accurate measurements on crystals at small K, no realistic calculations of $I_{\rm inc}$, including interatomic effects, have been made.

To be Compton scattered in an insulator or semiconductor at absolute zero of temperature, a photon must give up at least the band-gap energy. Suppression of scattering with small $\Delta\lambda$ is reported[9] from spectral measurements on diamond, with a 7-eV band gap. Analogous reduction of $I_{\rm inc}$ at angles less than a minimum, θ_c, calculated from the slow, free-electron Compton relation, has been suggested[2,7,10] as an alternative explanation of the deficiency in $I_{\rm inc}$. Si has a 1.08-eV band gap, and with $\lambda=1.542$ Å, as in this work, $\theta_c=7°$. But the electrons in band-gap solids are not free and slow, so that large energy transfers at small θ may occur. In some cases the deficiency is by comparison with $I_{\rm inc}$ calculated for free closed-shell ions, which themselves have few low-lying excited levels. The idea is inapplicable, *a fortiori*, to a metal.

There is more justification for requiring conservation of quasimomentum, $\mathbf{k}'-\mathbf{k}=\mathbf{K}+\mathbf{K}_L$, from (1). $\mathbf{k}$, $\mathbf{k}'$, are the wave vectors of the excited electron in the initial and final states. $\mathbf{K}_L$ is a vector of the reciprocal lattice. Knowledge of the band structure of Si[11] shows that the addition of this requirement scarcely increases the predicted θ_c, for $\mathbf{K}$ along the [001] direction. However, this kind of description of the excited states seems inadequate.

B. Thermal Scattering

Thermal scattering involves emission or absorption of phonons, but it can be treated classically, and is well understood for harmonically vibrating crystals.[1,12,13]

Since the two primitive sublattices in Si are identical, their amplitudes must be equal in each normal mode. Then the harmonic, one-phonon scattering is[12]

$$I_{\rm th}(\mathbf{K})=\tfrac{1}{2}m^{-1}\exp(-2M)K^2|f|^2 \times\Big[(1+\cos\mathbf{K}_L\cdot\boldsymbol{\varrho})\sum_{i=1}^{3}E_i\omega_i^{-2}\cos(\mathbf{K},\mathbf{e}_i) +(1-\cos\mathbf{K}_L\cdot\boldsymbol{\varrho})\sum_{i=4}^{6}E_i\omega_i^{-2}\cos^2(\mathbf{K},\mathbf{e}_i)\Big] \quad (4)$$

in e.u./atom. The two summations extend over the acoustic and optical modes, respectively. $\mathbf{K}$ is in the zone centered on $\mathbf{K}_L$, $\mathbf{q}=\mathbf{K}-\mathbf{K}_L$, $\omega_i/2\pi$ is the frequency of the ith mode with propogation vector $\mathbf{q}$, $E_i=\frac{1}{2}\hbar\omega_i\times\coth(\hbar\omega_i/2kT)$, $2|f|^2(1+\cos\mathbf{K}\cdot\boldsymbol{\varrho})$ is the usual structure factor, m is the atomic mass, and $(\mathbf{K},\mathbf{e}_i)$ is the angle between $\mathbf{K}$ and the polarization vector $\mathbf{e}_i$. The Debye-Waller factor $\exp(-2M)$ can be neglected in this work, since $2M=0.3\sin^2\theta/\lambda^2$ in Si at 300°K. n-phonon scattering is given by the M^n term of a power series in M. Since M is so small here, multiple-phonon scattering is negligible, and it vanishes in general at $K=0$.

At $K=0$, the optical modes do not contribute, since their phase velocities $\omega_i/K\to\infty$ as $K\to 0$. Nor do purely transverse waves, for which $(\mathbf{q},\mathbf{e}_i)=90°$, contribute when $\mathbf{K}$ is in the first zone, where $\mathbf{q}=\mathbf{K}$. Hence, in directions of such high symmetry that the modes are purely transverse or longitudinal at $\mathbf{q}=0$ (⟨001⟩, ⟨111⟩, and ⟨110⟩ in cubic crystals), the harmonic thermal scattering is

$$I_{\rm th}(0)=m^{-1}|f(0)|^2kTV^{-2} \quad (5)$$

at $K=0$. V is the adiabatic velocity of sound in the direction of $\mathbf{K}$. The correction for anharmonicity is to replace V by the isothermal velocity.[14] The difference is negligible in hard solids.

The calculated thermal scattering in Si is shown in Fig. 1 for $\mathbf{K}$ along each of the three symmetry directions.

II. EXPERIMENTS AND DISCUSSION

A rotating water-cooled Cu anode was used, at 33 kV and 98 mA, with monochromatization by a Ni filter and proportional counter-pulse-height analyzer. Slits 0.6-cm high collimated and analyzed the beam. With the slit widths used for $\theta\geqq 3.5°$, the rms resolution was 1.0° at $\theta=3.5°$, and decreased to 0.7° for $\theta\geqq 10°$. The resulting intense beam was needed to measure the weak scattering of Si at small K. The background was about 4 counts/min, and the smallest sample scattering at $\theta>2°$ was about 100 counts/min. Other experimental aspects have been described.[15] The accuracy of the intensity standardization[15] has been verified[16] within a few percent.

The sample was a (110) disc of 100 Ω-cm n-type Si, made by Philco Corp. Alternate polishing and etching reduced the thickness to 0.0102 cm, uniform to 0.0005 cm over the area used, with x-ray transmission 0.237. The final treatment was an etch, to minimize the damaged surface layer. Static imperfections in this grade of Si should produce completely negligible (volume) diffuse scattering. Low dislocation density was confirmed by Laue photographs and examination of etch pits.

The orientation was accurate to 1°. Since the sample

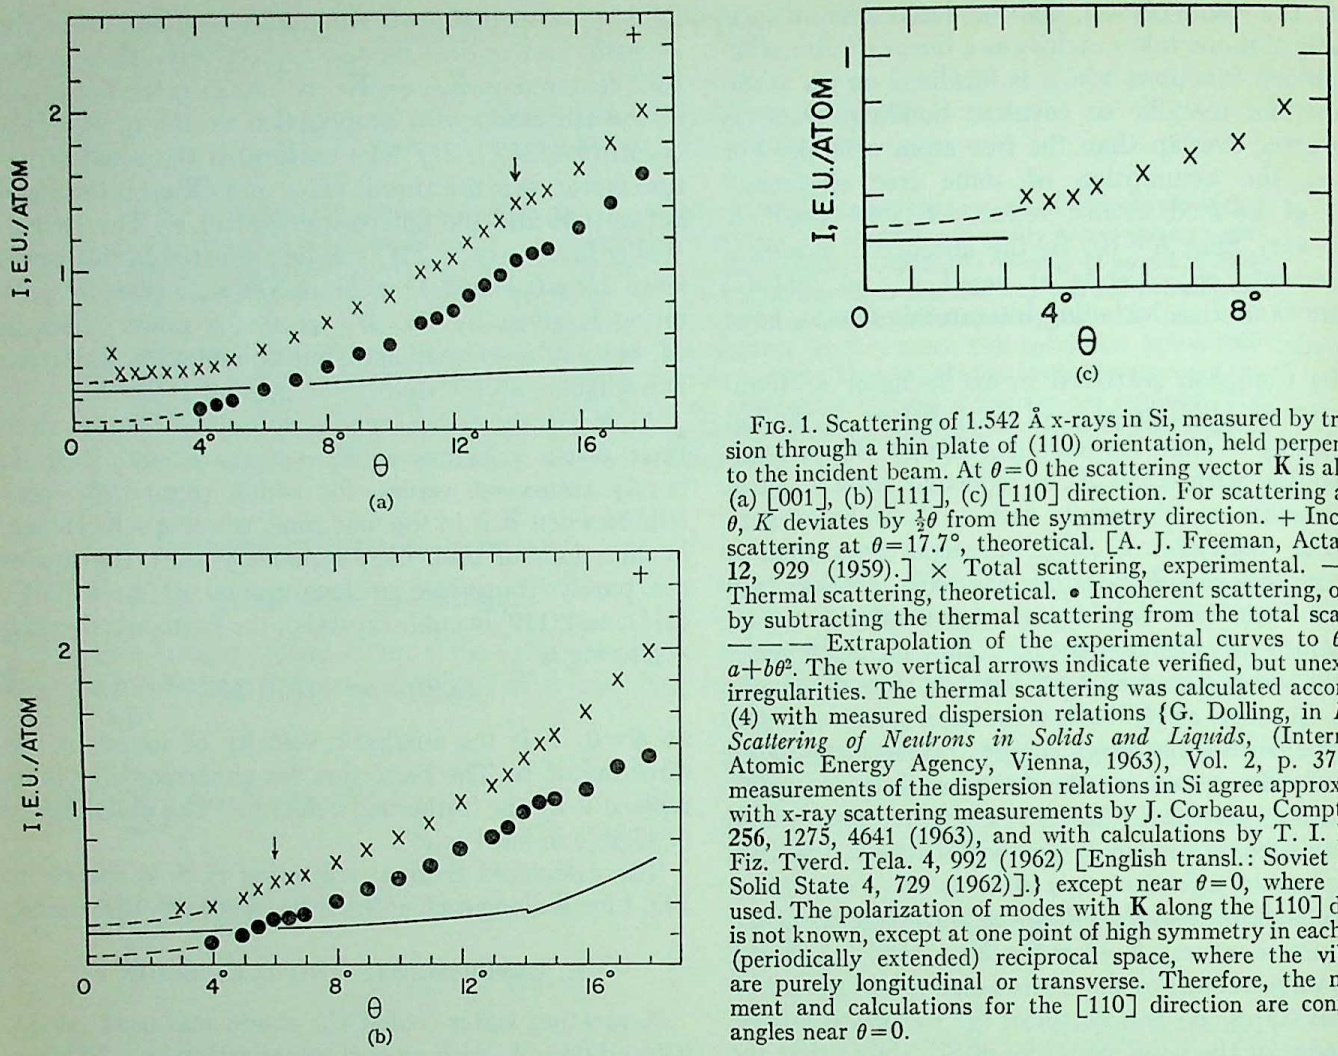

FIG. 1. Scattering of 1.542 Å x-rays in Si, measured by transmission through a thin plate of (110) orientation, held perpendicular to the incident beam. At $\theta=0$ the scattering vector **K** is along the (a) [001], (b) [111], (c) [110] direction. For scattering at angle θ, K deviates by $\frac{1}{2}\theta$ from the symmetry direction. + Incoherent scattering at $\theta=17.7°$, theoretical. [A. J. Freeman, Acta Cryst. 12, 929 (1959).] × Total scattering, experimental. ——— Thermal scattering, theoretical. • Incoherent scattering, obtained by subtracting the thermal scattering from the total scattering. — — — Extrapolation of the experimental curves to $\theta=0$ as $a+b\theta^2$. The two vertical arrows indicate verified, but unexplained irregularities. The thermal scattering was calculated according to (4) with measured dispersion relations {G. Dolling, in *Inelastic Scattering of Neutrons in Solids and Liquids*, (International Atomic Energy Agency, Vienna, 1963), Vol. 2, p. 37. These measurements of the dispersion relations in Si agree approximately with x-ray scattering measurements by J. Corbeau, Compt. Rend. 256, 1275, 4641 (1963), and with calculations by T. I. Kucher, Fiz. Tverd. Tela. 4, 992 (1962) [English transl.: Soviet Phys.—Solid State 4, 729 (1962)].} except near $\theta=0$, where (5) was used. The polarization of modes with **K** along the [110] direction is not known, except at one point of high symmetry in each zone of (periodically extended) reciprocal space, where the vibrations are purely longitudinal or transverse. Therefore, the measurement and calculations for the [110] direction are confined to angles near $\theta=0$.

was normal to the incident beam, **K** varied in direction at half the rate at which θ changed, when the analyzing slits were rotated. Figure 1 shows the measurements, corrected for background (angularly dependent), absorption, polarization, and slit-height smearing. The correction[15] for this last effect is a factor $[1+(b/a)\times(\theta^2-4.76)]/[1+(b/a)\theta^2]$, b/a in deg^{-2}, where the expression $a+b\theta^2$ is fitted to the experimental total-scattering curve at θ. The factor is 0.90 to 0.91 at $\theta=0$.

The experimental values for $I(0)$ are from 16 to 30% too large in the three directions. Only measurements made during the first month after the final etch are reported because the scattering is found to increase with time, most conspicuously at the smallest θ. The increase must represent deterioration, either surface corrosion or possibly x-ray damage. Scattering from surface roughness is known[17] to be prominent at small θ, especially in otherwise perfect crystals, where the volume scattering is small. Comparison of surface conditions shows that it accounts at least primarily for the deviation, at $\theta<4°$, of the experimental curves in Fig. 1 above the expected $a+b\theta^2$ variation. The observed excess in $I(0)$ is attributed to this cause. The time variation in $I(\theta)$ is approximately independent of θ, so that it is believed the final curve should be lowered uniformly by about 0.05 e.u./atom.

Similar experiments on quartz, in two directions, also show surface scattering, similar agreement with (5) (piezoelectric effects are negligible), and I_{inc} less than theory.[6] However, the phonon dispersion relations are not known.

Optically Active Phonon Processes in CdS and ZnS*

R. Marshall and S. S. Mitra
Physics Division, IIT Research Institute,† Chicago, Illinois
(Received 26 December 1963)

Transmission spectra of thin (10 to 30 μ) CdS single-crystal samples have been recorded in the hitherto uninvestigated region of 250 to 400 cm^{-1}. A number of new absorption maxima are located which necessitated a new phonon assignment with considerably lower values of the acoustic modes. Some 30 absorption peaks are attributed to multiphonon combinations of the following Brillouin zone-edge frequencies: LO = 295 cm^{-1}, TO$_1$ = 261 cm^{-1}, TO$_2$ = 238 cm^{-1}, LA = 149 cm^{-1}, TA$_1$ = 79 cm^{-1}, and TA$_2$ = 70 cm^{-1}. The transmission spectrum of hexagonal ZnS is obtained for the first time in the region 300 to 750 cm^{-1}. Again some 27 absorption maxima are assigned to multiphonon combinations of LO = 346 cm^{-1}, TO$_1$ = 318 cm^{-1}, TO$_2$ = 297 cm^{-1}, LA = 181 cm^{-1}, TA$_1$ = 92 cm^{-1}, and TA$_2$ = 73 cm^{-1}. The phonon assignment for the optical lattice absorption in cubic ZnS due to Deutsch is shown to be inconsistent with the requirements of the Brout sum rule and other regularities expected for the zincblende-type semiconductors. Two new assignments (LO = 339 cm^{-1}, TO = 298 cm^{-1}, LA = 155 cm^{-1}, and TA = 93 cm^{-1}, and LO = 339 cm^{-1}, TO = 298 cm^{-1}, LA = 190 cm^{-1}, and TA = 115 cm^{-1}) only slightly different from each other are proposed. The characteristic phonon frequencies are discussed in terms of structure and effective ionic charge.

1. INTRODUCTION

INFRARED lattice absorption arising from multiphonon combinations has been observed in many group III–V compounds and group IV elements.[1,2] The combination bands are a continuous absorption. However, peaks in absorption occur because of singularities in the phonon frequency distribution. These singularities arise from critical points in the Brillouin zone where the frequency wave vector ($\mathbf{k}$) curves have zero slope. Such critical points are believed to occur at or near the zone boundary. Usually the critical point characterizes a phonon branch and the combination bands may be classified into summations or differences of the longitudinal optical (LO), transverse optical (TO), longitudinal acoustic (LA) and transverse acoustic (TA) phonons at the zone edge. The interaction of an infrared photon with the lattice vibrations are governed only by the conservation of energy and wave vector. Turner and Reese[1] have assigned some forty components in the lattice absorption of AlSb in this manner.

Only a limited amout of experimental evidence of these effects has been obtained for group II–VI compounds. Mitra[3] has recently explained the infrared absorption observed in ZnSe by Aven *et al.*[4] in terms of phonon combinations, and it appears that the conditions are similar to those governing the behavior of III-V compounds. In the case of CdS, Collins[5] using the reflection technique located the zone-center optical transverse mode at 241 cm^{-1}. Subsequently, Balkanski and Besson[6] reported seven absorption maxima between 400 and 600 cm^{-1} which were assigned to various binary combinations using four assumed characteristic frequencies. Spitzer[7] has recently shown that the same two-phonon bands can also be explained by another set of four-phonon frequencies; one of which is different from those used by Balkanski and Besson. Deutsch[8] has reported a few additional bands, resolved under polarized radiation, in the same region. He proposed two different sets of assignments which almost fully explained his own observations but failed to explain some of the bands reported by Balkanski and Besson. Mitra[9] observed further absorption bands in the region 600–1400 cm^{-1} and used a five-frequency assignment for a comprehensive explanation. They were composed of the four frequencies of Balkanski and Besson and the alternative frequency of Spitzer.

All transmission measurements on CdS to date have been confined to frequencies greater than 400 cm^{-1}, despite the observation of Collins that the zone-center transverse optical-mode phonon has a value of 241 cm^{-1}. Thus, it was felt that a transmission study in the region below 400 cm^{-1} could provide additional important information, particularly regarding the low-frequency characteristic phonons. These were considerably larger than in the case of ZnSe[3] and the III–V compounds.[1] Furthermore, if the proposed frequencies are designated LO, TO, LA, and TA phonons, there is a lack of consistency with various correlations described by Keyes,[10] Mitra,[3] and Mitra and Marshall,[11] including the Brout sum rule.[12] It was also anticipated that by using very thin crystals, structure in the broad absorption bands would be resolved and be of considerable assistance in obtaining a reliable assignment.

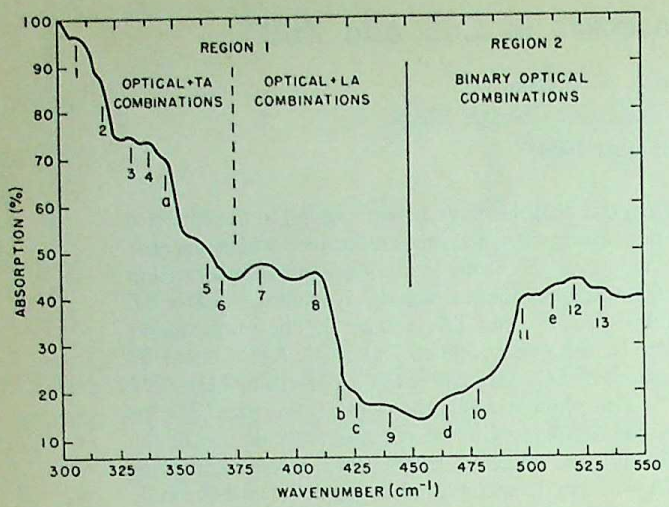

FIG. 1. Transmission spectrum of CdS in the region 300 to 550 cm^{-1}.

In the case of ZnS, Deutsch[13] has studied absorption in the cubic modification, over the frequency range 410–830 cm^{-1}. His assignment fails to explain the strong absorption at 431 cm^{-1}. Furthermore, the characteristic frequencies used (particularly the low-frequency value), as in the case of CdS, do not conform with the correlations mentioned earlier. Thus a new assignment for cubic ZnS, with lower values for the acoustic branches, seemed necessary.

Lattice absorption in hexagonal ZnS is reported here for the first time. Thin crystals have been used in order to cover the optical-acoustical phonon combination region and to resolve the structure involved in the anticipated removal of degeneracy of the zone-boundary TO mode and possibly the TA mode as well.

2. EXPERIMENTAL

Platelet crystals of CdS and ZnS, grown from the vapor phase by nucleation on a quartz seed as described by Fochs and Lunn,[14] were used in this investigation. This growth technique yields thin crystals ($\sim 10\ \mu$) of high optical quality and low impurity content, but relatively small surface areas ($<0.5\ cm^2$).

Absorption data was obtained for both compounds over the region 300–800 cm^{-1} using a Perkin Elmer double-beam spectrometer (model 521) with grating optics.

divided into three regions: (1) the group of strong bands below 450 cm^{-1}, (2) bands of medium absorption between 450 and 710 cm^{-1}, and (3) the weak bands above 700 cm^{-1}. Since the zone-center transverse optical-phonon frequency as determined by Collins is at 241 cm^{-1}, these three regions may be considered as arising from one, two, and three optical-phonon processes. First, considering the second region the six prominent bands [Nos. 10, 11, 12, 13 (Fig. 1) and Nos. 14 and 15 (Fig. 2)] are assigned to various binary combinations of the three zone-boundary optical phonons, $LO=295\ cm^{-1}$, $TO_1=261\ cm^{-1}$, and $TO_2=238\ cm^{-1}$. It may be commented here that the first two char-

[13] T. Deutsch, in *Proceedings of the International Conference on Semiconductors, Exeter, 1962* (The Institute of Physics and Physical Society, London, 1962), p. 505.

acteristic phonons have been considered by all the previous investigators, Balkanski and Besson, Deutsch, Spitzer, and Mitra. Since the zone-center value of the transverse phonon is 241 cm^{-1}, it seems reasonable that the zone-boundary phonons should split into 261 and 238 cm^{-1} in the hexagonal wurtzite structure.

Balkanski and Besson have studied the temperature dependence of the prominent bands in the two-optical-phonon region. In Table II, we have made a comparison, based on our assignment, between the calculated and observed values of the absorption coefficient at 80 and 293°K. It may be shown[15] that the net power absorbed in a two-phonon summation band $\nu_n+\nu_k$ is proportional to

$$\alpha_c=1+F_n+F_k, \quad (1)$$

where

$$F_n=[\exp(hc\nu_n/kt)-1]^{-1}, \quad (2)$$

and ν_n = wave number of the nth phonon. Thus the terms f_c and f_0 listed in Table II are

$$f_c=\alpha_c(80°K)/\alpha_c(293°K), \quad (3)$$

and

$$f_0=\alpha_0(80°K)/\alpha_0(293°K), \quad (4)$$

where α_0 is the observed absorption coefficient at the peak absorption after correction for background. The excellent agreement shown in Table II between the calculated and the observed temperature dependencies, although perhaps a bit fortuitous, is a further confirmation of the essential correctness of the assignment of the optical modes.

Having obtained the optical-mode frequencies, the acoustical-mode frequencies at the zone boundary are obtained from the prominent bands in region (1). A perusal of region (1) reveals that one may further subdivide it into two groups: one above and one below 375 cm^{-1}. The three bands at 387, 410, and 442 cm^{-1} (numbers 7, 8, and 9, respectively, in Fig. 1) seem an obvious choice for the bands arising from combinations of the three optical modes with the longitudinal acoustical mode at the zone boundary. Each one of them yields a value close to 149 cm^{-1} for LA. Below 375 cm^{-1} there

555	$LO+TO_1$	0.64	0.598
590	2LO	0.63	0.624

[a] Determined from Balkanski and Besson's data (Ref. 6).

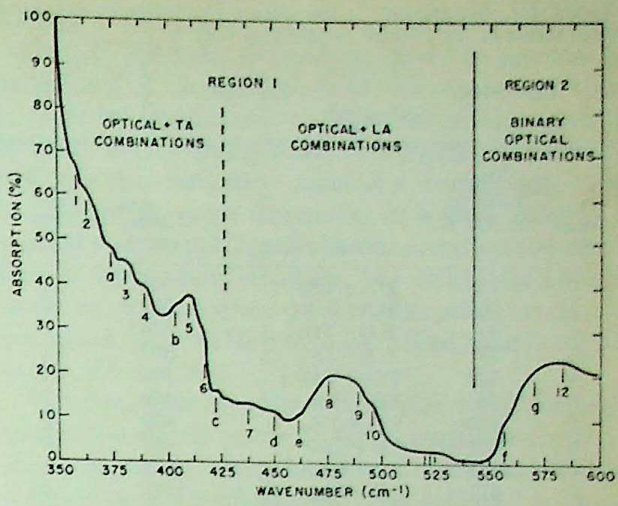

FIG. 3. Infrared absorption in wurtzite ZnS (350 cm^{-1} to 600 cm^{-1}).

are six prominent bands (Nos. 1 to 6 in Fig. 1). They occur as three pairs, each with an average splitting of 9 cm^{-1}. This splitting is attributed to two transverse acoustical phonons, which, like the transverse optical phonons, seem to be in order for the wurtzite structure. The two zone-boundary acoustical phonons assigned in this manner are $TA_1=79$ cm^{-1} and $TA_2=70$ cm^{-1}. The complete assignment for all the observed absorption maxima is presented in Table I.

b. Wurtzite ZnS

The absorption spectrum of wurtzite ZnS is shown in Figs. 3 and 4 and the band positions are listed in Table III. In this case, the absorption regions are not as clearly defined as in CdS, but similar broad classifications can be made: region 1—below 545 cm^{-1}, can further be divided into regions above and below 430 cm^{-1}; region 2—between 545 and 700 cm^{-1}, and region 3—above 700 cm^{-1}.

The absorption in region 2 is again thought to arise primarily from the binary combination of optical phonons with assumed characteristic phonon frequencies, $LO=346$ cm^{-1}, $TO_1=318$ cm^{-1}, and $TO_2=297$ cm^{-1}. In region 1 two areas are distinctive, comprising

[a] Relatively intense bands.

the absorption maxima arising from the combination of the optical phonons with the zone boundary TA (between 370 and 450 cm^{-1}) and with the zone boundary LA (between 435 and 525 cm^{-1}) phonons. Six components are observed in the optical-plus-TA region, and again it has been necessary to assume that the TA modes are nondegenerate. Characteristic phonon frequencies of $TA_1=92$ cm^{-1} and $TA_2=73$ cm^{-1} predict the observed structure in the absorption spectrum with good accuracy. From the optical-plus-LA combination bands (8, 10, 11, Fig. 3), a value of $LA=181$ cm^{-1} has been obtained. This also explains the relatively intense absorption band observed at 362 cm^{-1} as a 2LA combination.

c. Zincblende ZnS

The lattice infrared spectrum of cubic ZnS single crystals was investigated by Deutsch.[13] The reflectivity was measured between 15 and 34 μ. The reststrahlen band with a reflectivity maximum at 30.8 μ was located. A Kramers-Kronig dispersion analysis of the reststrahlen band gave a value of 312 cm^{-1} for the zone-center transverse optical phonon (ν_t). The transmission spectrum of cubic ZnS was measured between 1 and 24 μ by Deutsch. The transmission is essentially constant up to 14 μ. Ten absorption maxima were observed at longer wavelengths between 430 and 820 cm^{-1}. These bands were attributed to optically active two- and three-phonon processes. Using characteristic zone-boundary phonon frequencies of $A=379$ cm^{-1}, $B=297$ cm^{-1}, $C=263$ cm^{-1}, and $D=228$ cm^{-1}, Deutsch could explain seven out of the ten observed bands.

Since a diatomic cubic crystal usually has two optical and two acoustic branches, the higher two phonons must be from optical and lower two from acoustic branches. In a predominantly ionic crystal like ZnS, one would expect that the LO modes should have a higher frequency than the TO modes throughout the Brillouin zone. One may thus identify the four characteristic phonon frequencies, A, B, C, and D assigned by Deutsch as zone boundary LO, TO, LA, and TA, respectively. However, a comparison[3] with the phonon frequencies of the other zincblende-type crystals reveals that the acoustical phonon frequencies as assigned by Deutsch are unusually large. Furthermore, since the zone-center longitudinal optical phonon frequency (ν_l) is 377 cm^{-1} as calculated from the Lyddane-Sachs-Teller formula,[16] a value of 379 cm^{-1} for the zone boundary LO seems improbable. The Brout sum at the zone center amounts to 1.200×10^{28} sec^{-2} as compared with a value of 1.754×10^{28} sec^{-2} near the zone edge. This large difference (45%) is quite unexpected for a predominantly ionic cubic crystal such as ZnS, and may be attributed to high values of LA and TA phonons as assigned by Deutsch. The discrepancy is even larger if one uses the ν_t given by Mitsuishi, Yoshinaga, and Fuyita.[17]

A fresh assignment of the zone-boundary characteristic phonon frequencies of cubic ZnS with lower values of the acoustic modes has therefore been attempted.

TABLE IV. Assignment of the multiphonon absorption bands in cubic ZnS.

	Deutsch			Present study

677	2LO	0.80	1.12	0.671	1.28

[a] Determined from Deutsch's spectra (Ref. 13).
[b] Assignment 1.
[c] Assignment 2.

With assumed values of LO = 339 cm^{-1}, TO = 298 cm^{-1}, LA = 155 cm^{-1}, and TA = 93 cm^{-1}, all the observed absorption maxima could be satisfactorily explained. However, the LA-phonon frequency seems to be a bit low when compared with the corresponding phonon frequency of the hexagonal ZnS. An alternative assignment with the same LO and TO but LA = 190 cm^{-1} and TA = 115 cm^{-1} seems also possible although the numerical agreement with the observed band positions is a trifle worsened in this case. The assignments are shown in Table IV.

Deutsch's data are used for the comparison of observed and calculated temperature dependences. Table V shows the calculated and observed temperature factors for the relatively prominent bands. There are usually two contributions to the background absorption; the first due to free charge carriers and the second to the tail of the resonance absorption at ν_t. The former is expected to decrease with the energy of the absorbed photon. Since the background absorption in the high-frequency side of the lattice bands of ZnS is very low and independent of temperature, the contribution of free carrier absorption to the background may be completely neglected. This is to be expected for a crystal of large band gap. The essentially temperature-independent contribution from ν_t to the background absorption is obtained from the extinction coefficient calculated from the reststrahlen spectrum (the temperature-dependent portion chiefly arises from the multiphonon processes). For the bands where data is available, the absorption coefficient is rather temperature insensitive. Thus the agreement between the observed and the calculated values may be regarded as only fair. The two assignments proposed here only differ in the case of the band at 491 cm^{-1}. Temperature dependence alone can not therefore decide between the two assignments. A fresh high-resolution transmission study of the cubic sample seems desirable.

4. DISCUSSION

As noted earlier, the multiple structure observed in the lattice infrared spectra of the zincblende-type crystals can usually be accounted for in terms of four characteristic phonon energies belonging to the four branches: TA. LA, TO, and LO at the Brillouin zone boundary. In certain cases, notably diamond[2] and GaAs,[15] it has been deemed necessary to assume the breakdown of the degeneracy of the transverse modes in order to satisfactorily account for all the observed optically active multiphonon combinations. Since the Brillouin zone-boundary value of a branch may differ in different $\mathbf{k}$ space directions, it is only natural to assume such a splitting of the transverse modes in the case of the wurtzite structure. For satisfactory assignments of the numerous lattice absorption maxima in hexagonal CdS and ZnS we have indeed taken recourse to two TA and two TO phonons.

The transverse frequency is smaller than the longitudinal one for all values of the propagation vector for the acoustical branches, except at the zone center where both are zero. Therefore there is no difficulty in identifying the lowest characteristic phonon frequencies with definite TA and LA modes. However, the identification of the optical-branch phonons to definite transverse and longitudinal modes is not so clear cut, and some confusion has resulted in the past.

Keyes[19] has noted some correlation between the zone-boundary optical-phonon energies of the zincblende-type crystals and the effective ionic charge q^*, derived from the Szigeti relation.[18] For a purely covalent crystal ($q^*=0$) such as diamond or Ge, the transverse and longitudinal optical branches are degenerate at the zone center whereas TO > LO at the zone boundary. Although $\nu_1 > \nu_t$ at $\mathbf{k}=0$ (Lyddane-Sachs-Teller formula[16]) for weakly ionic crystals like InSb ($q^*=0.42$), TO is still greater than LO at the zone boundary. In the case of a crystal of intermediate ionicity ($q^* \simeq 0.7$), Keyes predicted that LO = TO at $\mathbf{k}_{max}$, which indeed is the case with ZnSe as shown by Mitra.[3] However, strongly ionic crystals ($q^* > 0.7$) such as the alkali halides[19] are expected to have LO greater than TO for all values of $\mathbf{k}$.

The effective ionic charge on CdS and ZnS is 1.00 and 0.854, respectively. The highest characteristic phonon frequency for these materials may therefore be termed the zone boundary LO. The next two characteristic frequencies of the hexagonal CdS and ZnS, and the next single characteristic frequency of the cubic ZnS may now be identified with the TO modes. For predominantly ionic crystals, the transverse optical branches as a rule undergo only limited dispersion. The zone boundary values of $TO_1 = 261$ cm^{-1} and $TO_2 = 238$ cm^{-1} for CdS, $TO_1 = 318$ cm^{-1} and $TO_2 = 297$ cm^{-1} for the wurtzite ZnS and TO = 298 cm^{-1} for the zincblende ZnS are not too different from their zone-center values, 241 cm^{-1} and 312 cm^{-1}, respectively, for CdS and ZnS. The zone boundary LO, TO, LA, and TA phonon fre-

quencies for a number of IV-IV, III-V and II-VI compounds along with their effective ionic charge are listed in Table VI. Keyes noted that $(LO/TO)^2$ is a linear function of q^{*2} for crystals of diamond and zincblende-type structures. Such a plot is shown in Fig. 5. The crystals of wurtzite structure also seem to follow the general pattern if one uses the mean of the two TO values.

The Brout sum rule[20] for lattice vibrations,

$$\sum_i \omega_i^2(\mathbf{k}) = \text{constant}, \qquad (5)$$

where $\omega_i(\mathbf{k})$ is the circular frequency in the ith branch when the wave vector is $\mathbf{k}$, was believed to be strictly valid for diatomic ionic crystals of cubic symmetry,

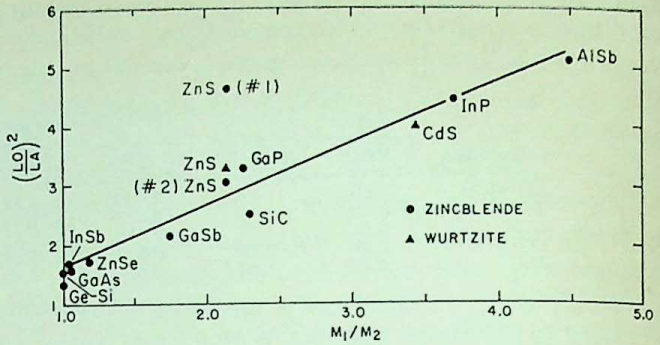

FIG. 6. The effect of mass difference on the separation between the optical and the acoustical branches.

whose constituent atoms interact only by Coulomb forces between all ions and the repulsive interaction is between nearest neighbors alone. However, relation (5) seems to hold reasonably well for a number of zincblende[1,3]-type crystals. Rosenstock[21] has recently demonstrated that Eq. (5) with little or no modification can also be applied to more general force models and to nonionic crystals.

In Table VII the zone-edge Brout sums $(\nu_1^2+2\nu_t^2)$ for CdS and ZnS are compared with their zone-boundary values $(LO^2+2TO^2+LA^2+2TA^2)$. The agreement is fair. Such a comparison may therefore be regarded as a check on the upper bounds of the zone-boundary phonon frequencies of diatomic crystals.

Other than the numerical agreement between the observed and calculated positions of infrared absorption peaks involving the acoustical modes, there are but few checks on the soundness of the LA and TA assignments. In analogy with the diatomic linear chain, Keyes has shown that one may expect a linear relationship between $(LO/LA)^2$ and σ, the ratio of the larger to the smaller ionic masses for the zincblende-type crystals. Such a plot is shown in Fig. 6, in which the wurtzite crystals are included as well. The LA assignment of hexagonal CdS and ZnS seems reasonable. For the cubic ZnS assignment, No. 2 seems to be more probable. If such is the case, the difference between the hexagonal and cubic ZnS characteristic phonon frequencies is not very

Theory of Electron Backscattering*

ROGER F. DASHEN†
Sandia Laboratory, Albuquerque, New Mexico
(Received 23 December 1963)

An exact integral equation is derived for the backscattering coefficient as a function of energy and angle. The equation has an approximate symmetry which allows one to determine the conditions under which backscattering will be independent of the energy of the incident electrons. The validity of some approximations is discussed, and a possible method for obtaining numerical solutions is proposed. It is found that small and large-angle individual scatterings are of about equal importance. For those electrons that have lost very little energy, the equation can be solved exactly, and some interesting results are obtained.

1. INTRODUCTION

WHEN a beam of electrons is directed against a thick solid target, many of the electrons stop in the target but some are scattered back out. These are the backscattered electrons.[1] Over the past few years a considerable amount of experimental information has been collected [2–6] and from an empirical point of view there now exists a fairly complete picture of the phenomenon. On the other hand, attempts at a theoretical interpretation of the data[7–10] have been based on rather severe approximations and have met with only limited success. The purpose of this paper is to present a reformulation of the problem which circumvents many, but by no means all of the difficulties which one encounters in trying to treat backscattering through the usual methods of multiple-scattering theory.

Mathematically, the problem can be formulated as follows. Given a uniform, monoenergetic flux of electrons incident on a semi-infinite block of scattering material, what is the energy and angular distribution of electrons that are scattered back out? In order to solve this problem using standard multiple-scattering theory, one must find the distribution function for the electrons at each point within the block. A more economical method would be to obtain an equation for the distribution of backscattered electrons alone, thereby freeing ourselves from the unnecessary task of finding the distribution within the block. In the following section we will derive an integral equation for the backscattering coefficient as a function of energy and angle. An application of this equation to the energy dependence of the backscattering coefficient is given in Sec. 3. Section 4 contains a critical analysis of some

approximate methods along with some interesting numerical results based on the assumption that small-angle scattering is unimportant. Finally, in Sec. 5 we discuss the possibility of more extensive calculations.

2. THE BASIC EQUATION

Given a uniform flux of electrons incident on a plane surface (Fig. 1), we define the backscattering coefficient R to be

$$R(\mathbf{n},E;\mathbf{n}',E')=\frac{\text{outgoing flux per unit solid angle per unit energy interval}}{\text{incident flux}}, \tag{1}$$

where E=incident energy, E'=outgoing energy, $\mathbf{n}$=unit vector *antiparallel* to the incoming direction, $\mathbf{n}'$=unit vector *parallel* to the outgoing direction. One will note that the quantity measured in the laboratory is not R, but $R(\mathbf{n},E,\mathbf{n}'E')\sec\theta\cos\theta'$, where θ is the angle between the $\mathbf{n}$ and the normal to the surface. This is due to the fact that we have assumed a uniform, infinitely broad, incoming beam whereas in the laboratory the incoming beam is confined to a thin pencil.

To derive an integral equation for R, we will follow a chain of thought that has proven to be very fruitful in similar contexts and generally goes under the title of "invariant imbedding." Our application of these ideas will be of the most rudimentary nature. For a thorough exposition of this manner of thinking and its many applications, the interested reader is referred to the review article of Bellman, Kalaba, and Wing.[11] The basic idea is very simple. Suppose we add a thin layer of the same material to the surface of our target thereby increasing its thickness by an amount Δt. Since we have assumed that our target was already infinitely thick, the backscattering coefficient must remain unchanged. If we take the new layer to be differentially thin, this simple device will lead to an integral equation for R.

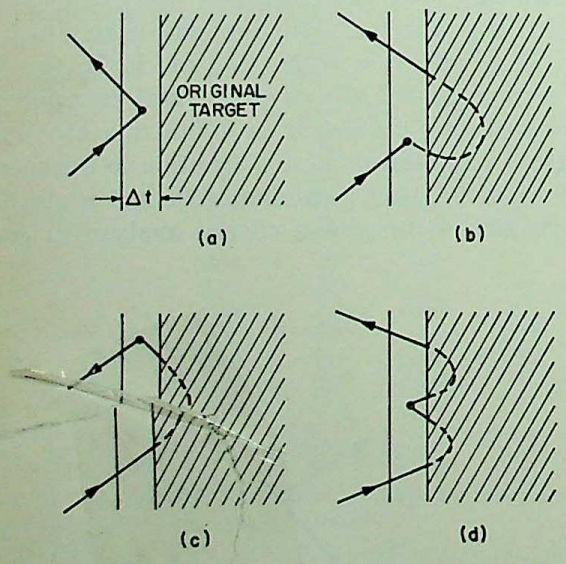

FIG. 2. New paths created by increasing the thickness of the target. The dots represent a single elastic or inelastic collision in the new layer, and the broken lines indicate backscattering in the original target.

[11] R. Bellman, R. Kalaba, and G. Wing, J. Math. Phys. 1, 280 (1960).

As notational difficulties would tend to obscure the basic simplicity of the argument, we will not follow the derivation in mathematical detail. The reader, if so inclined, can easily fill in the gaps.

Apart from normalization factors, the backscattering coefficient $R(\mathbf{n},E;\mathbf{n}',E')$ is imply the probability that an electron will follow any path which can lead to backscattering from the state $(\mathbf{n},E)$ to the state $(\mathbf{n}',E')$. By adding a layer of scattering material we have created some new paths. These are the paths where the electron makes a collision, either elastic or inelastic, somewhere in the new layer. They are illustrated schematically in Fig. 2. Note that we need not consider paths where the electron makes two or more collisions in the added layer since the probability that an electron will follow one of these paths is of order $(\Delta t)^2$. To calculate the *increase* in R due to fact that we have added some extra paths, we must add up the probabilities that an electron will follow each of the new paths. Referring to Fig. 2 we see that the sum over paths of type (a) is simply a normalization factor times the atomic cross section. Again, apart from normalization factors, the paths of type (b) can be summed by multiplying the atomic cross section for scattering from the state $(E,\mathbf{n})$ to a state $(E'',\mathbf{n}'')$ times the "original" backscattering coefficient $R(\mathbf{n}'',E'';\mathbf{n}',E')$ and summing over all intermediate states $(\mathbf{n}'',E'')$. Paths of type (c) are treated similarly. The sum over paths of type (d) contains the atomic cross section times the square of the "original" backscattering coefficient and a double summation over intermediate states.

Since the total variation in R must be zero, the increase in probability of backscattering due to the increased number of available paths must be exactly cancelled by a decrease in the probability that an electron will follow one of the old paths; i.e., a path along which it makes no collisions in the added layer. It is immediately obvious that the net probability that an electron will follow one of the original paths is decreased since the probability that an electron will pass twice through the new layer without making a collision is less than one. More specifically, the *reduction* in the probability that an electron will follow one of the old paths is simply the "original" backscattering coefficient times the total probability that the electron will make a collision as it passes twice through the new layer.

Digitized by Arya Samaj Foundation Chennai and eGangotri

At this point we make the usual assumption that inelastic collisions with the atomic electrons contribute only to energy loss and do not change the incident electrons' direction of motion. This simplification is not in principle necessary, but it is a very good approximation and has the pleasant feature that the cross sections for angular deflection and energy loss become independent. Combining this assumption with the analysis of the preceding paragraphs, one finds that R satisfies the integral equation

$$\begin{aligned}&[(\sigma_T(E)+\omega_T(E))\sec\theta+(\sigma_T(E')+\omega_T(E'))\sec\theta']\\&\qquad\times R(\mathbf{n},E;\mathbf{n}',E')\\&=\sigma(E,-\mathbf{n}\cdot\mathbf{n}')\sec\theta'\delta(E-E')\\&\quad+\int_{E'}^{E}[\omega(E,E'')\sec\theta R(\mathbf{n},E'';\mathbf{n}',E')\\&\quad+\omega(E'',E')\sec\theta' R(\mathbf{n},E;\mathbf{n}',E'')]dE''\\&\quad+\int[\sigma(E,\mathbf{n}\cdot\mathbf{n}'')\sec\theta'' R(\mathbf{n}'',E;\mathbf{n}',E')\\&\quad+\sigma(E',\mathbf{n}''\cdot\mathbf{n}')\sec\theta' R(\mathbf{n},E;\mathbf{n}'',E')]d\mathbf{n}''\\&\quad+\int_{E'}^{E}\int\int R(\mathbf{n},E;\mathbf{n}'',E'')\sigma(E'',-\mathbf{n}''\cdot\mathbf{n}''')\\&\qquad\times\sec\theta''' R(\mathbf{n}''',E'';\mathbf{n}',E')dE''d\mathbf{n}''d\mathbf{n}''',\end{aligned}\tag{2}$$

where $\sigma(E,\cos\Theta)$ is the atomic cross section for elastic scattering through an angle Θ, $\omega(E,E')$ is the atomic cross section for an inelastic collision leading to an energy loss $E-E'$, $\sigma_T(E)$ and $\omega_T(E)$ are the total elastic and inelastic cross sections, $\sec\theta$ is the secant of the angle between $\mathbf{n}$ and the normal, and the angular integrations run over the hemisphere of unit vectors pointing out of the target. The first term on the right of Eq. (2) is the probability that an electron will follow one of the new paths of type (a). In accord with our assumption that inelastic collisions do not cause angular deflection, we have included only the elastic cross section in this term. The two single integrals are the sum over paths of types (b) and (c) and the triple integral is the sum over paths of type (d). Finally, the left-hand side is the net reduction in the probability that an electron will follow one of the old paths. The geometrical factors $\sec\theta$ are the usual ones which arise because the effective volume of the layer available for scattering into a direction $\mathbf{n}$ is proportional to $\Delta t\sec\theta$. In writing down Eq. (2) we have omitted a factor $\Delta t\times$(number of atoms per unit volume) which multiplies each term as it is of no consequence. Physically, this means that backscattering is independent of the density of the scattering material.

For future purposes it is convenient to write Eq. (2) in the form

$$\begin{aligned}&\int_{E'}^{E}\int[\delta(E-E'')\omega_T(E)-\omega(E,E'')]\\&\qquad\times\sec\theta''\delta(\mathbf{n}-\mathbf{n}'')R(\mathbf{n}'',E'';\mathbf{n}',E')dE''d\mathbf{n}''\\&\quad+\int_{E'}^{E}\int R(\mathbf{n},E;\mathbf{n}'',E'')[\delta(E''-E')\omega_T(E')\\&\qquad-\omega(E'',E')]\sec\theta'\delta(\mathbf{n}'-\mathbf{n}'')dE''d\mathbf{n}''\\&=\sigma(E,-\mathbf{n}\cdot\mathbf{n}')\sec\theta'\delta(E-E')\\&\quad+\int_{E'}^{E}\int[[\sigma(E,\mathbf{n}\cdot\mathbf{n}'')-\delta(\mathbf{n}-\mathbf{n}')\sigma_T(E)]\\&\qquad\times\sec\theta''\delta(E-E'')R(\mathbf{n}'',E'';\mathbf{n}',E')]dE''d\mathbf{n}''\\&\quad+\int_{E'}^{E}\int[R(\mathbf{n},E;\mathbf{n}'',E'')[\sigma(E'',\mathbf{n}'\cdot\mathbf{n}'')\\&\qquad-\delta(\mathbf{n}'-\mathbf{n}'')\sigma_T(E'')]\sec\theta'\delta(E''-E')]dE''d\mathbf{n}''\\&\quad+\int_{E'}^{E}\int_{E'}^{E''}\int\int R(\mathbf{n},E;\mathbf{n}'',E'')\\&\qquad\times\sigma(E'',-\mathbf{n}''\cdot\mathbf{n}''')\sec\theta'''\delta(E''-E''')\\&\qquad\times R(\mathbf{n}''',E''';\mathbf{n}',E')dE''dE'''d\mathbf{n}''d\mathbf{n}''',\end{aligned}\tag{3}$$

where $\delta(\mathbf{n}-\mathbf{n}')$ is the delta function on the unit sphere.

In the remaining sections of this paper we will restrict ourselves to electron energies that are nonrelativistic but large compared to the binding energy of the atomic electrons. This is a permissible limitation since from the form of Eq. (2) it is apparent that for a given maximum value of E and minimum value of E', R does not depend on reflection coefficients whose energy indices lie outside this range. Under these conditions the elastic cross section is simply the Rutherford cross section[12]

$$\sigma(E,\cos\Theta)=\frac{Z^2e^4}{4E^2}\frac{1}{(1-\cos\Theta+\gamma)^2},\tag{4}$$

where γ is the screening parameter. The inelastic cross section can be sufficiently well approximated by[13]

$$\omega(E,E')=\frac{\pi e^4 Z}{E}\frac{1}{(E-E')^2},\quad \epsilon_{\max}>E-E'>\epsilon_{\min}\tag{5}$$

where $\epsilon_{\min}$ and $\epsilon_{\max}$ are the minimum and maximum energy losses.[13] For our purposes it is sufficient to know that $\epsilon_{\max}$ is proportional to E and that the usual range-

energy relation is given by[12]

$$\int_0^E \omega(E,E')(E-E')dE' = -\frac{dE}{dx} = \frac{2\pi Ze^4}{E}\ln\left(\frac{2E}{I}\right), \quad (6)$$

where the unit of length has been chosen so that there is one atom per unit volume and I is a mean ionization potential.

In writing down Eq. (3) we have placed the factors in a particular order to bring out the fact that the integrations over energy and angle can be considered as matrix multiplications. This observation leads to a more economical notation and allows us to use the methods of matrix analysis to manipulate the equation. We consider $R(\mathbf{n},E;\mathbf{n}',E')$ as a matrix with two sets of indices, $\mathbf{n}$ and E, and define the following matrices

$$S_B = 4(e^4Z^2)^{-1}\sigma(E, -\mathbf{n}\cdot\mathbf{n}')\sec\theta'\delta(E-E'), \quad (7a)$$

$$S_F = 4(e^4Z^2)^{-1}[\sigma(E,\mathbf{n}\cdot\mathbf{n}')-\delta(\mathbf{n}-\mathbf{n}')\sigma_T(E)] \times\sec\theta'\delta(E-E'), \quad (7b)$$

$$W = (2\pi e^4Z)^{-1}[\delta(E-E')\omega_T(E)-\omega(E,E')] \times\sec\theta'\delta(\mathbf{n}-\mathbf{n}'). \quad (7c)$$

Equation (2) can now be written as

$$WR+RW = (Z/8\pi)(S_B+S_FR+RS_F+RS_BR). \quad (8)$$

Owing to the fact that none of the matrices S_B, S_F, and W commute, Eq. (8) cannot be solved explicitly. We can, however, put it in a more advantageous form. It is a standard theorem of matrix calculus[14] that a formal solution to (8) is given by

$$R = \frac{Z}{8\pi}\int_0^\infty \exp(-Wt)(S_B+S_FR+RS_F+RS_BR) \times\exp(-Wt)dt, \quad (9)$$

which holds provided that the integral converges. To see that the integral does converge one need only consider the physical meaning of the exponentials. Writing the matrix $\exp(-tW)$ in the form

$$\exp(-tW) = P(E,E';t\sec\theta)\delta(\mathbf{n}-\mathbf{n}'), \quad (10)$$

we find that P satisfies the differential equation and boundary condition

$$\frac{d}{d(t\sec\theta)}P(E,E';t\sec\theta) = (2\pi e^4Z)^{-1}\int_{E'}^{E}[\omega(E,E'')-\delta(E-E'')\omega_T(E)] \times P(E'',E',t\sec\theta)dE'', \quad (11)$$

$$P(E,E';0) = \delta(E-E'),$$

from which one easily sees that $P(E,E';t\sec\theta)$ is simply the probability that an electron will suffer an energy loss $E-E'$ while traversing a path of length $t\sec\theta$ where the unit of distance is chosen such that $2\pi e^4Z \times$(number of atoms per unit volume)$=1$. Now for fixed E and E', P tends rapidly to zero for large t and the integral converges. Landau[15] has given explicit expressions for the function P so we now have an equation that can, at least in principle, be solved by successive approximations.

Equations (8) and (9), being quadratic in R, most likely have more than one solution. Obviously the physically interesting solution has the property that, considered as a function of Z, it tends smoothly to zero for small Z. We will now give a heuristic proof that Eq. (9) has a unique solution with this property. Strictly speaking, the atomic screening radius γ and the minimum energy loss $\epsilon_{\min}$ are functions of Z. In the next section, however, we will see that the dependence of R on these quantities is rather unimportant and to a good approximation we can take the matrices S_F, S_B, and W to be independent of Z. With this assumption one can easily see that Eq. (9) has a unique formal solution as a power series in Z. To see that this series is, in fact, convergent we need only observe that an expansion of R in powers of Z corresponds exactly to an expansion in the number of times an individual electron is elastically scattered before leaving the target. Now a large number of scatterings requires a long time spent in the target, but for a given energy loss very long paths are highly improbable. Therefore, for fixed $E-E'$, the coefficient of Z^N must tend to zero for large N and the series converges. Since we have found that (8) has a unique solution which is analytic around $Z=0$, any extraneous solutions must have some singular behavior for small Z.

3. DEPENDENCE ON THE INCIDENT ENERGY

Perhaps the most striking experimental observation is that the number of backscattered electrons and their distribution in energy and angle are, over a broad range of energies, very nearly independent of the incident energy. The first application of our formalism will therefore be to investigate the energy dependence of R. Since the parameters γ and $\epsilon_{\min}$ appearing in (5) are rather poorly known functions of E and Z, our first task must be to see if R is sensitive to moderate variations of these parameters. For fast incident electrons both γ and $\epsilon_{\min}/E$ are very small numbers, generally being on the order of 10^{-3}. In the limit as γ and $\epsilon_{\min}$ tend to zero both the elastic and inelastic cross sections diverge, but one can easily verify that they have the symbolic expansions

$$\sigma(E,\mathbf{n}\cdot\mathbf{n}') = \sigma_T(E)\delta(\mathbf{n}-\mathbf{n}') - e^4Z^2(2E)^{-2} \times\ln(1/\gamma)\delta'(1-\mathbf{n}\cdot\mathbf{n}')+O(1), \quad (12)$$

$$\omega(E,E') = \omega_T(E)\delta(E-E') - 2\pi Ze^4E^{-1} \times\ln(2E/I)\delta'(E-E')+O(1), \quad (13)$$

where the symbol $O(1)$ has been used to denote finite terms independent of γ or ϵ_{min} plus terms which vanish as γ or ϵ_{min} tends to zero and we have used Eq. (6) to simplify (13). Referring to Eq. (3) we see that the terms proportional to σ_T and ω_T drop out so the dependence of R on ϵ_{min} and γ is only logarithmic.

Upon inserting the cross sections (4) and (5) into Eq. (2), one can verify by a simple change of variables that if $R(\mathbf{n},E;\mathbf{n}',E')$ is a solution so is $\lambda R(\mathbf{n},\lambda E;\mathbf{n}',\lambda E')$ where λ is any positive number, *provided* that one neglects the energy dependence of the logarithms $\ln(1/\gamma)$ and $\ln(2E/I)$ appearing in (12) and (13). When the latter is a good approximation we can apply our uniqueness "theorem" which then yields

$$R(\mathbf{n},E;\mathbf{n}'E')\approx\lambda R(\mathbf{n},\lambda E;\mathbf{n}',\lambda E'). \quad (14)$$

Physically this means that increasing the incoming and outgoing energies in the same proportion will leave the whole backscattering process unchanged, except for a scaling factor which is precisely that needed to keep the integrated coefficient at a constant value.

While it is reassuring to derive this well verified symmetry from theory, it is perhaps more important to investigate the conditions under which it is valid. To begin with, Eq. (14) does not hold unless we can neglect the energy dependence of the logarithms in (12) and (13). Roughly speaking, this requires that the incident energy be greater than the K-shell binding energy of the scatterer. For carbon the K-shell energy is roughly 300 eV and one finds experimentally that the total backscattering coefficient is very nearly constant for $E\gtrsim 500$ eV.[2,3] On the other hand, the K-shell energy of silver is about 25 keV and one indeed finds that the number of backscattered electrons does not become constant until E is on the order of 15 keV.[2,3] A second breakdown of (14) occurs when the angle of incidence is near 90° (Fig. 1). In this case the incoming electrons can take full advantage of the forward peak in the Rutherford cross section which is extremely sensitive to γ. With an incident angle of 80°, Kanter[4] has found that the energy distribution of electrons backscattered from aluminum varies considerably for incident energies between 10 and 70 keV even though the K-shell energy of aluminum is on the order of 1.5 keV. Since backscattering is largest at grazing incidence, this breakdown of (14) for $\theta\approx 90°$ will have a disproportionate effect when the incident flux is isotropic. Formally, Eq. (14) breaks down near $\theta=90°$ because $\ln\gamma$ multiplies an angular derivative which becomes very large when the initial direction is parallel to the surface of the target. Finally, if the relativistic cross sections, rather than those given by (4) and (5) are used in Eq. (2), one finds that the resulting equation has a different dependence on the energy variables and (14) no longer holds. Experimentally[5] one finds that in the relativistic region the backscattering coefficient is not independent of the incident energy, but shows a marked decrease from the nearly constant nonrelativistic value.

4. APPROXIMATIONS

Most theories of electron transport are based on the assumption that electrons lose energy continuously according to the usual range-energy relationship. This is definitely an approximation since energy loss, like angular deflection, is a stochastic process. To determine the accuracy of this approximation when applied to backscattering, we must examine the integrals on the left-hand side of Eq. (3). For simplicity, we will consider only the first integral and assume that the integration over the angular delta function has already been carried out. The inelastic cross section $\omega(E,E'')$ is very strongly peaked near $E=E''$, which suggests that we change the lower limit of integration from E' to zero and, keeping E' fixed, expand $R(\mathbf{n},E'';\mathbf{n}',E')$ in a Taylor series around $E''=E$. The zeroth-order term in the expansion is exactly cancelled by the $\delta(E-E'')\omega_T(E)$ term and the first integral becomes

$$\sec\theta\left[\int_0^E \omega(E,E'')(E-E'')dE''\right]\frac{\partial}{\partial E}R(\mathbf{n},E;n',E')$$

$$-\tfrac{1}{2}\sec\theta\left[\int_0^E \omega(E,E'')(E-E'')^2dE''\right]\frac{\partial^2}{\partial^2 E}$$

$$\times R(\mathbf{n},E;\mathbf{n}',E')+\cdots. \quad (15)$$

According to (6) the first term in (15) can be written as

$$-\sec\theta\frac{dE}{dx}\frac{\partial}{\partial E}R(\mathbf{n},E;\mathbf{n}',E').$$

On the other hand, in the continuous approximation the probability of energy loss per unit path length $\omega(E;E')$ would be

$$(dx)^{-1}\delta[E-E'-(dE/dx)dx].$$

In this case ω_T is simply $(dx)^{-1}$, and upon inserting these expressions into the first term on the left-hand side of (3) and taking the limit $dx\rightarrow 0$, one finds that the continuous energy loss approximation is exactly equivalent to keeping only the first term in (15). Since $\omega(E,E'')$ is peaked near $E=E''$, the coefficient of the first term in (15) will be considerably larger than the coefficients of the higher order terms so that dropping these terms will be a good approximation unless R is so rapidly varying that the higher derivatives are large. To estimate these derivatives one must remember that we are considering R as a function of E for fixed E'. Experimentally one finds that for low-Z targets, R is a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

slowly varying function and the approximation should be very good but for high-Z targets R changes by an order of magnitude between $E/E'=1$ and $E/E'=2$. A rough calculation indicates that for Z greater than about 40, the second term in (15) can be nearly as large as the first. One cannot, therefore, expect a theory based on a continuous energy loss to give detailed, quantitative results for high-Z materials. This conclusion is in agreement with Monte Carlo calculations carried out by MacCallum,[16] who found that calculations based on the usual range-energy relationship gave the details of the energy distribution of backscattered electrons correctly only for low-Z scatterers.

The easiest way to incorporate this approximation into the present formalism is through Eq. (9). If the energy loss is assumed to take place continuously, the function $P(E,E';t\sec\theta)$ defined in (10) is obviously just a delta function whose argument is determined by the range-energy relation which in terms of t is given by $dE/dt=-E^{-1}\ln(2E/I)$. If we want our solution to obey Eq. (14) we must neglect the energy variation of the logarithm in which case the range-energy relation can be integrated analytically and we find

$$P(E,E';t\sec\theta)=2E'\delta(E^2-E'^2-Ct\sec\theta), \quad (16)$$

where $C=2\ln(2E/I)$. There is, of course, some ambiguity in assigning a numerical value to the "constant" $\ln(2E/I)$. However, one will note that (16) is simply a restatement of the Thompson-Whiddington law[9] and Terrill[17] has found that this simplification of the range-energy relationship is fairly accurate provided that one takes $C\approx 10$. Since one might argue that this value of C is not the proper one to use in backscattering problems, it is interesting to observe that C can be determined directly by studying the behavior of R in the limit $E'\to E$. Clearly an electron which has lost very little energy cannot have spent enough time in the target to have been scattered more than once, which means that in the limit $E'\to E$ the first-order term in an expansion of R in powers of Z is exact. This term can be obtained simply by setting $R=0$ on the right hand side of Eq. (9).

At this point it is convenient to introduce some notation which will be used throughout the rest of this section. Since we will be interested only in solutions which satisfy Eq. (14), it is advantageous to work with the dimensionless function

$$r(\mathbf{n},\mathbf{n}';\xi)=E\cos\theta' R(\mathbf{n},E;\mathbf{n}',E'), \quad (17)$$

where $\xi=E'/E$ and the factor $\cos\theta'$ has been added to facilitate comparison with experimental data. That r is a function only of E'/E follows directly from (14).

Substituting (16) into Eq. (9) and integrating over the delta functions, one easily verifies that to order Z

$$r(\mathbf{n},\mathbf{n}';\xi)=\frac{Z}{4\pi C}\frac{\xi\cos\theta\cos\theta'}{\cos\theta+\xi^2\cos\theta'}\frac{1}{(1+\mathbf{n}\cdot\mathbf{n}'+\gamma)^2}. \quad (18)$$

Taking $C=10$, we find that for $\xi=1$ and $\theta=0$ (normal incidence) r should behave as shown in Fig. 3. The curves are in excellent agreement with the experimental points of Kulenkampff and Rüttiger.[6] One will note that in the limit $\xi\to 1$ it is not an approximation to neglect the energy dependence of the $\ln(2E/I)$ term in the range-energy relation which means that for $\xi=1$ Eq. (18) is, within the approximation of continuous energy loss, exact and C has the unambiguous value of $2\ln(2E/I)$ where E is the incident energy. Since the experimental points were taken at 30 keV, this would yield an ionization potential $I\approx 400$ eV independent of Z whereas one usually takes $I\approx(13.4\text{ eV})Z$. This is indeed a remarkable occurrence for which there appears to be no immediate explanation.

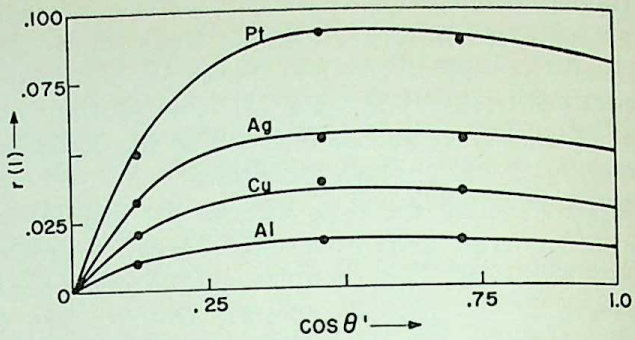

FIG. 3. Behavior of r for $\xi=1$ and normal incidence. The dots are the experimental points of Kulenkampff and Rüttiger (Ref. 6).

Recently there have been attempts to explain backscattering in terms of a single large-angle scattering.[9,10] Since a theory that includes only a single scattering necessarily corresponds to the first term in an expansion of R in powers of Z, it must be exact in the limit $Z\to 0$, and one might hope that it would be valid for low-Z materials of experimental interest. Further motivation for this approach can be found in the fact that for Z between 6 and 40 the total backscattering coefficient for normal incidence is about $0.013Z$ which is suggestive of a first-order term in Z. However, for $\theta=0$, Eq. (18) yields a total coefficient of $[8C]^{-1}[1-\ln 2]Z+0(Z^2)$ which for $C=10$ is about $0.004Z$. Everhart[9] has suggested treating C as a phenomenological parameter which should be adjusted to give the observed backscattering. In view of the accuracy with which Terrill's value reproduces the experimental points at $\xi=1$ this is hardly a permissible procedure. Moreover, the energy distribution of backscattered electrons predicted by (17) is in violent disagreement with experiment so we are forced to the conclusion that a single-scattering theory is not valid for realistic values of Z. Apparently the linear behavior of the total coefficient for low-Z materials is accidental.

Having found that a theory based on a single large-angle scattering is not realistic, one might be tempted to go to the opposite extreme and use a small-angle approximation in which one keeps only the forward peak of the cross section. The possibility of constricting a quantative theory of this sort is imbedded in what is perhaps the most interesting question in backscattering theory: Which is the more important, small- or large-angle scattering? One way to answer this question is simply to chop off the small-angle part of the Rutherford cross section, calculate the resulting backscattering coefficient, and compare the results with experiment. We have made a number of such calculations by iterating Eq. (9) in the continuous energy-loss approximation (16). Other motivations for the calculations were the hope that we might obtain quantitative results for low-Z targets and to find out if matrix equations like (9) are suitable for machine calculations. More specifically, we replaced the Rutherford cross section $[1-\cos\Theta+\gamma]^{-2}$ with $[1-\cos\Theta]^{-2}\exp[-b^2/(1-\cos\Theta)^2]$ and iterated (9) starting with $R=0$. As long as Z was not large or b too small, the iterates converged satisfactorily becoming almost constant after about six iterations. However, for large Z or very small b satisfactory convergence could be obtained only for values of ξ close to one. This was due to the fact that the matrix S_F is the difference between two terms which partially cancel each other, and if either S_F or R becomes too large or rapidly varying, the equation becomes numerically unstable. For this reason, the method is not practical for applications of the theory and it would not be worth while to go into the details.

Some typical results obtained for $b=0.1$ are shown in Figs. 4 and 5. While the calculated curves lie considerably lower than the experimental ones, the results are remarkable considering that we have in effect said that if an electron is not scattered through an angle greater than about 25°, it is not scattered at all. Particularly surprising is the fact that the calculated curve for copper is about as close to the experimental one as it is for aluminum, even though the atomic number of copper is over twice that of aluminum. This appeared to be a general trend. Our results for carbon and silver were percentage wise, in about the same agreement as those for copper and aluminum. Apparently the physical reason for this is that the increased probability of small angle scattering in the higher Z materials is being compensated for by the shorter time which a typical backscattered electron spends in the target. One will also note that the relative discrepancy between the calculated and observed curves is larger for $\theta'=83°$ than for $\theta'=43°$. This is to be expected since the points at $\theta'=83°$ corresponds to deflection through a smaller angle, which is more likely to be effected by small-angle scattering. As the cutoff angle was decreased, the calculated points rose towards the experimental values. However, the difference between the curves computed with cutoffs of 25° and 12° was only about 15% which indicates that the bulk of the discrepancy is due to scattering at angles well inside the forward peak of the Rutherford cross section. The conclusion is that quite independently of Z, about half the backscattering arises from a relatively small number of large-angle scatterings, with the remainder being due to the diffusive effects of small-angle scattering. In retrospect, this is not a surprising result since the mean-square scattering angle is on the order of γ so one needs roughly γ small-angle scatterings to deflect an electron through 90°, but about one out of every γ collisions will give rise to a single scattering through an angle greater than 90°.

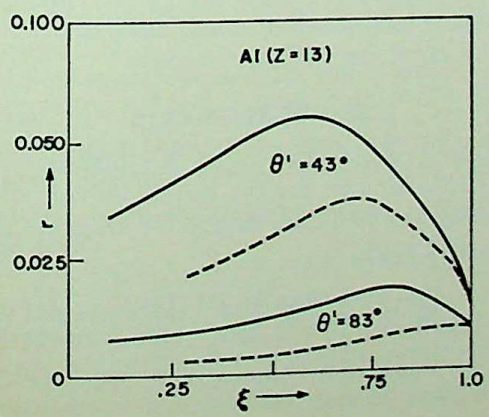

FIG. 4. Results of the cutoff calculations (dashed line) for normal incidence compared with the experimental data (Ref. 6) of Kulenkampff and Rüttiger (solid line).

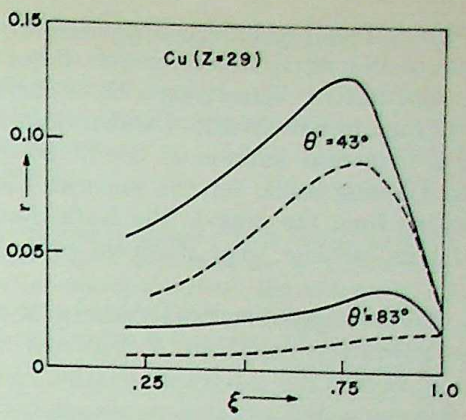

FIG. 5. Results of the cutoff calculations (dashed line) for normal incidence compared with the experimental data (Ref. 6) of Kulenkampff and Rüttiger (solid line).

5. A POSSIBLE METHOD FOR NUMERICAL SOLUTION

The main result of the previous section was that backscattering is a very complicated problem. For one thing, we found that both the forward peak of the scattering cross section and the details of its large-angle tail are important. Also, it appears that for high-Z materials one must include the stochastic nature of energy loss. For these reasons it seems very doubtful that a simplified treatment will ever lead to more than

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

a crude estimate of the total coefficient. Barring the appearance of an entirely new formalism, if one wishes to make quantitative calculations, he is faced with either resorting to the Monte Carlo method or attempting a numerical solution of one of the present equations. Leaving aside, for the moment, the difficulties arising from the peak in the Rutherford cross section, let us consider some pertinent properties of Eq. (2).

The factors $\sec\theta$ appearing in (2) blow up at $\theta=90°$. Since the laboratory coefficient $R\sec\theta\cos\theta'$ is well behaved at $\theta=90°$ the integrand remains finite. In carrying out our cutoff calculations we approximated the angular integrals with a Gaussian quadrature scheme which avoids the ambiguous points at $\theta=90°$ and found that these apparent divergences caused no difficulty.

Since the problem has rotational symmetry around an axis perpendicular to the target, $R(\mathbf{n},E;\mathbf{n}',E')$ has the property that its average over the azimuthal angle of either $\mathbf{n}$ or $\mathbf{n}'$ is equal to its average over the azimuthal angle of both $\mathbf{n}$ and $\mathbf{n}'$. Using this property, one readily verifies that averaging (2) over the azimuthal angles of $\mathbf{n}$ and $\mathbf{n}'$ yields an equation for the corresponding average of R. The resulting equation is still of the matrix form (8) and the same techniques can be applied to both the full and averaged equations. This procedure will greatly reduce the number of points needed to carry out the angular integrations.

Another simplification arises if the solution is required to satisfy (14). As one would expect, (2) then becomes an equation for the dimensionless function r defined in (17) and the number of energy variables is cut in half. We have pointed out that $R(\mathbf{n},E;\mathbf{n}',E')$ is independent of reflection coefficients whose energy indices are greater than E or less than E' which means that the integral equation for r is of the Volterra type as far as the ξ variable is concerned. One can therefore compute r out to some minimum value of ξ without having to find the function for smaller values of ξ. The validity of forcing R to satisfy (14) is, however, not *a priori* known.

The major stumbling block will, of course, be the strong forward peak in the Rutherford cross section. One will note, however, that the matrix W is also ill behaved, but when it was exponentiated to obtain Eq. (9) its singular behavior ceased to cause any difficulty. The latter equation can be obtained by multiplying (8) from both right and left by $\exp(-Wt)$, noticing that the left-hand side is a total derivative and integrating from zero to infinity. More generally, suppose we take any matrix function $A(t)$ which has the properties, $A(0)=I$ and $A(\infty)=0$, and carry out the same manipulations. One easily verifies that the analog of (9) is then

$$R=\frac{Z}{8\pi}\int_0^\infty A(t)[S_B+B_1(t)R+RB_2(t)+RS_BR]A(t)dt,$$

$$B_1(t)=\frac{8\pi}{Z}\left[-A^{-1}(t)\frac{d}{dt}A(t)-W+\left(\frac{Z}{8\pi}\right)S_F\right], \tag{19}$$

$$B_2(t)=\frac{8\pi}{Z}\left[-\left[\frac{d}{dt}A(t)\right]A^{-1}(t)-W+\left(\frac{Z}{8\pi}\right)S_F\right].$$

The game is now to choose A so that the matrices B_1 and B_2 are well behaved. The ideal choice would be $\exp[-(W-Z/8\pi S_F)t]$, but from the analog of Eq. (11) one finds that the $(\mathbf{n},E;\mathbf{n}',E')$th element of this matrix is the probability that an electron will be scattered from the state $(\mathbf{n},E)$ to the state (n',E') while passing through a slab of thickness t, provided that one only includes scatterings such that the electron is always traveling into the target. Evaluating this matrix would be as difficult a problem as solving the original equation. On the other hand, the theory of small-angle multiple scattering[18,19] has provided a number of approximate evaluations of this matrix. These approximations are only valid for small-angle deflections, but one will note that this is all that is needed to insure that B_1 and B_2 are well behaved. The scheme is, therefore, to calculate $\exp[-(W-Z/8\pi S_F)t]$ in some tractable small-angle approximation, use this matrix for $A(t)$ in (19), and solve the resulting equation by iteration starting with $R=0$. Any reasonable approximation for the above exponential should remove most of the small-angle scattering from B_1 and B_2, and the successive iterates should converge like an expansion in the number of large-angle scatterings. Our experience with the cutoff calculations described in the previous section indicate that such a series would converge rapidly after about five iterations. Furthermore, any iterative solution to (19) is clearly well behaved for small Z, so if the iterates converge they are guaranteed to yield the correct solution. The author has not investigated the above scheme in detail but preliminary investigations indicate that it may lead to a practical method for obtaining numerical results.

Growing Helical Density Waves in Semiconductor Plasmas*

C. E. HURWITZ AND A. L. MCWHORTER
Lincoln Laboratory† and Electrical Engineering Department, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received 2 December 1963)

An experimental and theoretical investigation is made of growing screw-shaped plasma density waves in a semiconductor bar subjected to parallel electric and magnetic fields. A particularly simple mode is used, requiring only a thermal-equilibrium electron-hole plasma, low-recombination surfaces, and moderate fields. It is shown that in extrinsic material the growth is spatial, corresponding to stable traveling-wave amplification, while for nearly equal densities of positive and negative carriers the wave is absolutely unstable and corresponds to the oscillistor phenomenon. Experimental observations of the waves were made in germanium at and above room temperature for frequencies from 20–400 kc and with electric and magnetic fields from 25–60 V/cm and 0–11 kG, respectively. The growth rates and phase characteristics were found to be in excellent agreement with theory and gain in excess of 35 dB/cm was obtained. At higher temperatures, corresponding to nearly intrinsic material, evidence of instability was found in accordance with the theoretical prediction.

I. INTRODUCTION

HELICAL plasma density waves were originally proposed by Kadomtsev and Nedospasov[1] to account for an instability that occurs in the positive column of a gas discharge in a longitudinal magnetic field. Subsequently, Glicksman[2] suggested that a slightly generalized form of this theory could explain the oscillistor effect in semiconductors.[3–5] In its simplest form the oscillistor is a semiconductor bar that exhibits terminal voltage and/or current oscillations when an electron-hole plasma is created by injection or light generation and sufficiently large parallel electric and magnetic fields are applied. Further refinements of the theory for semiconductors and experimental confirmation of the helical nature of the oscillistor instability have been provided by several other authors,[6–13] leaving no doubt as to the correctness of Glicksman's basic idea. However, the feature from which the oscillistor takes its name, the terminal voltage-current oscillation, has not been adequately accounted for up to now, nor has it been determined whether the oscillation is caused by an absolute instability or a convective instability with feedback.[14–19]

The present work indicates that the oscillistor instability is an absolute one and that the terminal oscillations can result from nonlinearities alone. The bulk of the paper, however, is devoted to the theoretical and experimental investigation of a completely different aspect of these helical waves, that of traveling-wave amplification. In this study, a preliminary account of which has been given earlier,[20] a mode is utilized that is much simpler than the one considered by previous authors and which involves only the thermal-equilibrium hole-electron plasma. In these other treatments the growth was always assumed to be temporal, representing instability, and the possibility of stable amplification was not considered, perhaps because the high degree to which the growth and propagation constants are influenced by the net difference in hole and electron densities was not fully appreciated. It will be shown that using nothing more than a uniform bar of germanium at room temperature with a low-recombination surface, Ohmic contacts, and moderate applied electric and magnetic fields, controlled amplification of as much as 35 dB/cm can be achieved. In the limit of nearly equal hole and electron densities (intrinsic material or material with a high level of injected carriers) the helical wave becomes absolutely unstable, corresponding to the oscillistor situation mentioned above.

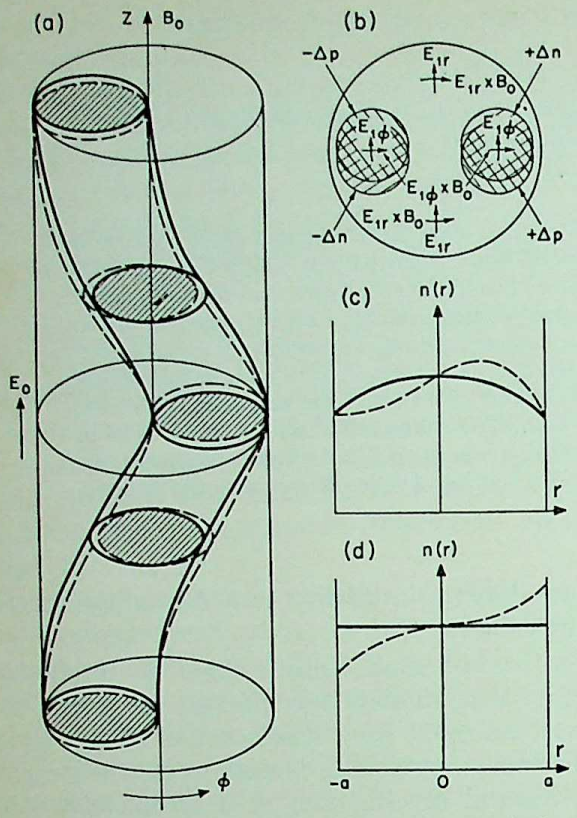

FIG. 1. Right-handed helical perturbation for $|m|=1$. (a) Perturbed-electron distribution indicated by dashed lines and perturbed hole distribution by solid lines. [After Hoh and Lehnert (Ref. 21).] (b) Cross-sectional view showing charge separation and resulting perturbed electric fields E_1. Directions of carrier flow due to the combined effect of E_1 and B_0 are indicated by the vectors $\mathbf{E}_1 \times \mathbf{B}_0$. (c) and (d) Carrier density versus radius along a horizontal diameter through the cross section of (b) for the equilibrium-gradient mode and the surface-density mode, respectively. Solid lines correspond to unperturbed distributions and dashed lines to distributions altered by radial and azimuthal flows.

II. PHYSICAL MODEL

A physical model of the growth mechanism of the helical wave was developed by Hoh and Lehnert[21,22] for the gas-discharge case. We will include an additional part of the mechanism and modify the picture to apply to semiconductors. The argument is begun by assuming a small, quasineutral, screw-shaped perturbation of positive and negative carriers to be superimposed on the steady-state unperturbed distribution. The general form, in cylindrical coordinates, would be $F(r)\exp(i\omega t - ikz - im\phi)$ with $F(r)$ determined by the boundary condition at the wall; however, for the present argument we consider only the lowest mode $m=\pm 1$, as the full mathematical treatment shows that this mode has the lowest threshold for growth. The perturbation is shown schematically in Fig. 1(a) for m and k having opposite signs (a right-handed helix). The longitudinal electric field E_0 tends to separate the superimposed positive and negative screws axially, which is equivalent to a rotation of one screw relative to the other, as shown in Fig. 1(a) and in the cross-sectional view of Fig. 1(b). The resulting charge separation creates both an azimuthal and a radial electric field, $E_{1\phi}$ and E_{1r}, respectively. The radial field was neglected by Hoh and Lehnert but it is no less important than the azimuthal field in the description of the total growth mechanism. In the linear approximation these fields, together with the longitudinal magnetic field B_0, act on the unperturbed distribution to produce a radial and azimuthal flow of particles, indicated in Fig. 1(b) by the vectors $\mathbf{E}_{1\phi} \times \mathbf{B}_0$ and $\mathbf{E}_{1r} \times \mathbf{B}_0$. If the unperturbed distribution has a radial gradient, as it does in a gas discharge or in the usual form of the oscillistor (due to the finite recombination of injected carriers at the walls), this flow is not divergenceless and hence can feed particles from the main distribution into the screw with the proper phase, thus producing a growth of the perturbation. This may be seen more clearly in Fig. 1(c), where the carrier density is plotted as a function of radius along a diameter horizontally through the cross section of Fig. 1(b). For the signs of E_0 and B_0 chosen, the flow adds carriers to the assumed excess in the region $r>0$ and removes carriers from the assumed deficit in the region $r<0$, thus enhancing the perturbation.

When the influx of particles is sufficiently large to overcome the dissipative effects of diffusion and recombination the helix will grow. It may thus be expected that for a given value of electric field E_0 there will be a threshold value of magnetic field B_{0c} above which growth is observed. There should also be an optimum wavelength, for if the wavelength is too long the charge separation and therefore the driving electric fields will be too small, while for a very short wavelength the diffusive effects will take over and dissipate the perturbation. If the sample or plasma column is long enough that end effects are negligible, the wavelength should be independent of the sample length. For the electric and magnetic fields as shown in Fig. 1(a) the screw of opposite sense will clearly be attenuated since the radial and azimuthal flows now reverse directions and tend to destroy the perturbation. In general it may be stated[9] that the helix which can exhibit growth is right- (left-) handed for the electric and magnetic fields parallel (antiparallel).

In a semiconductor a radial gradient of the unperturbed distribution can be produced in thermal equilibrium by proper doping (e.g., by indiffusion or outdiffusion of impurities), eliminating the need for a steady-state injected or optically-generated plasma with all of its inherent complications. Of course, the radial gradients of the holes and electrons in this "equilibrium-gradient mode" will be in opposite directions, producing a partial cancellation in the growth process, but as shown in a calculation of the threshold for this mode in Appendix A there can still be a net buildup of the perturbation.

However, except for this calculation, we will be concerned with an even simpler mode of semiconductor operation requiring no unperturbed radial gradient at

all, merely a sufficiently low surface recombination. In this mode, called here the "surface-density mode," growth occurs because the radial and azimuthal flows can pile up or deplete the carriers at the surface in the proper phase, as illustrated in Fig. 1(d). The role of the dc-electric and magnetic fields in producing the flow is the same as before. Experimentally the surface-density mode is easier to achieve than the equilibrium-gradient mode, and also the mathematical theory for the surface-density mode can be formulated with fewer approximations.

In addition to the growth properties, the motion of the wave can also be ascertained from the physical model. As is well known, a quasineutral density perturbation under the influence of an applied electric field E_0 propagates in the direction of minority carrier drift with a velocity $v_d=\mu_a E_0$, with μ_a, the ambipolar drift mobility, being given by

$$\mu_a=[\mu_e\mu_h(n_0-p_0)]/(n_0\mu_e+p_0\mu_h),$$

where n_0 and p_0 are the equilibrium densities of electrons and holes, and μ_e and μ_h are their respective mobilities. Thus, the helix performs a bodily translation with the ambipolar drift velocity v_d. In addition, there is a rotation of the helix due to diffusion and conduction of carriers across the magnetic field. (Another mechanism for rotation, due to the radial ambipolar electric field, also exists when the unperturbed carrier distribution has a radial gradient.) The total motion of the helix is composed of these two parts. For extrinsic semiconductors the translation will dominate, while for intrinsic semiconductors the ambipolar mobility is zero and the motion is therefore purely rotational. Discussion of the direction of rotation will be postponed until the next section where the necessary mathematical expressions are derived. It should be noted that because of the nature of a helix both motions when viewed in any cross-sectional plane produce a rotation of the carrier density and field patterns about the axis.[23]

The ambipolar drift of the helix also plays a crucial role in distinguishing instability from stable growth. A detailed discussion is presented in the next section, but to complete the physical picture the basic ideas are outlined here. Three fundamental processes govern the change in amplitude of the perturbation with time at any point in space: the growth mechanism previously described, diffusion, and ambipolar drift down the bar. Above threshold the growth is enough to overcome diffusion, but for a sufficiently large drift velocity the disturbance is swept away, growing as it moves. At any point in space the perturbation remains bounded in time, and the result is simply a spatially growing wave. However, if the ambipolar drift velocity is very small the perturbation may build up faster than it can diffuse and drift away. At a point in space it may then grow temporally, corresponding to an absolute instability. Clearly the first case is pertinent to extrinsic semiconductors, and the latter to semiconductors with nearly equal electron and hole densities and to gaseous plasmas.

It should also be mentioned that Gurevich and Ioffe[24] have proposed a very similar mechanism which can lead to growing density waves in thin semiconductor slabs. In their model a steady-state density gradient and electric fields are set up either by illumination of one surface or by the Hall effect. Then the addition of a wave-like density perturbation creates a perturbed electric field through charge separation in the steady-state electric and magnetic fields. As in the case of the helical wave, this perturbed field acts on the unperturbed distribution to produce a carrier flow in the correct direction to enhance the perturbation. The applied electric and magnetic fields perform different functions in the chain of physical argument, but the fundamental process of coupling an unperturbed density gradient with a perturbed electric field to achieve growth is basically the same as for the helical wave. Experimental observations of instability under conditions similar to those considered by Gurevich and Ioffe have been reported[25,26] and may well be explained in terms of their model.

III. MATHEMATICAL THEORY

With the preceding physical picture in mind, we now formulate a quantitative mathematical description of the helical wave in the surface-density mode. The equilibrium-gradient mode is considered in Appendix A. Using the equations of motion and continuity for electrons and holes, the dispersion relation governing the growth and propagation of the helical wave will be derived. From this equation will then follow both the threshold conditions and the growth and phase constants for stable growth as well as the threshold for instability.

Consider a cylindrical bar of semiconductor, long in the z direction so that end effects may be neglected. The bar is assumed to be uniform and in thermal equilibrium and therefore to contain a uniform density n_0 of electrons and p_0 of holes with $n_0-p_0=N_D-N_A$, where N_D and N_A are the densities of ionized donor and acceptor impurities, respectively. Under the assumption that the times and distance of interest are much larger than the mean free times and paths of the free carriers, we may write the following equations to describe the behavior of

[23] The contribution of the drift motion to this rotation was first pointed out by Okamoto *et al.* (Ref. 6).

the carriers under applied electric and magnetic fields:

$$\mathbf{J}_e = nq\mu_e\mathbf{E} + qD_e\nabla n - \mu_e\mathbf{J}_e\times\mathbf{B}, \quad (1)$$

$$\mathbf{J}_h = pq\mu_h\mathbf{E} - qD_h\nabla p + \mu_h\mathbf{J}_h\times\mathbf{B}, \quad (2)$$

$$\partial n/\partial t = (1/q)\nabla\cdot\mathbf{J}_e + \gamma, \quad (3)$$

$$\partial p/\partial t = -(1/q)\nabla\cdot\mathbf{J}_h + \gamma, \quad (4)$$

$$\nabla\cdot\mathbf{E} = -q(n-p)/\epsilon. \quad (5)$$

The subscripts e and h refer to the electrons of density n and holes of density p, respectively; μ is the mobility, D is the diffusion constant, γ is the net rate of bulk generation (which in the absence of trapping is the same for both carriers), ϵ is the dielectric constant of the semiconductor, q is the magnitude of the electronic charge, J is the current density, and E and B are the electric and magnetic fields, respectively.

In order to effect a considerable simplification in the mathematics it will be assumed throughout that the square of the Hall angle for each carrier is small; i.e., that $\mu_{e,h}{}^2B^2\ll 1$. Under this assumption and also assuming that the self-magnetic fields are negligible with respect to the applied uniform magnetic field B_0, Eqs. (1)–(4) may be combined to yield

$$\partial n/\partial t = n\mu_e\nabla\cdot\mathbf{E} + \mu_e\mathbf{E}\cdot\nabla n + D_e\nabla^2 n + \mu_e{}^2\mathbf{E}\cdot(\nabla n\times\mathbf{B}_0), \quad (6)$$

and

$$\partial p/\partial t = -p\mu_h\nabla\cdot\mathbf{E} - \mu_h\mathbf{E}\cdot\nabla p + D_h\nabla^2 p + \mu_h{}^2\mathbf{E}\cdot(\nabla p\times\mathbf{B}_0). \quad (7)$$

The bulk generation term has been omitted as it is a simple matter to reinsert it if desired near the end of the calculation.

Equations (6) and (7) are now linearized for small perturbations about equilibrium by writing

$$n = n_0 + n_1, \quad p = p_0 + p_1, \quad E = E_0 - \nabla\psi_1, \quad (8)$$

where the subscripts 0 and 1 refer to the equilibrium quantities and their perturbations, respectively. Assuming quasineutrality (i.e., $n_1\approx p_1$, but $\nabla^2\psi_1\neq 0$), eliminating ψ_1 from the linearized equations, and restricting ourselves to the particular case of interest where E_0 and B_0 are both in the z direction, we have the familiar ambipolar continuity equation for n_1:

$$\partial n_1/\partial t = D_a\nabla^2 n_1 - \mu_a E_0(\partial n_1/\partial z), \quad (9)$$

where

$$\mu_a \equiv [\mu_e\mu_h(n_0-p_0)]/(n_0\mu_e + p_0\mu_h)$$

and (10)

$$D_a \equiv (n_0\mu_e D_h + p_0\mu_h D_e)/(n_0\mu_e + p_0\mu_h)$$

are the ambipolar mobility and diffusion constant, respectively.

To obtain the normal modes for the problem, the perturbations n_1 and ψ_1 are Fourier analyzed in cylindrical coordinates (r,ϕ,z) in the form

$$n_1 = N_1(r)\exp(i\omega t - ikz - im\phi),$$
$$\psi_1 = \Psi_1(r)\exp(i\omega t - ikz - im\phi), \quad (11)$$

and (9) is solved for $N_1(r)$, the radial part of n_1, with the result

$$N_1(r) = c_1 I_m(\beta r), \quad (12)$$

where $I_m(\beta r)$ is the modified Bessel function of the first kind of order m, c_1 is an arbitrary constant, and

$$\beta^2 \equiv [(\omega - \mu_a E_0 k)/D_a] + k^2. \quad (13)$$

The potential $\Psi_1(r)$ is obtained from the continuity equations (6) and (7), which after linearization and for E_0 and B_0 in the z direction may be combined in the form

$$\nabla^2\psi_1 + A\nabla^2 n_1 = 0, \quad (14)$$

where

$$A \equiv -i\frac{E_0 k(\mu_e+\mu_h)}{(n_0\mu_e+p_0\mu_h)(\beta^2-k^2)} + \frac{D_e-D_h}{n_0\mu_e+p_0\mu_h}. \quad (15)$$

Therefore,

$$\psi_1 = An_1 + \text{a solution of Laplace's equation.} \quad (16)$$

The appropriate solution of Laplace's equation is a modified Bessel function $I_m(kr)$, and as a result

$$\Psi_1(r) = Ac_1 I_m(\beta r) + c_2 I_m(kr). \quad (17)$$

To complete the solution, the boundary condition at the surface $r=a$ of the cylinder must be applied. These conditions have the form

$$-(1/q)J_{er}(a) = (1/q)J_{hr}(a) = sn_1(a), \quad (18)$$

where $J_{er}(a)$ and $J_{hr}(a)$ are respectively the radial components of the electron and the hole current at the surface, s is the surface recombination velocity and $n_1(a)$ is the excess carrier density at the surface. From (1) and (2), for E_0 and B_0 in the z direction and for $\mu_{e,h}{}^2B_0{}^2\ll 1$, we have to first order in the perturbation quantities

$$-\frac{1}{q}J_{er} = n_0\mu_e\left(\frac{\partial\psi_1}{\partial r} - \frac{\mu_e B_0}{r}\frac{\partial\psi_1}{\partial\phi}\right) - D_e\left(\frac{\partial n_1}{\partial r} - \frac{\mu_e B_0}{r}\frac{\partial n_1}{\partial\phi}\right) \quad (19)$$

and

$$-\frac{1}{q}J_{hr} = -p_0\mu_h\left(\frac{\partial\psi_1}{\partial r} + \frac{\mu_h B_0}{r}\frac{\partial\psi_1}{\partial\phi}\right) - D_h\left(\frac{\partial n_1}{\partial r} + \frac{\mu_h B_0}{r}\frac{\partial n_1}{\partial\phi}\right). \quad (20)$$

Substituting these expressions into (18) and introducing the solutions (11), (12), and (17) into the resulting equations we obtain two linear, homogeneous equations for the coefficients c_1 and c_2. The dispersion relation relating the frequency ω and propagation constant k is obtained by setting the determinant of these equations equal to zero. The result, after inserting the value of A from (15) and performing some algebraic manipulation,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is the following equation:

$$(m\mu_M^2 E_0 B_0/D_a)[k/(\beta^2-k^2)]$$
$$\times[\beta I_m'(\beta a)I_m(ka)-kI_m(\beta a)I_m'(ka)]$$
$$+a\beta kI_m'(\beta a)I_m'(ka)-im\mu_H B_0\beta I_m'(\beta a)\,I_m(ka)$$
$$+[(sa/D_a)-im\mu_a B_0]kI_m(\beta a)I_m'(ka)$$
$$-im\mu_H B_0(s/D_a)I_m(\beta a)I_m(ka)=0, \quad (21)$$

where μ_a, the ambipolar mobility, is as defined in (10),

$$\mu_H=R_H\sigma_0=(p_0\mu_h^2-n_0\mu_e^2)/(n_0\mu_e+p_0\mu_h) \quad (22)$$

is the mixed conduction Hall mobility, and

$$\mu_M^2=n_0p_0\mu_e\mu_h(\mu_e+\mu_h)^2/(n_0\mu_e+p_0\mu_h)^2 \quad (23)$$

is a quantity with the dimensions of mobility squared which appears also in the theory of transverse magnetoresistance. In obtaining (21) use has been made of the definition (10) of D_a and, consistent with the earlier approximation $\mu_{e,h}^2B_0^2\ll1$, a term in B_0^2 has been dropped.

This dispersion relation (21) is rather complex and extremely difficult to treat as it stands. Besides being transcendental, it contains both ω and k in the arguments of the Bessel functions (through the quantity β). Fortunately, for much of the region of interest it is a reasonable approximation to expand the Bessel functions in Taylor series to obtain an algebraic equation for ω and k. In the section on experimental results some numerical solutions of (21) will be presented which indicate the range of validity of these expansions. Further, since we are dealing with the surface-density mode, it is expected that surface recombination will have to be small in order to obtain growth. Therefore, we make the approximation that $s\ll D_a/a$ and neglect the terms involving s. In addition, it is assumed that bulk recombination is also sufficiently small so that $\tau_b\ll a^2/D_a$, which makes it unnecessary to reinsert the bulk recombination term. In Appendix B the modifications due to recombination are taken into account and it is found that for the experimental situation of interest the correction is negligible.

For simplicity we consider here only the lowest order $|m|=1$ mode as this mode has the lowest threshold for growth. In Appendix C the general m mode is considered. Expanding the Bessel functions, we keep only the first two terms of the Taylor series, which will be valid as long as β^2a^2 and $k^2a^2\ll20$. Substituting the expansions in (21), neglecting terms in β^2k^2, and eliminating β^2 by means of (13) we obtain for the simplified dispersion relation:

$$k^2a^2[3+2i(\mu_e-\mu_h)B_0]+i(a^2/2D_a)$$
$$\times(\omega-\mu_aE_0k)[3-i(3\mu_H+\mu_a)B_0]$$
$$+(\mu_M^2E_0B_0/D_a)ka^2+4[1+i(\mu_e-\mu_h)B_0]. \quad (24)$$

Threshold Conditions

As discussed in Sec. II, it is expected that for a given electric field there should be a critical magnetic field and a critical frequency at which growth is first observed. At this point, which we shall call the threshold, the frequency ω and propagation constant k are both real, corresponding to neither growth nor attenuation. Therefore, at threshold the real and imaginary parts of (24) may be separated and ω eliminated between the resulting equations. Neglecting terms of order $\mu_{e,h}^2B_0^2$ compared with unity the result is

$$3k^2a^2+(\mu_M^2E_0B_0/D_a)ka^2+4=0. \quad (25)$$

It is evident that only the product E_0B_0 enters (25). Since we seek the minimum value of the applied fields for which growth is first observed we minimize the E_0B_0 product with respect to k. In this manner we obtain from (25) the threshold value of k, denoted by k_c:

$$k_c^2=4/3a^2, \quad (26)$$

and also the threshold value of E_0B_0. For ease in comparing theory with experiment, the latter is written as an expression for the threshold magnetic field B_{0c}, which is then a function of E_0:

$$B_{0c}=-\frac{6k_cD_a}{m\mu_M^2}\frac{1}{E_0}, \quad (27)$$

with $|m|=1$.

The critical frequency f_c is obtained from (24). Since at threshold $E_0\sim B_{0c}^{-1}$ from (27), we must consider two limiting cases in order to remain consistent with the assumption $\mu_{e,h}^2B_0^2\ll1$. For extrinsic material, such that $|(n_0-p_0)/(n_0+p_0)|\gg\mu_{e,h}^2B_0^2$, all terms except the one involving μ_a are neglected, so that

$$f_c=(1/2\pi)\mu_aE_0k_c. \quad (28)$$

For intrinsic or nearly intrinsic material, where $|(n_0-p_0)/(n_0+p_0)|\ll\mu_{e,h}^2B_0^2$, only the terms in $\mu_{e,h}B_0$ are retained, with the result

$$f_c=-(20mD_a/9\pi a^2)(\mu_e-\mu_h)B_{0c}. \quad (29)$$

Equation (28) corresponds to the translation of the helix at the ambipolar drift velocity (μ_aE_0), while (29) corresponds to the rotation of the helix due to diffusion and conduction across the magnetic field. In the intermediate case $|(n_0-p_0)/(n_0+p_0)|\approx\mu_{e,h}^2B_0^2$, the total motion is composed of both translation and rotation; however, a correct expression for f_c cannot be obtained in the approximation $\mu_{e,h}^2B_{0c}^2\ll1$.

From (26) it is evident that just the magnitude of k_c is determined. This is simply a consequence of the fact that for a wave of the form $\exp(i\omega t-ikz-im\phi)$ only the relative signs of k, m, and ω are significant. We will choose the signs of k_c and m to make $f_c>0$ in (28) or (29) and to satisfy (27). The resulting signs of ω, k, and m for various directions of E_0 and B_0 and for different types of material are listed in Table I. We have assumed $\mu_e>\mu_h$. The sense and motion of the helix may be deduced immediately from this table.

In agreement with the predictions of the physical

TABLE I. Relative signs of ω, k, and m for helical wave of proper sense to permit growth.

Directions of E_0 and B_0	n-type material	p-type material	Intrinsic material
$E_0>0$ $B_0>0$	$\omega>0$ $k>0$ $m<0$	$\omega>0$ $k<0$ $m>0$	$\omega>0$ $k>0$ $m<0$
$E_0>0$ $B_0<0$	$\omega>0$ $k>0$ $m>0$	$\omega>0$ $k<0$ $m<0$	$\omega>0$ $k>0$ $m>0$
$E_0<0$ $B_0<0$	$\omega>0$ $k<0$ $m>0$	$\omega>0$ $k>0$ $m<0$	$\omega>0$ $k<0$ $m>0$
$E_0<0$ $B_0>0$	$\omega>0$ $k<0$ $m<0$	$\omega>0$ $k>0$ $m>0$	$\omega>0$ $k<0$ $m<0$

model, the helix that can exhibit growth is right- (left-) handed for B_0 parallel (antiparallel) to E_0, irrespective of the type of material. In each case the screw of opposite sense has no threshold and is always attenuated, as will be seen in a subsequent calculation of the growth constant. In any cross-sectional plane, the direction in which the helix appears to revolve about its axis is independent of the direction of E_0 and reverses sign with a reversal of B_0. Further, for a given E_0 and B_0 this direction of apparent revolution is the same for n-type and intrinsic material and is in the opposite direction for p-type material.

Growth and Phase Constants

Having established that a threshold for growing helical waves does indeed exist and having calculated the critical fields, wave number, and frequency, we now examine in detail the functional behavior of the propagation constant of the waves both above and below threshold. In particular we will consider sufficiently extrinsic material that the waves exhibit only stable spatial growth. The question of instability will be taken up in detail later and it will be seen just how extrinsic the material must be to assure stable growth.

We seek solutions of the dispersion relation in the form of traveling waves, excited at a specific frequency and varying spatially. Therefore, ω is considered to be a real variable and k is allowed to become complex, i.e., $k=k_r+ik_i$, where k_r is the phase constant and k_i the growth constant. The wave will then travel with phase velocity $v_{ph}=\omega/k_r$ and will vary in amplitude as $\exp(k_i z)$. Equation (24) is now solved directly for k, and for material sufficiently extrinsic that

$$\mu_a E_0 \gg D_a/a\,, \tag{30a}$$

$$|(n_0-p_0)/(n_0+p_0)| \gg \mu_{e,h}{}^2 B_0^2\,, \tag{30b}$$

and

$$(\mu_a E_0)^2 \gg \omega D_a\,, \tag{30c}$$

the square root in the quadratic formula can be expanded in a Taylor series. In performing the expansion we retain real terms to first order and imaginary terms to second order. Further, we choose the root corresponding to the negative square root; the other choice leads to $k_i \approx \mu_a E_0/2D_a$ which by (30a) is much greater than unity and is thus not self-consistent with the earlier Bessel function expansion. Actually the full transcendental dispersion relation leads to an infinite number of other roots, which presumably correspond to strongly damped modes. For the correct root we have

$$k \approx (\omega/\mu_a E_0) - i(8D_a/3a^2\mu_a E_0)[1+\tfrac{3}{4}(\omega a/\mu_a E_0)^2 + (\omega a^2 \mu_M{}^2 B_0/4\mu_a D_a)]. \tag{31}$$

A considerable simplification of this result may be achieved through the use of the previously derived expressions (27) and (28) for the threshold frequency and magnetic field. The propagation constant $k=k_r+ik_i$ is then

$$k \approx \frac{\omega}{\mu_a E_0} + i\frac{8D_a}{3a^2\mu_a}\frac{1}{E_0}\left[2\frac{fB_0}{f_c B_{0c}} - \left(\frac{f}{f_c}\right)^2 - 1\right]. \tag{32}$$

Equation (32) corresponds to the helical wave of proper sense to permit growth, as given by Table I. The propagation constant for the wave of opposite sense is obtained by simply reversing the sign of the term $(2fB_0/f_c B_{0c})$.

Since $k_r \gg k_i$, we have from (32)

$$v_{\text{phase}} = v_{\text{group}} = \mu_a E_0\,, \tag{33}$$

confirming our earlier assertions that for extrinsic material the wave translates with the ambipolar drift velocity.

We see further that the wave will grow spatially ($k_i>0$ for waves traveling in the direction of increasing z and $k_i<0$ for those propagating in the opposite direction) when

$$2B_0/B_{0c} > (f/f_c)+(f_c/f) \tag{34}$$

and the wave of opposite sense is always attenuated.

Actually the existence of a value of k_i of the correct sign for growth is not sufficient to prove that the solution corresponds to a growing wave; it might also be an evanescent wave, such as in a waveguide beyond cutoff. However, the experimental results confirm the fact that (32) is a true growing wave solution, and we need not investigate this point further.

Instability

In the earlier discussion of the physical model for the helical wave it was reasoned that for sufficiently small ambipolar drift velocity a disturbance could grow temporally rather than spatially, resulting in instability as opposed to stable growth. We shall now derive this result mathematically by developing a quantitative stability criterion for the surface density mode of operation.

Stability criteria and the important distinction between convective growth and absolute instability in systems with growing wave behavior have been discussed by several authors.[14–19] The problem is essentially one of determining the response of the system to a spatially and temporally bounded, but otherwise arbitrary, excitation. If the response (which may be any physical quantity of interest) is bounded as $t \to \infty$ then the system is stable, and it is absolutely unstable otherwise. Assuming that only one dimension need be considered and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

that end boundaries are sufficiently far removed so that reflected waves are of no significance, it can be shown that for the purposes of determining the stability it is sufficient to investigate the response $\phi(z,t)$ to a δ-function excitation in space and time:

$$\phi(z,t)=\int_{C_L} e^{i\omega t}d\omega \int_{C_F} \frac{e^{-ikz}}{D(k,\omega)}dk, \tag{35}$$

where $D(k,\omega)=0$ is the dispersion relation for the system under consideration. The Laplace contour C_L runs in the lower half of the ω plane, below all singularities of the integrand, i.e., $-\infty-i\nu<\omega<\infty-i\nu$, where ν is a large positive number. For convenience we have set $s=i\omega$ in the conventional Laplace formulation. The Fourier contour C_F is as usual along the real k axis. For positive t the ω-integration contour is closed by a semicircle at infinity in the upper half-plane, and the k contour is closed in the upper or lower half-plane when the region of interest is for $z<0$ or $z>0$, respectively.

In general the integrals in (35) will be difficult and several authors[14–19] have proposed techniques for obtaining the stability information without explicitly evaluating these integrals. However, for the simplified helical-wave dispersion relation (24) for the surface-density mode, the integrations in (35) can be performed directly to investigate the behavior of $\phi(z,t)$ for large t. From the physical model presented in Sec. II it is expected that instability will be possible only for nearly equal densities of positive and negative carriers, so for simplicity we set $n_0=p_0$ in most terms of (24). However, we do not set $\mu_a=0$, and thereby retain the very important terms involving the quantity (n_0-p_0). This turns out to be equivalent to neglecting terms of the order of $(n_0-p_0)/(n_0+p_0)$ with respect to unity, but not with respect to quantities of order $\mu_{e,h}B_0$, which are much less than unity. This level of approximation will be maintained throughout the calculation. In several places we shall neglect to set $n_0=p_0$ purely to preserve the form of particular terms and to aid in their identification later; however, it is to be understood that the following calculations are correct only for $n_0\approx p_0$.

Equation (24), after rationalization of the leading term, may then be written in the form (assuming $\mu_{e,h}^2B_0^2\ll 1$ as usual):

$$D(k,\omega)=(k-k_0)^2-\alpha(\omega-\omega_0)=0, \tag{36}$$

where

$$k_0\equiv -m\mu_e\mu_hE_0B_0/6D_a+i[\mu_a/4D_a+\mu_e\mu_h(\mu_e-\mu_h)B_0^2/9D_a]E_0, \tag{37a}$$

$$\omega_0\equiv -(m\mu_e\mu_hE_0^2B_0/6)[\mu_a/D_a-5\mu_e\mu_h(\mu_e-\mu_h)B_0^2/3D_a]+i[8D_a/3a^2+(\mu_aE_0)^2/8D_a-\mu_M^4E_0^2B_0^2/18D_a]. \tag{37b}$$

$$\alpha\equiv[m(\mu_e-\mu_h)B_0-3i]/6D_a. \tag{37c}$$

Focusing our attention on the Fourier integral of (35) in the k plane, we see that only contributions to the integral will be at values of $k=k(\omega)$ such that $D(k,\omega)=0$. As the notation implies, these values of k depend parametrically on ω, where ω assumes all values on the Laplace contour C_L. Referring to (36) it is clear that there will be two lines of zeros of $D(k,\omega)$ in the k plane, corresponding to the two solutions

$$k_\pm(\omega)=k_0\pm[\alpha(\omega-\omega_0)]^{1/2}, \tag{38}$$

where

$$\omega=\omega(C_L). \tag{39}$$

Since C_L is below all singularities of the integrand in the ω plane, we may immediately conclude that the two lines of zeros do not cross the real k axis and that all of the zeros are simple. Further, using (37c) and (38) in (36) and recalling that ν may be an arbitrary large positive number, it is clear that $k_+(\omega)$ corresponds to the line of zeros in the upper half k plane, and $k_-(\omega)$ to that in the lower half-plane.

Since the zeros of $D(k,\omega)$ are simple, the poles of the integrand at $k=k_\pm(\omega)$ are also simple and the integral over k can be evaluated using the theory of residues. For $z>0$ the contour is closed in the lower half-plane enclosing the line of zeros corresponding to $k=k_-(\omega)$. The solution for $z<0$ proceeds analogously and will not be detailed. We may thus write for the response:

$$\phi(z,t)=\exp(-ik_0z)\int_{C_L}\frac{\exp\{i\omega t+i[\alpha(\omega-\omega_0)]^{1/2}\}}{[\alpha(\omega-\omega_0)]^{1/2}}d\omega. \tag{40}$$

The integral in (40) may be evaluated directly from a table of Laplace transforms,[27] with the result

$$\phi(z,t)=\frac{1}{(\alpha t)^{1/2}}\exp\left(i\omega_0t-i\frac{a}{4t}-ik_0z\right). \tag{41}$$

Writing $\omega_0=\omega_{0r}+i\omega_{0i}$, we immediately conclude that the system will be stable or absolutely unstable depending on whether ω_{0i} is positive or negative.

It therefore follows from (37b) that a long semiconductor bar with a low-recombination surface and with applied parallel electric and magnetic fields E_0 and B_0 will be stable ($\omega_{0i}>0$) when

$$(\mu_aE_0)^2+(8D_a/a\sqrt{3})^2\geq(\tfrac{2}{3}\mu_M^2E_0B_0)^2 \tag{42}$$

and will exhibit absolute instability when the inequality is reversed.

We may now make a plausible identification of the terms of (42). The quantity μ_aE_0 is simply the ambipolar drift velocity. The term $(8D_a/a\sqrt{3})$ is in the form of a diffusion velocity and is a measure of the effective velocity at which carriers diffuse out of the helix. To aid in the identification of the last term we note that the earlier results on the threshold for growth may be put in a form similar to (42). From (26) and (27) we may write that growth will obtain when

$$(\tfrac{2}{3}\mu_M^2E_0B_0)^2>(8D_a/a\sqrt{3})^2. \tag{43}$$

[27] See, for example, R. V. Churchill, *Operational Mathematics* (McGraw-Hill Book Company, Inc., New York, 1958), p. 328.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The right-hand term is again the square of the effective diffusion velocity. Since it is diffusion which must be overcome to obtain growth, we may conclude that the left-hand term is the square of the effective velocity at which carriers are driven into the helix by the combined action of E_0 and B_0, corresponding to the growth mechanism.

With these identifications in mind we may write the three quantities in (42) as v_{drift}^2, v_{diff}^2, and v_{growth}^2, respectively. From (42) and (43) it may then be stated that the helical wave will exhibit stable traveling-wave amplification when

$$v_{\text{drift}}^2+v_{\text{diff}}^2>v_{\text{growth}}^2>v_{\text{diff}}^2, \tag{44}$$

and will be unstable when the first inequality is reversed.

Although the above discussion is based on a plausible and not rigorously justified identification of terms in (42) and (43), we see that (44) leads us to essentially the same conclusions reached by physical reasoning. That is, when the flow of particles due to the growth mechanism is sufficiently strong to overcome diffusion, a disturbance will grow but will be swept away from its point of origin and spatial growth will result. Further, when the flow is sufficient to overcome both diffusion and drift, the disturbance will build up temporally at its point of origin, resulting in instability. It is not clear, however, why the above expressions involve the squares of the various velocities. Although these velocities are actually complex vectors, and some components will therefore be in either or both time and space quadrature, no explanation of the form of (44) has yet been obtained on this basis.

Several further interesting conclusions may be drawn from Eqs. (42)–(44). For $n_0\neq p_0$ the threshold for growth is lower than that for instability, and consequently as B_0 is increased for fixed E_0 the system passes successively from attenuated waves to stable growing waves to instability. For n_0 exactly equal to p_0, however, there is no region of stable gain and above threshold the system is immediately unstable. The instability threshold value of E_0 decreases monotonically with increasing B_0, but there is a minimum value of B_0 given by

$$B_{0,\min}=3\mu_a/2\mu_M^2 \tag{45}$$

below which there can be no instability regardless of the value of E_0. The instability threshold value of B_0 also decreases monotonically with E_0 and although (42) predicts no corresponding minimum E_0 for instability, there presumably is such a minimum due to saturation of the growth term when $\mu_{e,h}B_0\gg1$. The terms which lead to this saturation have, of course, been neglected throughout the calculations.

Finally, we may calculate the frequency and wave number at which instability is first predicted, i.e., when $\omega_{0i}=0$ and (42) becomes an equality. These quantities are just ω_{0r} and k_{0r}, respectively, and are given by (37a) and (37b), where E_0 and B_0 are the instability threshold values and are related by (42) with the inequality sign replaced by an equal sign.

IV. EXPERIMENTAL PROCEDURE

In order to provide quantitative verification of the theory presented in the preceding section, a long, uniform cylindrical semiconductor sample was required with accurately known carrier densities and mobilities and with bulk and surface recombination sufficiently low that $\tau_b\gg a^2/D_a$ and $s\ll D_a/a$. Further, it was necessary that the longitudinal electric field, pulsed to avoid heating, be applied by means of truly Ohmic contacts in order not to alter the uniform equilibrium carrier distribution. Finally, a means of exciting and detecting the helical wave without altering the number of minority carriers was required.

The samples were fabricated from high-quality, uncompensated n-type germanium with a room-temperature resistivity of about 30 ohm-cm and a bulk lifetime of 1400 μsec. Accurate values for the carrier densities at each temperature of interest (290–360°K) were computed from the value of $n-p=N_D-N_A=3.16\times10^{13}$, obtained by Hall measurements at 77°K, plus the reported value[28] of the np product. In order to ensure that the net donor density was given correctly by the usual expression $N_D-N_A=-(R_Hq)^{-1}$, where R_H is the Hall coefficient, the measurements were made with a magnetic field of 20 kG oriented in a ⟨001⟩ crystallographic direction.[29] Further, the Hall sample had a length-to-width-ratio of 6 to prevent shorting of the Hall field by the end contacts.[30] The uncertainty in the resulting value of N_D-N_A is estimated to be $\pm3\%$.

Carrier-drift mobilities were obtained by scaling the reported[31] lattice mobilities at 300°K according to the experimentally obtained[32] power law appropriate to each carrier for lattice scattering; i.e., $\mu_e=(3900)(T/300)^{-1.66}$ and $\mu_h=(1900)(T/300)^{-2.33}$. This computation was felt to be fully valid in view of the fact that in high-quality uncompensated germanium, lattice scattering is completely dominant in this temperature range.[31,32] Further, the measured resistivities at each temperature (using voltage probes and electric fields of about 0.05 V/cm to avoid complications due to contacts) agreed well within experimental error with the values calculated from the above densities and mobilities.

Samples of both square and circular cross section were used. The samples were first lapped and then etched to final size to remove all damaged surface layers. Dimensions after etching were approximately 25 mm long$\times$1 mm diam for the cylindrical samples and 25$\times$1$\times$1 mm for those of square cross section. To comply with the requirement of the theory, the samples should be much longer than the attenuation length of

any reverse wave so that the presence of the ends cannot be communicated to a significant portion of the bar. Since it is not known theoretically if a reverse wave does exist and if so what its properties are, the sample length was arbitrarily made approximately ten times the threshold wavelength [see Eq. (26)]. Experimentally, no significant effects due to end boundaries were observed.

The etching procedure was quite complex and has been described in detail elsewhere.[33] Using this procedure, which was concluded by protecting the surfaces with silicone oil, it was possible to achieve and maintain surface recombination velocities which were regularly less than 50 cm/sec and often as low as 20 cm/sec. These values of s were computed[34] from the lifetime of injected carriers, measured by decay of photoconductivity for each sample, and the similarly measured bulk lifetime of the original crystal.

The relatively high-resistivity material and strong electric fields (20–60 V/cm) precluded the use of the usual methods for making Ohmic contacts. Metallic soldered, plated, or alloyed contacts always gave p^+n or n^+n junctions which interfered with the flow of carriers. Depending on the direction of current flow a p^+n contact injected or extracted holes while an n^+n contact excluded or accumulated them. Sandblasting the surfaces near the contact to recombine an excess or make up a deficit of minority carriers failed because the electric field swept the carriers through any practical recombination-generation region much faster than they could diffuse to or from the surface.

The problem was solved by use of the arrangement shown in Fig. 2. Only one end of the bar is labeled but the other end is identical. The p^+ contact carries only the hole current and the parallel n^+ contacts carry only the electron current. The series resistors are much larger than the contact resistances. Thus, by adjusting the variable resistor in series with the p^+ contact, the relative electron and hole currents can be set to precisely the values required to maintain the thermal-equilibrium carrier distribution. The large resistors make the setting independent of the electric field, but of course the variable resistor has to be readjusted for each temperature of operation. With respect to fabrication, excellent contacts were formed by alloying In+1/2% Ga and Sn+5% Sb spheres to the sample followed by electrolytic etching.[33]

Excitation and detection of the waves were accomplished by means of pairs of small n^+ probes attached to the surface of the sample (see Fig. 2). These n^+n junctions conduct majority carriers (electrons) freely but are impervious to the flow of minority carriers (holes).[35]

Thus when a pair of probes (such as aa′) is driven

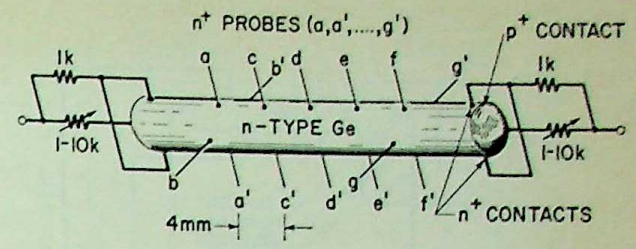

FIG. 2. Sketch of cylindrical sample, showing Ohmic end contacts and n^+ probes.

with an ac signal source, the electric field produced causes the holes to move back and forth in synchronism, perturbing the carrier distribution and initiating the wave. Actually, the linearly polarized excitation just described excites both the $m=\pm 1$ modes, but as discussed in the last section, one mode will always decay while the other can grow. By using two sets of probes (aa′ and bb′, for example) which are 90° apart around the circumference and driving them with two signals 90° out of time phase, one or the other of the circularly polarized modes may be excited preferentially.

The use of the n^+ probes in detecting the helical wave makes use of the fact that the electron quasi-Fermi level (QFL) is constant through the n^+n junctions. The open-circuit voltage between two probes then gives the difference between the electron QFL's just beneath the surface at the two points. However, for small signals the perturbed electron QFL is linearly related[36] to the perturbations in the density and potential, i.e.,

$$\phi_{e1}\approx\psi_1-(kT/q)(n_1/n_0).$$

Therefore, all information pertaining to the amplitude and phase characteristics of the waves may be obtained by measuring ϕ_{e1} with n^+ probes. Of course, it is also necessary that the contacts be impervious to the flow of holes in order to prevent their generation or recombination in the junctions.

These probes were fabricated by bonding 0.002-in. Sb-doped Au wires to the sample with pulses of current.[37] To assure that the two probes of a set (c and c′, for example) were aligned on the same cross-sectional plane of the sample, an electrical null technique was used to locate them.[33] All probes were checked for proper operation by using them to measure known changes in the electron QFL produced by illuminating the sample with penetrating light.[33] This test was also correlated with the current-voltage characteristics of the probes.

A diagram of the arrangement for the above-described excitation and detection of the waves is shown in Fig. 3. The phase shifter and probe driver provided signals 90° out of phase from low-impedance sources. The input impedance of the detecting and measuring circuits was

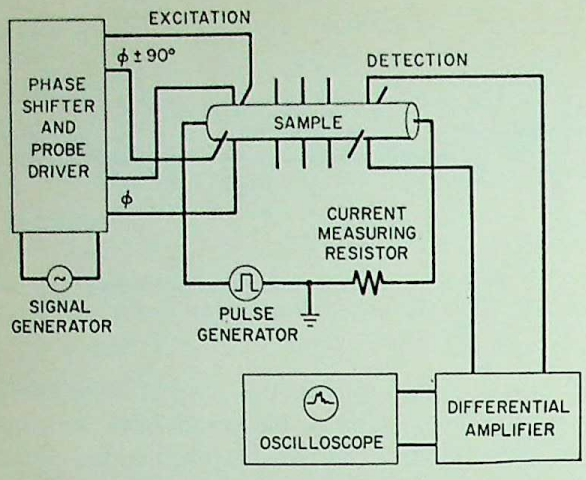

FIG. 3. Experimental arrangement for exciting and detecting helical waves. The differential amplifier may be connected to any desired set of probes.

sufficiently high to provide "open circuit" conditions up to frequencies in excess of 500 kc.

The completed sample, mounted in a jig, was attached to a holder which permitted rotation of the sample in a vertical plane for accurate alignment parallel to the magnetic field. This arrangement was mounted between the poles of an electromagnet which was rotatable in the horizontal plane to complete the alignment of sample and field. The sample and lower part of the holder were immersed in a bath of silicone oil which was maintained at a constant, controllable temperature. A thermocouple mounted on the jig next to the sample read the actual temperature. In this manner the temperature could be set and held to within $\pm 0.1°C$ of the desired value.

V. EXPERIMENTAL RESULTS AND COMPARISON WITH THEORY

The basic experiment consisted of applying parallel dc-magnetic and pulsed-electric fields to the sample, exciting the wave with a signal source at an appropriate set of probes, and then observing the excitation in magnitude and phase as it traveled down the bar.

Many samples of both square and circular cross section were fabricated and examined experimentally. All exhibited spatially growing waves whose properties agreed qualitatively with the predictions of the physical model and the mathematical theory. However, due to the involved fabrication procedure and the finite-failure rate at each step (a full set of properly operating n^+ probes was particularly difficult to achieve), only two samples, one square and one circular, were judged to fully meet the requirements discussed in the previous section and therefore to be suitable for accurate quantitative measurements. As will become evident in the following discussion, the agreement between experiment and theory is sufficiently good that although results for only two samples are reported, the theory can be considered completely verified in the region of stable growth.

The final dimensions of these two samples were 1.16 mm diam by 25.4 mm long for the cylindrical sample and $1.02 \times 1.02 \times 25.4$ mm for the one of square cross section.

The temperature of operation proved to be a particularly valuable parameter to vary as it provided a test of the functional dependence of the wave properties on the equilibrium carrier densities without the need for many samples of varying resistivities. In fact, by raising the temperature it was possible to pass from the extrinsic region in which stable spatial growth is observed to nearly intrinsic material where some of the considerations of instability and the oscillistor are of interest.

The extremely low yield of good samples precluded the use of sample geometry as another variable. The dependence on sample radius seems well enough confirmed by the general quantitative agreement of all measurements, but the question of how long is a "long" sample and the length dependence of the threshold in samples comparable in size to a wavelength would still be of interest. Except where otherwise stated, the data to be presented refer to the sample of circular cross section, for in this case there is no ambiguity as to the value of radius to be used in the theoretical expressions.

Helical Waveshape

The helical nature of the wave was confirmed by exciting the sample at probes aa′ and observing the relative phase of the resulting signals at probes ff′ and gg′. (See Fig. 2. The electric field is positive from left to right.) The resulting waveforms are shown in Fig. 4, and we see that for B_0 parallel to E_0 the signal at gg′ led that at ff′ by 90° and lagged by 90° when B_0 was reversed. The traces shown are for threshold, but the same phase relationship was found for all fields and frequencies. Adding to this result the fact that the phase and group velocities are in the direction of the electric field (see next section) it is clear that we do indeed have a helical wave, traveling in the direction of ambipolar drift, which as predicted is right- (left-) handed for B_0 parallel (antiparallel) to E_0.

Further, when a circularly polarized excitation was provided by driving probes aa′ and bb′ with signals 90° out of time phase, only the polarization direction cor-

responding to the predicted screw sense produced a growing wave. The opposite excitation produced only a strongly attenuated wave. That is, for excitation in the sense $a \rightarrow b' \rightarrow a' \rightarrow b$ the wave grew (for fields above threshold) for B_0 parallel to E_0 and always decayed when B_0 was reversed. For excitation in the sense $a \rightarrow b \rightarrow a' \rightarrow b'$ the converse was true. These results are in full agreement with the predictions of the physical model, Eq. (32) and Table I.

Phase Constant—Phase and Group Velocity

For a wave of the form $\exp[i\omega t - i(k_r + ik_i)z \pm i\phi]$ the phase difference $\Delta\Phi$ between two points differing in z by Δz at the same instant of time and same value of ϕ is simply

$$\Delta\Phi = -k_r \Delta z.$$

Thus the measurement of the relative phase of the signal at two sets of probes, such as dd′ and ff′, gives directly the phase constant k_r. In Fig. 5 we plot $-\Delta\Phi$, the amount by which the phase at ff′ lags that at dd′, and the resulting value of k_r, as a function of f/E_0 for several temperatures and electric fields. The probe spacing Δz in this case was 0.8 cm. Since the probes were several wavelengths apart there was always an uncertainty of $2n\pi$ in the absolute phase difference as related to that measured. However, for the extrinsic case we assume that we have a simple wave so that the extrapolated value of $\Delta\Phi$ is zero for $\omega = 0$. Therefore, to each set of experimental points (at a given temperature) we have added an appropriate multiple of 2π. For each set of points the required translation was always $2n\pi$ and n was just that integer required to make $k_r = 2/a\sqrt{3}$ at threshold, in agreement with (26).

The measured values of $\Delta\Phi$ and therefore k_r were, within experimental error, independent of magnetic field over the range 0–11 kG for all temperatures except 67°C and above, but in the latter range exhibited a very slight dependence at the lowest frequency and highest

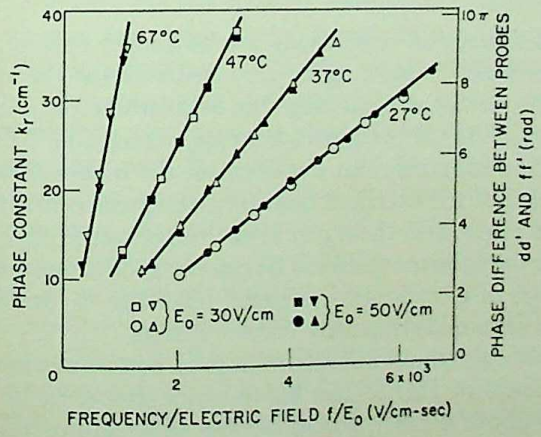

FIG. 5. Phase constant k_r (left-hand scale), computed from measured phase difference between probes dd′ and ff′ (right-hand scale), versus f/E_0, for several temperatures and electric fields. Points are experimental; curves are theoretical, calculated from Eq. (32).

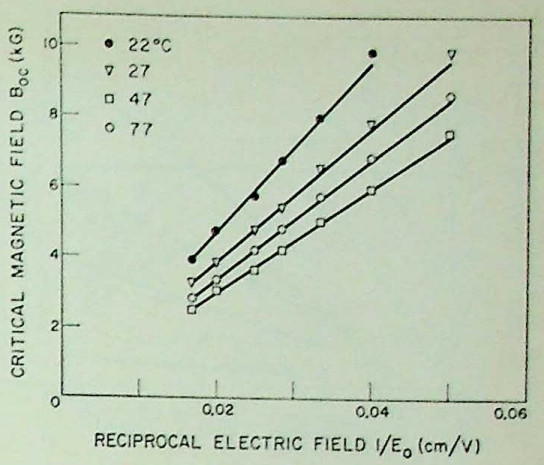

FIG. 6. Critical magnetic field B_{0c} versus $1/E_0$ for several temperatures. Points are experimental; curves are theoretical, calculated from Eq. (27).

magnetic fields. The theoretical curves were calculated from (32) and agreement is excellent. The slopes of the straight lines are just $\mu_a/2\pi$ and therefore, as predicted, $v_{\text{phase}} = v_{\text{group}} = \mu_a E_0$, the ambipolar drift velocity. Values of k_r obtained by numerical computation from the full dispersion relation (21) were insignificantly different from those given by (32).

Threshold Conditions

The threshold, by definition, is the point at which the z variation of the wave first changes from attenuation to growth. At this point $k_i = 0$ and the signal at each set of detecting probes must have the same magnitude. For a fixed electric field, the threshold frequency f_c and magnetic field B_{0c} were obtained by exciting the wave at probes aa′ and bb′ and then slowly raising the magnetic field while sweeping the frequency back and forth. The field and frequency at which the signals at probes dd′, and ee′, and ff′ first became equal were then the threshold values. For properly operating probes these signals became equal simultaneously. The signal at probes cc′ was usually slightly larger, presumably due to higher modes which had not decayed sufficiently that near to the excitation.

In Figs. 6 and 7 we have plotted the measured values of f_c and B_{0c} as a function of the applied electric field E_0 for various temperatures. The theoretical curves were calculated from (27) and (28). Agreement is again very good. The small deviations from theory of the values of f_c at the higher temperatures, lowest electric fields, and highest magnetic fields are presumably due to the beginning influence of the rotational contribution to the frequency. At high magnetic fields, B_{0c} also begins to deviate from theory due to breakdown of the assumption $\mu_{e,h}^2 B_0^2 \ll 1$. Note, however, that at moderate fields the theoretical and experimental values of B_{0c} agree very well at all temperatures. This is to be expected since no assumptions concerning the relative carrier densities were made in the theoretical calculation of

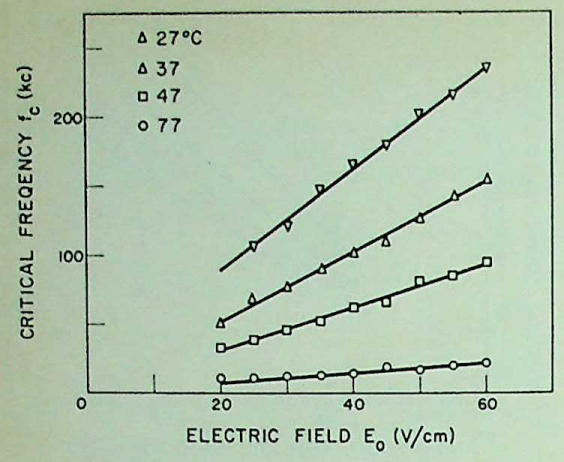

FIG. 7. Critical frequency f_c versus E_0 for several temperatures. Points are experimental; curves are theoretical, calculated from Eq. (28).

B_{0c}. As the temperature increases and $(n_0-p_0)\rightarrow 0$, f_c decreases rapidly, but B_{0c} quickly approaches a limiting value which is independent of the magnitude of n_0 and p_0, as may be seen from Eq. (27). However, when the mobilities are decreasing functions of temperature, as is the case here, B_{0c} reaches a minimum and then increases slightly with temperature. Thus, as we see in Fig. 6, the values of B_{0c} at 77°C are somewhat higher than at 47°C.[38]

Growth Constant

The exponential variation of the wave amplitude in the z direction was confirmed by measurement of the relative signal magnitudes at probes dd′, ee′, and ff′, with excitation provided at aa′ and/or bb′. More precisely, as long as the excitation was sufficiently small that the signal at any set of probes was less than 500 mV peak-to-peak, the wave varied longitudinally as $\exp(k_i z)$ where k_i is the growth constant. When the signal rose above this level, saturation effects began to set in and the linearized theory no longer applied. More will be said about nonlinear effects in the next section; in the present discussion we limit ourselves to the small-signal linear region.

Figures 8 and 9 show the theoretical and experimental variation of the growth constant k_i as a function of B_0 for various temperatures and values of E_0. In all cases the frequency was fixed at the threshold value f_c pertinent to the specific temperature and electric field. The dashed curves are calculated from (32); the full curves are the results of the exact (in the limit $\mu_{e,h}^2B_0^2\ll 1$) numerical solution of the full dispersion equation, (21). The approximate solution is clearly accurate only in the neighborhood of threshold ($k_i=0$), and deviates both above and below threshold where the

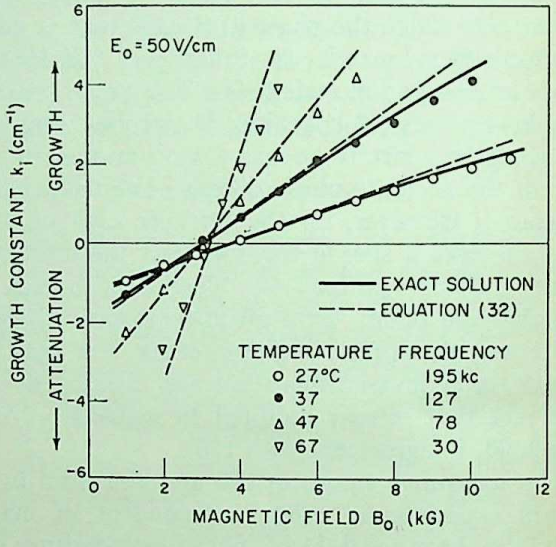

FIG. 9. Growth constant k_i versus B_0 for several temperatures at $E_0=50$ V/cm and $f=f_c$. Points are experimental; solid curves are exact theoretical solutions for $\mu_{e,h}^2B_0^2\ll 1$, and dashed curves are calculated from Eq. (32).

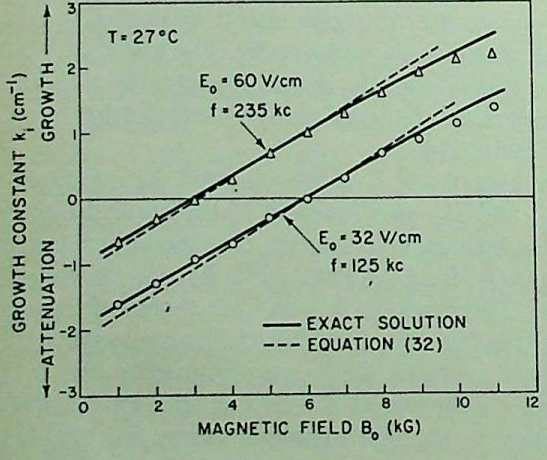

FIG. 8. Growth constant k_i versus B_0 for two values of E_0, at $T=27$°C and $f=f_c$. Points are experimental; solid curves are exact theoretical solutions for $\mu_{e,h}^2B_0^2\ll 1$, and dashed curves are calculated from Eq. (32).

[38] Since all measurements were made with small signals, no hysteresis effects such as described by B. Ancker-Johnson [Appl. Phys. Letters 3, 104 (1963)] were observed.

Bessel function expansions are no longer correct. The experimental results agree very well with the theoretical curves except at high magnetic fields where the assumption $\mu_{e,h}^2B_0^2\ll 1$ becomes a poor approximation. Numerical solutions were not obtained for the higher temperatures, but the excellent quantitative agreement between experiment and theory at lower temperatures indicates that the agreement should be equally good. Intermediate values of electric field, omitted from Fig. 9 for clarity, also gave quantitatively correct results.

Note the rapid increase of growth constant with temperature in Fig. 8. The highest measurable value of k_i was about 4 cm^{-1}, corresponding to a gain of approximately 35 dB/cm. For growth rates above this value the sample began to amplify appreciably its internal noise to values comparable with the maximum signal amplitudes obtainable under linear operation.

The frequency dependence of the growth constant is detailed in Figs. 10 and 11, where for $E_0=50$ V/cm the theoretically predicted and measured values of k_i have been plotted as a function of frequency at $T=27°C$ and $T=37°C$ for three values of magnetic field: $B_0<B_{0c}$, $B_0\approx B_{0c}$, and $B_0>B_{0c}$. Again the dashed curves are calculated from (32) and the full curves are the solutions obtained by numerical computation. The inadequacy of the simplified theory, except in the neighborhood of threshold, is strikingly evident. Equally apparent is the extremely good agreement between the experimental points and the exact theory.

In Figs. 12 and 13 similar measurements of k_i as a function of B_0 and f for the sample of square cross section are presented. An effective radius $a=0.053$ cm was chosen in plotting the theoretical curves from (32) in order to give the best fit to the experimental data. This choice is very nearly the radius of a cylinder with the same cross-sectional area as the sample. No numerical solutions were obtained for this case but, in light of the results for the circular sample, the behavior at frequencies and fields above threshold would presumably be in agreement with the exact solution. The gross disagreement at low frequencies, which is more than could be accounted for by the exact theory, is only an apparent one. It is due to the fact that linearly polarized (two-probe) excitation was used rather than the circularly polarized (four-probe) excitation employed for all measurements on the cylindrical sample. Examination of (32) shows that for $f<f_c$ and $B_0<B_{0c}$ the right- and left-handed helices have comparable attenuation rates. Since both are excited approximately equally, the measured value of k_i will be some combination of the two. This identical discrepancy was later noted on the cylindrical sample, but was eliminated by using four-probe excitation. Because the square samples were by then of little interest, no attempt was made to redo the earlier measurements.

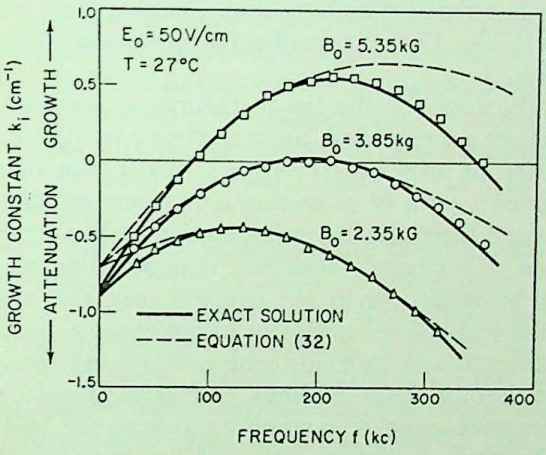

FIG. 10. Growth constant k_i versus f for $B_0<B_{0c}$, $B_0\approx B_{0c}$, and $B_0>B_{0c}$, at $T=27°C$ and $E_0=50$ V/cm. Points are experimental; solid curves are exact theoretical solutions for $\mu_e{}^2B_0{}^2\ll 1$, and dashed curves are calculated from Eq. (32).

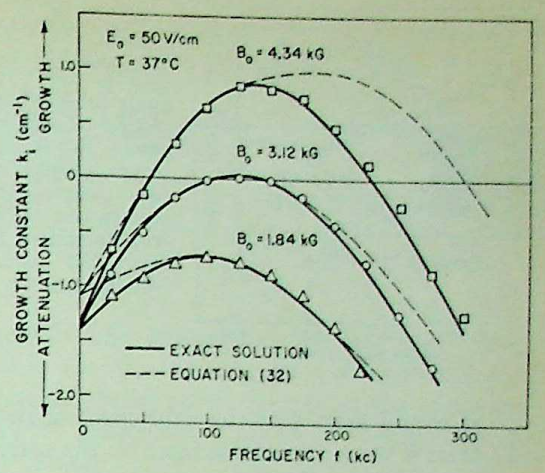

FIG. 11. Growth constant k_i versus f for $B_0<B_{0c}$, $B_0\approx B_{0c}$ and $B_0>B_{0c}$, at $T=37°C$ and $E_0=50$ V/cm. Points are experimental: solid curves are exact theoretical solutions for $\mu_e{}^2B_0{}^2\ll 1$, and dashed curves are calculated from Eq. (32).

An effort to measure directly the functional behavior of k_i for the helix of screw-sense opposite to the one exhibiting growth was made by simply reversing the rotation direction of the four-probe excitation, while maintaining the fields in the same direction. However, due to the fact that four points cannot give a perfect $\exp(i\phi)$ distribution, a sufficient amount of the growing wave was excited to completely obscure the measurements.

Along this same line an attempt was made to excite the next higher $|m|=2$ mode by connecting a and a′ together and b and b′ together, and then driving the resulting two terminals with the signal generator. Such an arrangement should preferentially excite the $|m|=2$ mode. However, again due to the imperfect excitation, enough of the $|m|=1$ mode was excited to drive the sample into strong nonlinear behavior and saturation before the higher $|m|=2$ mode threshold could be reached.

Finally, it should be mentioned here that the growth constant was found to be an extremely sensitive function of the angle between B_0 and E_0. Figure 14 illustrates this behavior. The value of k_i falls off so rapidly that at an angle greater than $\pm 3°$ the strong attenuation made measurements impossible. The reason for such a striking sensitivity to a very small transverse component of magnetic field is not known. In terms of the physi-

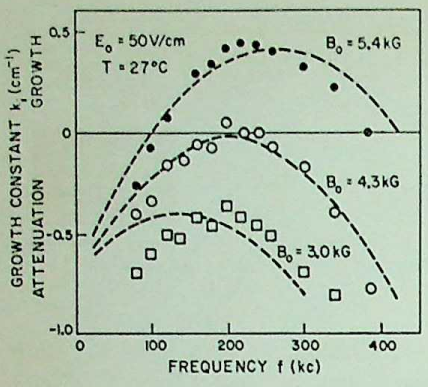

FIG. 13. Growth constant k_i versus f for $B_0 < B_{0c}$, $B_0 \approx B_{0c}$, and $B_0 > B_{0c}$, for square sample. Points are experimental; curves are theoretical, calculated from Eq. (32) with $a = 0.053$ cm.

cal model it would seem that the only effect of such a field is to exert a weak transverse force on the carriers, slightly altering their distribution and setting up a small Hall field. Mathematically, the introduction of a transverse component of B_0 complicates the problem considerably by destroying the azimuthal symmetry. It might be possible to effect some simplification by introducing the transverse component of field as a perturbation. However, such a calculation has not yet been attempted and the effect remains unexplained.

Nonlinear Effects and Current Oscillations

As stated earlier, when signals at the probes reached approximately 500 mV peak-to-peak, saturation began to set in, indicating the onset of nonlinear behavior. The probes farthest down the bar (in the direction of E_0) saturated first as expected, since the amplified signal is largest there. Further increase of the signal level by raising of the excitation or growth rate successively saturated the level at earlier probes, with the signal reaching a limiting value of about 1.5 V peak-to-peak at all probes. At temperatures of 47°C and above, the gain for large enough magnetic fields could be made sufficient to saturate at least the last probes of the sample on amplified internal noise. The spectral characteristics of this noise were quite unusual and will be the subject of further discussion in connection with current oscillations.

Two important effects were noted in conjunction with the onset of strong saturation, namely a marked increase in the dc sample resistance and appearance of oscillations in the terminal sample current. In Fig. 15 the measured dc resistance of the sample is plotted as a function of increasing magnetic field (and hence increasing growth rate). The point at which the resistance begins to increase over its equilibrium value coincides with nearly full saturation at the farthest set of probes (ff′). Current oscillations, shown in the inset of Fig. 15 begin to come into evidence at the same point.

The sample resistance change is a graphic manifestation of the onset of nonlinear behavior. The perturbed carrier density n_1 has now become comparable with the equilibrium densities n_0 and p_0, and the carriers are strongly bunched into the traveling helix. Although the total number of carriers in the sample has not changed, this bunching has produced a net increase in the resistance. The expected order of magnitude of this resistance change may easily be calculated. When strongly bunched, the carriers will be concentrated near the surface of the sample in a helix with pitch $2\pi/k$ and an effective radius approximately equal to the sample radius a. Most of the current will flow between the terminals in this helical path. Both the increased path length of the current and the reduced component of the electric field in the direction of current flow then act to increase the total sample resistance over the equilibrium value. It is a simple matter to show geometrically that the path length is increased by a factor of approximately $(1+k^2a^2)^{1/2}$, and that the component of electric field along the helix is also smaller than the applied fied by the same factor. Thus, with the onset of strong bunching the sample resistance may be expected to increase until it is about a factor of $(1+k^2a^2)$ larger than the unperturbed value. From (26) $k^2a^2 \approx 4/3$, so the resistance should approach a value about 2.3 times larger than that for no bunching. The measured values shown in Fig. 15 are in qualitative agreement with this estimate.

On the basis of the linear theory no terminal VI oscillations are predicted. Since all time-varying quantities vary as $\exp[i\omega t - ikz - im\phi]$, $m \neq 0$, the density integrated over a cross section is independent of time and hence there can be no oscillation of the total resistance. Glicksman's assertion that standing waves, set up by reflections at the contacts, can give rise to terminal oscillations[2] is clearly incorrect since the density still varies sinusoidally with ϕ and t and the integrated density again vanishes. One must therefore invoke nonlinearities or nonuniformities as the basis of the observed oscillation. Misawa[8] has proposed that mixing in of the $m=0$ mode due to deviations from circular symmetry, such as nonuniformities or transverse components of magnetic field, could account for the behavior, and this possibility cannot be ruled out. In fact Okamoto *et al.*[6] have observed that certain oscillistor samples show current oscillations only in the presence of a small transverse component of magnetic field. However, the above experimental observations that oscillations are present in extremely uniform cylindrical samples with strictly longitudinal fields, and that the onset of current oscillation is always associated directly with the onset of nonlinear behavior, provide

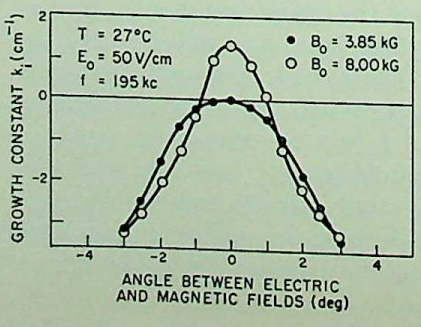

FIG. 14. Growth constant k_i versus angle between E_0 and B_0.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

quite conclusive evidence that large-signal nonlinearity is in itself sufficient to account for terminal oscillations.

The fact that current oscillations were observed in the region of *stable* amplification, requiring only that the gain and excitation be sufficiently large to reach saturation, shows further that instability is not required to obtain such oscillations. In this region the oscillations were essentially sinusoidal at the frequency of excitation, until very strong saturation occurred and some higher harmonic content became apparent. At temperatures below 67°C when the gain was raised sufficiently high to saturate the sample on its own noise, the resultant small current oscillations exhibited a similarly noisy frequency spectrum. However, at 67°C and above, further increase in the magnetic field resulted in a rapid narrowing of the frequency spectrum of both the signals at the probes and the current oscillations, until the frequency was nearly monochromatic and roughly equal to the threshold frequency. One might conceive of a situation in which the strong excursion into nonlinearity might produce a substantial narrowing of the bandwidth for amplification; however, it seems more satisfying to picture the cause as the onset of an instability and the consequent buildup of oscillation at a specific frequency. Indeed just such an instability was predicted from the theory for nearly intrinsic material (i.e., at high temperatures).

Unfortunately, as discussed earlier in connection with the instability theory, a region of stable growth precedes the onset of instability in extrinsic material. The resulting amplification of noise in anything but very nearly or absolutely intrinsic material drives the sample into saturation before instability is attained, so that the linear theory is no longer valid. Such was the case in all of our measurements, even at the highest temperature (87°C). We may, however, make the following qualitative observation. For the 30 ohm-cm germanium used in the measurements, and for $E_0=60$ V/cm and $B_0=11$ kG, the maximum values available with the present arrangement, Eq. (42) predicts that instability will be attainable for temperatures above 60°C. We note also that the rapid narrowing of the frequency spectrum of the amplified noise with increasing fields was observed experimentally only at temperatures above about 67°C. These two facts lead one to the plausible conclusion that this spectral narrowing is the result of the onset of instability and the resulting buildup of oscillations in a narrow band of frequencies; however, further quantitative verification of the theory would certainly be desirable.

Just how close to intrinsic the material must be to reach the instability threshold before nonlinearity occurs may be seen by returning to Eq. (37a) and solving for the growth constant k_{0i} at the point of instability. Neglecting the term $\mu_e\mu_h B_0^2$ which will almost always be negligible, the result is

$$k_{oi}\approx(\mu_a E_0/4D_a)=(qE_0/4kT)[(n_0-p_0)/(n_0+p_0)].$$

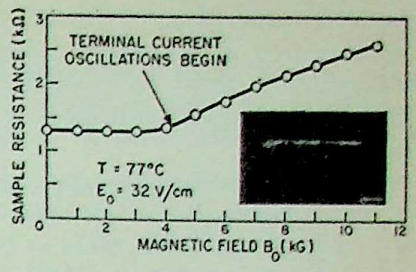

FIG. 15. Average sample resistance versus B_0. Inset is oscilloscope trace of terminal current oscillations which begin at the point indicated. Vertical scale: 10 mA/div. Horizontal scale: 200 μsec/div.

Experimentally it was observed that saturation began to set in when $k_i\approx 4$ cm^{-1}, and in order to keep $\mu_{e,h}B_0\ll 1$ so that the theory correctly applies, the minimum value of E_0 for instability is about 25 V/cm. Therefore we need to have

$$(q/kT)|(n_0-p_0)/(n_0+p_0)|<0.64\text{ V},$$

which for 30 ohm-cm germanium requires $T>100$°C. An easier method would be to start with much purer material. For $N_D-N_A<10^{12}$ cm^{-3} the threshold could be reached while still in the linear region at room temperature.

The Oscillistor

The above prediction and probable observation of absolute instability in a semiconductor bar, with nearly equal densities of electrons and holes and subjected to sufficiently large parallel and magnetic fields, leads naturally to a discussion of the oscillistor, for it is under precisely these conditions that the effect is observed.[3–5] It was shown experimentally that large signal nonlinearity could give rise to terminal VI oscillations and, of course, the instability can provide the mechanism for the rapid buildup of large signal behavior in the form of a strongly bunched helix of carriers.

Unfortunately the oscillistor effect as it is usually observed and reported in the literature presents such a complicated experimental situation that quantitative comparison with theory is prevented. The attainment of nearly equal carrier densities by double injection into a relatively pure bar of semiconducting (long *p-i-n* structure) leads not only to radial gradients of the carrier distribution but also to substantial longitudinal variations in the steady-state densities and electric field.[39] Such variations are not taken into account by the theory and to do so would hopelessly complicate the mathematics. Further, oscillistor samples are usually made with relatively low surface recombination, and as a result growth is probably due both to the steady-state density gradient and to some piling up of carriers at the surface.

Notwithstanding these complications, the essential features of the instability mechanism remain the same, and one would predict the occurrence of an absolute helical instability under the conditions pertinent to the

[39] M. A. Lampert and A. Rose, Phys. Rev. 121, 26 (1961).

oscillistor effect. This result coupled with experimental confirmation of the helical nature of the effect,[6,12,13] provides conclusive verification of Glicksman's proposal of a helical instability as the basis of the phenomenon.

Finally, it should be pointed out that for the gaseous plasma the unperturbed densities of electrons and ions are always equal and there is no ambipolar drift of the helical perturbation. There will therefore be no region of stable growth and, as assumed by Kadomtsev and Nedospasov[1] and Hoh and Lehnert,[21,22] only helical instability is possible.

VI. CONCLUSION

It is evident from the excellent agreement between experiment and theory that the treatment of Sec. III provides an accurate description of the properties of helical waves in the approximation $\mu^2B^2\ll1$. Further, all observations, except the unexpectedly strong dependence of the growth rate on the angle between the electric and magnetic fields, are consistent with the physical model presented in Sec. II.

Although the work was devoted almost entirely to the surface-density mode of operation, it is clear that the general arguments and results may be carried over to more complicated situations, such as the equilibrium-gradient mode or the case of an injected plasma. In addition, although germanium was the only material studied, other semiconductors and perhaps semimetals should exhibit growing helical waves for wide ranges of fields and frequencies, and in fact, oscillistor behavior has been observed in silicon and indium antimonide.[5,10] Unfortunately, in most materials surface and bulk recombination will produce such strong damping of the waves that growth may be difficult to achieve.

ACKNOWLEDGMENTS

We wish to express our appreciation to A. Bers for many fruitful discussions regarding the analysis of gain and instability. We are also grateful to D. K. Hartman of the General Electric Company for supplying several germanium crystals, A. J. Strauss for help with material evaluation, J. H. R. Ward for valuable technical assistance, and Mrs. Nancy Rawson for performing the numerical computations.

APPENDIX A: THRESHOLD CONDITIONS FOR EQUILIBRIUM GRADIENT MODE

We again consider a cylindrical sample of radius a, long in the z direction, but now assume that the equilibrium carrier densities n_0 and p_0 are graded in the radial direction. These gradients could be produced, for example, by the outdiffusion of impurities (consider donors to be specific) in which case n_0 and p_0 would be of the form[40]

$$\begin{aligned} n_0(r)&=n_0J_0(\alpha r)\,,\\ p_0(r)&=n_i^2/n_0(r)=p_0/J_0(\alpha r)\,, \end{aligned} \tag{A.1}$$

where n_i is the intrinsic density. For simplicity we consider the case of weak gradients ($\alpha^2a^2<2$); n_0 and p_0 may then be written as

$$\begin{aligned} n_0(r)&\approx n_0(1-\alpha^2r^2/4)\\ p_0(r)&\approx p_0(1+\alpha^2r^2/4)\,. \end{aligned} \tag{A.2}$$

We further assume that the surface recombination velocity s is large ($s=\infty$), in order to avoid considering an admixture of the equilibrium-gradient and surface-density modes. As usual it is assumed that the bulk lifetime $\tau_b\gg a^2/D_a$ and that the squares of the Hall angles $\mu_{e,h}^2B_0^2\ll1$.

In equilibrium the continuity equations (6) and (7) become, denoting equilibrium values by the subscript 0,

$$\begin{aligned} n_0(r)\mu_e\nabla\cdot\mathbf{E}_0+\mu_e\mathbf{E}_0\cdot\nabla n_0(r)+D_e\nabla^2n_0(r)\\ +\mu_e^2\mathbf{E}_0\cdot[\nabla n_0(r)\times\mathbf{B}_0]=0\,, \end{aligned} \tag{A.3}$$

$$\begin{aligned} p_0(r)\mu_h\nabla\cdot\mathbf{E}_0+\mu_h\mathbf{E}_0\cdot\nabla p_0(r)-D_h\nabla^2p_0(r)\\ -\mu_h^2\mathbf{E}_0\cdot[\nabla p_0(r)\times\mathbf{B}_0]=0\,. \end{aligned} \tag{A.4}$$

The magnetic field B_0 as before is in the z direction, whereas the electric field E_0, in addition to the applied z component E_{0z}, now has a radial ambipolar component E_{0r} due to the density gradients. With equilibrium densities as given in (A.2), Eqs. (A.3) and (A.4) may be readily solved for E_{0r}, with the result (assuming $T_e=T_h=T$)

$$E_{0r}\approx(\alpha^2kT/2q)r\,. \tag{A.5}$$

Following the solution for the surface-density mode, the continuity equations are linearized about equilibrium and quasineutrality is assumed. We then have

$$\begin{aligned} \frac{\partial n_1}{\partial t}&=-\mu_en_0(r)\nabla^2\psi_1+\mu_en_1\frac{1}{r}\frac{\partial}{\partial r}(rE_{0r})\\ &+\mu_e\left(E_{0r}\frac{\partial n_1}{\partial r}+E_{0z}\frac{\partial n_1}{\partial z}\right)-\mu_e\frac{\partial n_0(r)}{\partial r}\frac{\partial\psi_1}{\partial r}+D_e\nabla^2n_1\\ &+\mu_e^2B_0E_{0r}\frac{1}{r}\frac{\partial n_1}{\partial\phi}+\mu_e^2B_0\frac{1}{r}\frac{\partial\psi_1}{\partial\phi}\frac{\partial n_0(r)}{\partial r}=0\,, \end{aligned} \tag{A.6}$$

and

$$\begin{aligned} \frac{\partial n_1}{\partial t}&=\mu_hp_0(r)\nabla^2\psi_1-\mu_hn_1\frac{1}{r}\frac{\partial}{\partial r}(rE_{0r})\\ &-\mu_h\left(E_{0r}\frac{\partial n_1}{\partial r}+E_{0z}\frac{\partial n_1}{\partial z}\right)+\mu_h\frac{\partial p_0(r)}{\partial r}\frac{\partial\psi_1}{\partial r}+D_h\nabla^2n_1\\ &+\mu_h^2B_0E_{0r}\frac{1}{r}\frac{\partial n_1}{\partial\phi}+\mu_h^2B_0\frac{1}{r}\frac{\partial\psi_1}{\partial\phi}\frac{\partial p_0(r)}{\partial r}=0\,. \end{aligned} \tag{A.7}$$

[40] The problem is analogous to that of heat flow from a cylindrical rod. See H. S. Carslaw and J. C. Jaeger, *Conduction of Heat in Solids* (Oxford University Press, London, 1959), Ch. VII.

Due to the presence of terms arising from the equilibrium gradients, the equation for n_1 may not be decoupled as in the surface-mode solution (9). The coupled equations (A.6) and (A.7) are difficult to treat so, following the Kadomtsev and Nedospasov[1] treatment of the very similar gas-plasma case, we solve the problem only approximately in the following manner. The perturbations are Fourier analyzed as in Eq. (11) and only the lowest $|m|=1$ mode is considered. It is now assumed that $N_1(r)$ and $\Psi_1(r)$ have the approximate form

$$N_1(r)=c_1J_1(\beta_1 r),\qquad \Psi_1(r)=c_2J_1(\beta_1 r), \tag{A.8}$$

where $\beta_1 a$ is the first zero of J_1, equal to 3.83, and the c's are constants. Note that $n_1(a)=0$, as required by the assumption $s=\infty$. Equations (A.2), (A.5), and (A.8) are substituted into (A.6) and (A.7) and the resulting equations are averaged over r by multiplying them by $rJ_1(\beta_1 r)$ and integrating with respect to r.[41]

We thus obtain the following two algebraic equations for c_1 and c_2:

$$c_1\{2D_e(k^2+\beta_1^2)-\alpha^2(kT/q)(1+R)+i[2(\omega+\mu_eE_{0z}k)+\alpha^2(kT/q)\mu_e^2B_0]\}+c_2n_0\mu_e\{2(k^2+\beta_1^2)(Q-1)+\alpha^2(1-R)-i\mu_eB_0\alpha^2\}=0, \tag{A.9}$$

and

$$c_1\{2D_h(k^2+\beta_1^2)+\alpha^2(kT/q)(1+R)+i[2(\omega-\mu_hE_{0z}k)+\alpha^2(kT/q)\mu_h^2B_0\}+c_2p_0\mu_h\{2(k^2+\beta_1^2)(Q+1)+\alpha^2(1-R)+i\mu_hB_0\alpha^2\}=0, \tag{A.10}$$

where

$$R\equiv\beta_1\left[\int_0^a rJ_0(\beta_1 r)J_1(\beta_1 r)dr\right]\times\left[\int_0^a rJ_1^2(\beta_1 r)dr\right]^{-1}, \tag{A.11}$$

$$Q\equiv(\alpha^2/4)\left[\int_0^a r^3J^2(\beta_1 r)dr\right]\left[\int_0^a rJ_1^2(\beta_1 r)dr\right]^{-1}. \tag{A.12}$$

The integrals (A.11) and (A.12) are readily evaluated,[42] with the result $R=0$ and $Q=\alpha^2/12\beta_1^2$.

Equations (A.9) and (A.10) are a pair of linear homogenous equations in c_1 and c_2. The dispersion relation is obtained by setting the determinant of the equations equal to zero. Under the assumptions $\alpha^2\ll\beta_1^2$ and $\mu_{e,h}^2B_0^2\ll1$, we then have, after some straightforward algebra,

$$2D_a(n_0\mu_e+p_0\mu_h)(\beta_1^2+k^2)^2+\alpha^2E_{0z}B_0k\mu_e\mu_h(n_0\mu_e-p_0\mu_h)-\alpha^2\omega B_0(n_0\mu_e^2+p_0\mu_h^2)+i\alpha^2B_0\mu_e\mu_h(kT/q)(\beta_1^2+k^2)\times(n_0\mu_h+p_0\mu_e)+i\alpha^2B_0(\beta_1^2+k^2)(n_0\mu_e^2D_h+p_0\mu_h^2D_e)+i2(\beta_1^2+k^2)(n_0\mu_e+p_0\mu_h)(\omega-\mu_aE_{0z}k)=0, \tag{A.13}$$

where we have employed the definitions (10) of μ_a and D_a.

At threshold ω and k are real and (A.13) may be separated into real and imaginary parts. Elimination of ω from the resulting two equations yields

$$(\beta_1^2+k^2)^2+\frac{\alpha^2E_{0z}B_0k}{2D_a}\frac{n_0p_0\mu_e\mu_h(\mu_e^2-\mu_h^2)}{(n_0\mu_e+p_0\mu_h)^2}=0. \tag{A.14}$$

Minimizing the product $E_{0z}B_0$ with respect to k we obtain the threshold conditions:

$$k_c^2=\beta_1^2/3=4.89/a^2, \tag{A.15}$$

and

$$B_{0c}=-\frac{32\beta_1^2k_c}{3m\alpha^2}\frac{D_a(n_0\mu_e+p_0\mu_h)^2}{n_0p_0\mu_e\mu_h(\mu_e^2-\mu_h^2)}\frac{1}{E_0}. \tag{A.16}$$

The result, as expected, is very similar to that for the surface-density mode. The fact that B_{0c} appears to become infinite when $\mu_e=\mu_h$ is a consequence of the fact that the equilibrium gradients of n_0 and p_0 are in opposite directions, producing a partial cancellation of the growth mechanism. In the simple approximation (A.2) used here these gradients are exactly equal and opposite, so that the cancellation appears to be complete when $\mu_e=\mu_h$. In an exact solution this cancellation would be substantial but not complete.

The threshold frequency is obtained from (A.13) where, as discussed in the derivation of (28) and (29) for the surface-density mode, we take care to remain consistent with the assumption $\mu_{e,h}^2B_0^2\ll1$. We then have for $|(n_0-p_0)/(n_0+p_0)|\gg\mu_{e,h}^2B_0^2$,

$$f_c=(1/2\pi)\mu_aE_{0z}k_c \tag{A.17}$$

which, as before, corresponds to the translation of the helix with the ambipolar drift velocity in extrinsic material.

For intrinsic material, $|(n_0-p_0)/(n_0+p_0)|\ll\mu_{e,h}^2B_0^2$,

$$f_c=-\frac{\alpha^2B_{0c}}{2\pi}\left[\frac{kT}{q}\frac{\mu_e\mu_h(n_0\mu_h+p_0\mu_e)}{n_0\mu_e+p_0\mu_h}+\frac{n_0\mu_e^2D_h+p_0\mu_h^2D_e}{n_0\mu_e+p_0\mu_h}\right]. \tag{A.18}$$

The first term is the rotation due to the built-in ambipolar field E_{0r} and the second term arises from the diffusion and drift of carriers across the magnetic field. Equation (A.19) may be simplified considerably by using the Einstein relation $D_{e,h}=(kT_{e,h}/q)\mu_{e,h}$, assuming $T_e=T_h=T$, and by setting $n_0=p_0$, since (A.19) applies to the nearly intrinsic case. Then

$$f_c=-\frac{m\alpha^2}{2\pi}\frac{kT}{q}\mu_e\mu_hB_{0c}. \tag{A.19}$$

[41] See Refs. 1 and 22 for discussion of the validity of this approximate method.

APPENDIX B: EFFECT OF SMALL SURFACE AND BULK RECOMBINATION

Equation (9) with the inclusion of the bulk term is

$$\frac{\partial n_1}{\partial t}=D_a\nabla^2 n_1-\mu_a E_0\frac{\partial n_1}{\partial z}-\frac{n_1}{\tau_b}, \tag{B.1}$$

where γ has been replaced by $(n-n_0)/\tau_b=n_1/\tau_b$. Recombination has been assumed to take place without trapping so that a single bulk lifetime τ_b may be used for both carriers. Such a treatment is fully satisfactory for germanium at and above room temperatures. In the Fourier analysis (11), $n\sim e^{i\omega t}$ so that (B.1) can be written in the form

$$(i\omega+1/\tau_b)n_1=D_a\nabla^2 n_1-\mu_a E_0(\partial n_1/\partial z). \tag{B.2}$$

Bulk recombination may therefore be included simply by replacing ω by $(\omega-i/\tau_b)$ in (24).

To include surface recombination we proceed from (21) exactly as in the derivation of Eq. (25), but now retain the terms involving s. As a result for small bulk and surface recombination, (25) is replaced by

$$3k^2a^2+(\mu_M{}^2E_0B_0ka^2/D_a)(1-sa/D_a)+4(1+sa/3D_a)+3a^2/2D_a\tau_b=0, \tag{B.3}$$

where second-order small terms involving $(sa/D_a)^2$ and $(sa/D_a)(a^2/D_a\tau_b)$ and $\mu_{e,h}{}^2B_0{}^2$ have been dropped. Proceeding exactly as in the derivation of (26) and (27) we have finally at threshold:

$$k_c{}^2=\frac{4}{3a^2}\left(1+\frac{sa}{3D_a}+\frac{3a^2}{8D_a\tau_b}\right), \tag{B.4}$$

$$B_{0c}=-\frac{6k_cD_a}{m\mu_M{}^2}\left(1+\frac{sa}{3D_a}\right)\frac{1}{E_0}, \tag{B.5}$$

and

$$f_c=(1/2\pi)\mu_aE_0k_c, \qquad \left|\frac{n_0-p_0}{n_0+p_0}\right|\gg\mu_{e,h}B_{0c}{}^2 \tag{B.6}$$

$$=-\frac{20mD_a}{9\pi a^2}(\mu_e-\mu_h)B_{0c}\left(1+\frac{2sa}{3D_a}\right),$$

$$\left|\frac{n_0-p_0}{n_0+p_0}\right|\ll\mu_{e,h}{}^2B_{0c}{}^2. \tag{B.7}$$

As expected, recombination, being a loss mechanism, has raised the threshold fields. However, for the experimental situation of interest: $s\approx30$ cm/sec, $\tau_b\approx1400$ μsec, $a=0.058$ cm, and $D_a\approx60$ cm^2/sec, the correction to k_c and f_c is about 1.5% and that to B_{0c} is about 2.5%. These corrections are less than the experimental error and are therefore negligible.

APPENDIX C: THRESHOLD CONDITIONS FOR GENERAL AZIMUTHAL MODE

In the dispersion relation (21) we again expand the modified Bessel functions in Taylor series expansions except that now we consider a general m instead of $m=\pm1$. The case of $m=0$ can be treated and eliminated at the outset. In (21), setting $m=0$ we have simply

$$\alpha\beta kI_0(\beta a)I_0(ka)=0. \tag{C.1}$$

The magnetic field does not enter this expression at all, so there is no threshold. The solutions therefore correspond to damped or evanescent waves and need not be considered further.

For $m\neq0$ modes we keep only the first two terms of the expansions and substitute them in (21). Proceeding as in Sec. III we arrive at the equivalent of (24) for general m:

$$\begin{aligned}k^2a^2[&|m|(|m|+2)+im(|m|+1)(\mu_e-\mu_h)B_0]\\&+i[a^2(\omega-\mu_aE_0k)/2D_a][|m|(|m|+2)\\&+im(|m|+2)\mu_HB_0-im|m|\mu_aB_0]\\&+m\mu_M{}^2E_0B_0ka^2/D_a+2m^2(|m|+1)\\&+2m|m|(|m|+1)(\mu_e-\mu_h)B_0=0.\end{aligned} \tag{C.2}$$

Separating the real and imaginary parts of (C.2) for real k and ω and eliminating ω from the resulting pair of equations, we then have

$$|m|(|m|+2)k^2a^2+(m\mu_M{}^2E_0B_0/D_a)ka^2+2(|m|+1)=0. \tag{C.3}$$

Therefore, at threshold

$$k_c{}^2=2|m|(|m|+1)/(|m|+2)a^2 \tag{C.4}$$

and

$$B_{0c}=-\frac{2m(|m|+2)D_ak}{|m|\mu_M{}^2}\frac{1}{E_0}. \tag{C.5}$$

From (C.5) it is evident that the $m=1$ mode has the lowest threshold for growth.

Returning to (C.2) we have, following the derivation of (28) and (29), the threshold frequency:

$$f_c=(1/2\pi)\mu_aE_0k_c, \qquad \left|\frac{n_0-p_0}{n_0+p_0}\right|\gg\mu_{e,h}{}^2B_0{}^2 \tag{C.6}$$

$$=-\frac{2m(|m|+1)(2|m|+1)D_a}{\pi(|m|+2)a^2}(\mu_e-\mu_h)B_{0c},$$

$$\left|\frac{n_0-p_0}{n_0+p_0}\right|\ll\mu_{e,h}{}^2B_0{}^2. \tag{C.7}$$

Relationship between Neutron-Produced Prismatic Dislocations and the Change in Volume during Annealing in Copper*

I. G. GREENFIELD† AND J. R. DEMOS‡
The Franklin Institute Laboratories, Philadelphia, Pennsylvania
(Received 20 August 1963; revised manuscript received 27 January 1964)

Two groups of copper single crystals of various orientations were irradiated with neutrons in the BNL reactor between 50°C and 70°C; one group was exposed to 0.53×10^{18} *nvt* (total epicadmium flux) and the other 1.1×10^{18} *nvt* (total epicadmium flux). An irradiated and a nonirradiated crystal of each orientation were isothermally annealed in a specially constructed dilatometer at temperatures ranging from 75°C to 350°C, and the irreversible differential changes in length were measured. In addition, electron microscope studies were made of the size distribution of irradiation-produced prismatic dislocations after several of the annealing treatments. These experiments revealed that (1) a direct relationship exists between the magnitude of shrinkage after annealing treatments and the total neutron exposure, (2) during annealing dislocation loops decrease in diameter until they disappear, (3) the decrease in dislocation density is related to the volume shrinkage, (4) the changes in loop distribution could be predicted by a line-tension-climb equation, and (5) the activation energy for the annealing of irradiation-produced loops lies between 2.08 eV and 2.10 eV. The results indicated that the annealing process in neutron-irradiated copper is not the same as observed in quenched metals although a self-diffusion mechanism appears to be the controlling factor.

INTRODUCTION

IRRADIATION of copper with high-energy particles results in defects that produce an expansion in the lattice. Vook and Wert[1] bombarded copper foils with deuterons of an average energy of 8.5 MeV at 15°K and found that copper expanded; subsequent annealing to about 280°K resulted in a shrinkage curve which is the same form as the resistivity curve determined by other workers.[2,3] Although several experiments concerned with the dilatation of copper[4] were made, a detailed account of the effect of annealing after irradiation with neutrons at reactor temperature of approximately 50°C has not been reported. Experiments show, however, that the physical and mechanical properties of irradiated copper are affected by subsequent annealing[4,5] between 0 and 500°C. Moreover, Coltman, Klabunde, McDonald, and Redman[6] have shown that thermal neutrons as well as fast neutrons produce measurable damage at low temperatures; however, more investigation is necessary to ascertain the relationship between the effect of slow neutron bombardment at pile temperatures (50–70°C) and the recoverable damage.

Transmission electron microscopy investigations of neutron-irradiated copper revealed dark spots in copper which are believed to be prismatic dislocation loops.[7,8] These prismatic dislocation loops do not form in all cases, but their production is found to be dependent upon the material irradiated and the temperature of irradiation.[9,10] In copper the density and size distribution of these spots are related to the total radiation exposure and the neutron spectrum.[11] As the irradiation exposure is increased, the density increases to a saturation value and the loops grow in size; subsequent annealing of this material will lower the density of the loops.[7,11,12] Since the disappearance of these loops is equivalent to a decrease in dislocation density, the present experiments were designed to obtain data from which the change in volume of the copper could be correlated with the change in dislocation density during the annealing of irradiated copper. Conclusions can be made concerning (1) the amount of point defects remaining in the lattice after irradiation, (2) the volume occupied by the dislocation loops, and (3) the mode of diffusion during annealing treatments.

EXPERIMENTAL PROCEDURE

Single crystals, 3 mm in diameter by 140 mm long, of high-purity copper (99.9995%) were grown in graphite molds in a vacuum. These crystals were mechanically cut into two equal parts, 70 mm long, in order to make pairs of crystals of identical orientations suitable for the precise length change measurements.

TABLE I. Neutron spectrum for irradiation treatments (temperature between 50–75°C).

Exposure	Specimens	Thermal flux	Epicadmium flux	Flux above 1 MeV	Effective time	Total thermal flux	Total epicadmium flux	Total flux 1 MeV
		(10^{13} *nv*)	(10^{11} *nv*)	(10^{11} *nv*)	(10^6 sec)	(10^{19} *nvt*)	(10^{18} *nvt*)	(10^{17} *nvt*)
A	70, 81, 82	1.0	3.8	2.7	3.0	3.0	1.14	8.10
B	66	1.3	2.8	...	1.9	2.47	0.532	...

To reduce the possibility of spurious effects due to oxygen entering the lattice during the initial annealing treatments, the copper specimens were heated in an evacuated quartz tube in the presence of a zirconium getter. After annealing for 12 h one crystal from each orientation was sent to Brookhaven and irradiated in the BNL graphite reactor. Specimens 70, 81, and 82 were irradiated together in the same hole with a total integrated epicadmium flux of 1.14×10^{18} (*nvt*), exposure A, whereas specimen 66 was exposed to about one-half of this dose, exposure B. Table I contains the pertinent data concerning the neutron bombardment.

The dilatometer[13] used in these experiments was designed to compare irreversible differential changes in length resulting from the rearrangement of point defects between an irradiated and a nonirradiated crystal of the same orientation. The dilatometer was similar in construction to the one used by J. Takamura in the study of changes in length of quenched metals after annealing at temperature near 20°C.[14] The present dilatometer can be operated in the temperature range from 75 to 400°C. The relative changes in length between the irradiated and nonirradiated crystals were magnified by an optical level system and a telescope; when necessary, the readings thus procured were recorded by a slow motion cine technique. In order to obtain precision measurements, the dilatometer was kept in a room in which the temperature did not vary more than 1.0°C over a 24-h period. It was necessary, however, to monitor the temperature of certain components of the dilatometer in order that accurate corrections could be applied to the dilatometer scale readings. An analysis of the calibration data has shown that the sensitivity was about 200 Å with the standard deviation of ±500 Å for the maximum variation of temperature of the components of the dilatometer. All annealing experiments were carried out in an atmosphere of high-purity argon that was passed over hot zirconium chips.

The size distribution and the density of dislocation loops were measured from micrographs in regions about 2000 Å thick. The thickness was measured, where possible, by calculating the perpendicular projection to the surface of the intersections of slip traces. Although dislocations producing these traces were active after long exposures to the electron beam, the dislocations were not always present in the regions where the density measurements were made. As a result some interpolation was necessary; however, the accuracy falls within ±500 Å of the thickness measurement.

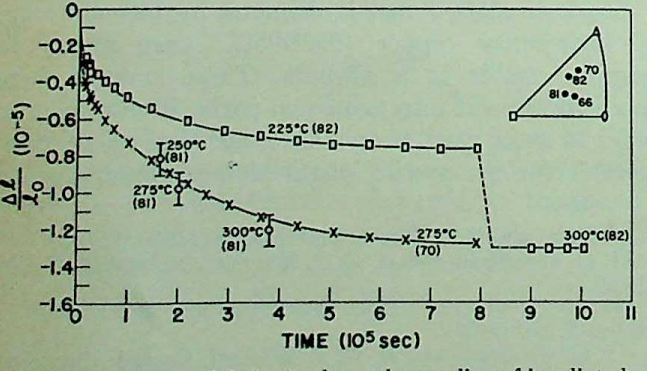

FIG. 1. Change in $\Delta l/l_0$ for isothermal annealing of irradiated copper crystals 70, 81, 82; irradiation exposure A.

[13] I. G. Greenfield and J. Takamura (to be published).
[14] J. Takamura, Acta Met. 9, 547 (1951).

RESULTS

Length Changes Due to Annealing

The effect of isothermal annealing on the change in length of single crystals of copper irradiated with neutron exposure A is shown in Fig. 1. In this graph of specific length change, $\Delta l/l_0$, is plotted against annealing times at the desired temperature. Consider first the results of annealing at 225°C (specimen 82) for 7.9×10^5 sec. The continuous record of the length changes has shown a high rate of shrinkage during the early part of the annealing treatment; however, after approximately 6×10^5 sec, the rate of shrinkage became negligible. Precise measurements of the irreversible difference in length were then made at room temperature after the irradiated specimen and the dummy specimen were cooled to room temperature; the measurements agreed with those taken at the annealing temperature. Then the specimen was heated to 300°C and again a rapid shrinkage took place during the initial heating; however, after about 0.5×10^5 sec, $\Delta l/l_0$ became constant. The total value for the specific change in length for 225°C was found to be -0.76×10^{-5} and for 300°C, -1.30×10^{-5}.

The isothermal annealing treatment carried out at 275°C (specimen 70) was also characterized by an initial rapid shrinkage rate that was greater than observed with the 225°C annealing treatment, and after about 7×10^5 sec, $\Delta l/l_0$ reached a constant value. The total specific length change was not significantly

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

different from the value of -1.30×10^{-5} found in the 300°C annealing treatment discussed above. The irradiated crystal treated at 275°C was not annealed at a higher temperature since it was necessary to preserve the prismatic-dislocation-loop distribution in the specimen for an electron microscope investigation that will be discussed later in this paper. Specimen 81 was annealed at 250, 275, and 300°C for lengths of time indicated in Fig. 1. The results of these dilatometric measurements agree with those described earlier. Annealing at higher temperatures, up to 350°C, did not produce significant additional shrinkage, and thus the maximum $\Delta l/l_0$ for this neutron exposure was -1.30×10^{-5}.

Thus, for the neutron dose A no detectable shrinkage occurred below 200°C; above 225°C considerable shrinkage initially took place, and, as the annealing time was increased, the shrinkage rate approached zero. Additional shrinkage occurred when the temperature was raised higher than this annealing temperature; however, after being annealed in the range of 275°C for more than 7×10^5 sec or 300°C for a shorter time, no additional changes in $\Delta l/l_0$ are detected. The maximum $\Delta l/l_0$ was about equal to -1.30×10^{-5} for this irradiation dose.

For the lower irradiation exposure B, on the other hand, the shrinkage behavior was somewhat different. Specimen 66 was annealed at temperatures and times listed in Table II. The annealing treatment was extended until it was certain the rate of change of $\Delta l/l_0$ reached zero; then the specimens were cooled to room temperature before the next isothermal treatment. The times listed in Table II are not necessarily the minimum time for $\Delta l/l_0$ to reach a constant value. Above 325°C additional shrinkage was not seen. If the specific shrinkages in Table II are compared with those shown in Fig. 1, it can be concluded that the cumulative $\Delta l/l_0$ for the crystals exposed to the smaller neutron dose approached a constant value at about 325°C, whereas for the greater dose the maximum $\Delta l/l_0$ is found at about 275°C. In addition, the maximum shrinkage for the lower dose is less than one-half that for the higher irradiation exposure. Thus, the range of temperature in which shrinkage of the specimen occurs and the total $\Delta l/l_0$ attainable depends upon the irradiation dose.

TABLE II. Annealing treatments for specimen 66; neutron exposure B.

Annealing temperature (°C)	Time at temperature (10^5 sec)	Cumulative $\Delta l/l_0$ (10^{-5})
75, 100, 150, 175, 200	...	...
250	2.52	0.24
275	1.80	0.34
300	3.42	0.75
325	2.16	0.82
350		0.82

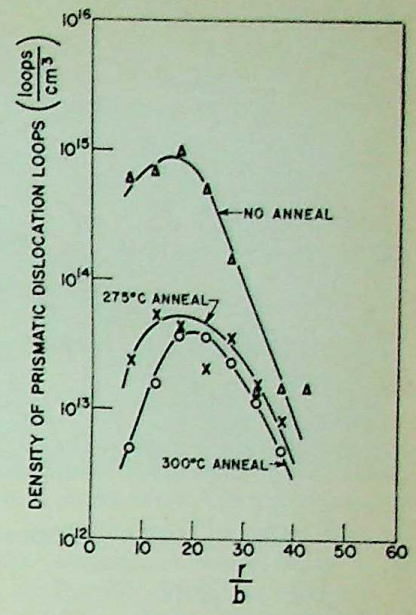

FIG. 2. Size distribution of prismatic dislocation loops in neutron irradiated copper after annealing.

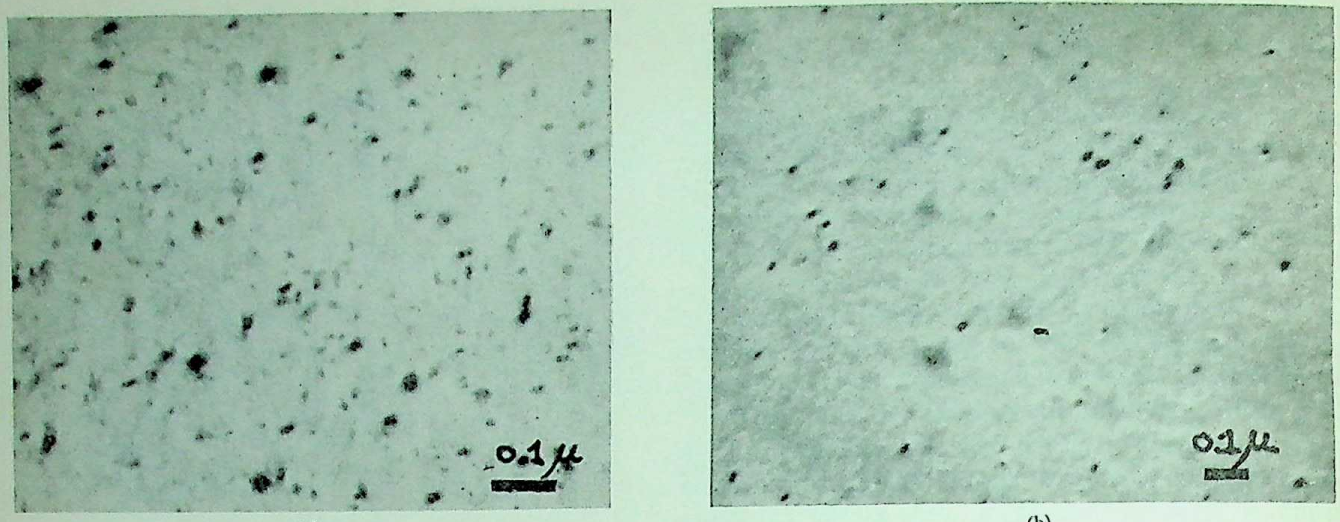
Density and Distribution of Dislocation Loops after Annealing



The distributions of prismatic dislocation loops in neutron irradiated copper before and after annealing are shown in Fig. 2. The parameter r/b is the radius of the loop divided by the distance of closest approach between atoms. The upper curve represents the configuration observed in the copper crystals following irradiation treatment A (see Table I). Figures 3(a) and 3(b) are electron micrographs of specimens in the as-irradiated state and the annealed state. Small dark spots less than 25 Å in diameter were not seen in abundance as reported by Makin *et al.*[11] The geometry of the diffraction contrast in the small spots did not reveal, in general, the nature of the irradiation-produced defects, and consequently, it was not possible to infer whether these structures were tetrahedrons or small dislocation loops. Since the density and size distribution were measured in rather thick regions, the amount of inelastic scattering of the electrons has contributed to the limited image resolution.

The density of dislocation loops were decreased more than a factor of 10 after annealing crystal 70 at 275°C see Fig. 2. Moreover, the average size of loops has only increased slightly, indicating that loop growth plays a minor role during the annealing of neutron irradiated copper. After treating specimen 82 at 300°C, the loop distribution was not altered greatly although the average loop radius was slightly higher. Figure 3 illustrates the typical micrographs before and after annealing. It should be pointed out that loop size measurements are most accurate at the large-radii part of the distribution curve, and the density measurements are most accurate when the loop density is above 10^{13}/cc.

The most significant result due to annealing is the

(a) (b)

FIG. 3. Electron micrographs of irradiated copper (exposure A) (a) before annealing and (b) after annealing at 275°C for 7×10^5 sec.

great decrease in density of dislocation loops with only a slight increase in average radii of the loops.

ANALYSIS OF RESULTS

Dependence of Prismatic Loop Size on Annealing Conditions

Silcox and Whelan[15] have demonstrated that the shrinkage of prismatic dislocation loops formed by quenching in aluminum can be described by an equation originally derived by Friedel.[16] It was shown that the rate of change of the radius of a prismatic-dislocation loop is related to three temperature-dependent conditions: (1) diffusivity of the point defects, (2) the line tension of the dislocation loop and (3) the supersaturation of point defects in the vicinity of the loop.

The rate of change of the radius is then

$$dr/dt=-Z\nu_a b\exp(-E/kT)\times[\exp(F_c b^2/kT)-\exp(F_s b^2/kT)]C_c, \quad (1)$$

where Z is the atomic coordination number, ν_a is the atomic frequency, b is the Burgers vector, E is the activation energy for vacancy diffusion, $F_c=Gb\ln(r/b)/[4(1-\sigma)r/b]$, G is the shear modulus, σ is Poisson's ratio, and $F_s=(kT/b^2)\ln(c/c_0)$. The factor $\exp(F_c b^2/kT)$ is dependent upon the line tension of the loop, and the factor $\exp(F_s b^2/kT)$ is the supersaturation term which indicates whether the loop will accept or emit vacancies. The term C_c is considered to be the concentration of jogs and in a prismatic dislocation loop can be considered as equal to $\frac{1}{2}$. Friedel[17] has pointed out that this analysis depends upon the assumption that the growth process is controlled by climb and not by the migration of point defects to sinks. It has been shown that when loops are considered in thin foils, Eq. (1) can be simplified by considering the surface as a sink for the vacancies. Then c/c_0 is approximately equal to unity (i.e., nearly an equilibrium concentration of vacancies), and Eq. (1) can be written as

$$dr/dt=-\tfrac{1}{2}Zb\nu_a\exp(-E/kT)[\exp(F_c b^2/kT)-1]. \quad (2)$$

Since prismatic dislocation loops are produced in copper by neutron bombardment, it may be assumed (1) that shrinkage of these irradiation-produced loops is controlled by the same forces as the quenched-in loops, and (2) sinks and sources of point defects are available during annealing, and (3) the average distance between sinks and sources of point defects is about the same as the average distance between loops. In contrast to the annealing behavior of isolated loops which have been studied,[15] this investigation is concerned with a multitude of small loops in bulk material, however, if the assumption is made that the vacancies move to sinks faster than they are produced by the loops and clusters, then Eq. (2) can be used.

For aluminum and copper which contain loops of sizes larger than 50 atomic diameters in radius, this equation may be simplified since the reciprocal of the bracketed term is merely a linear function of r/b.

For loops of smaller radii, this relationship is not linear; and, to determine the time required for a prismatic dislocation loop to shrink to a given size, it is necessary to consider the bracketed term in Eq. (2) for various values of r/b (radius/Burgers vector). If Eq. (2) is rearranged into the following form and integrated between the limits indicated,

$$\int_{t_0}^{t}dt=-\frac{2}{Z\nu_a}\exp\left(\frac{E}{kT}\right)\times\int_{r_0/b}^{r/b}\left[\exp\left(\frac{F_c b^2}{kT}\right)-1\right]^{-1}d\left(\frac{r}{b}\right), \quad (3)$$

then the time necessary for a prismatic dislocation loop climbing from radius r_0 to radius r can be determined.

Equation (3) can be integrated numerically after the values of the constants are substituted. It has been found that the appropriate value for the activation energy E falls between 2.08 and 2.10 eV (the evidence for these values will be discussed later) and the relationships between r/b and time for various size loops are shown in Figs. 4 and 5. In Fig. 4 the solid lines represent the theoretical shrinkage of dislocation loops at 275° with a self-diffusion activation energy of 2.08 eV. The initial values for r/b are found at the ordinate when the annealing time is zero and the values of r/b decrease in a homologous manner during the annealing treatment.

From this graph the change in loop sizes can be estimated for the irradiated copper single crystal 70 after annealing at 275°C for 7.9×10^5 sec. For example the loops represented by $r/b=60$ shrink to $r/b=58$; the loops of initial size $r/b=30$ shrink to $r/b=19$; and loops of initial sizes below about $r/b=26$ completely disappear after this annealing treatment.

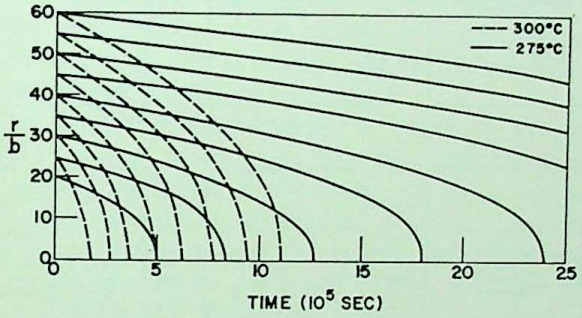

FIG. 4. Shrinkage of loops of size r/b when $E=2.08$ eV at 275 and 300°C.

A similar analysis can be made from the data in Fig. 5 where $E=2.10$ eV. With this information and the original size distribution after irradiation, a new size distribution can be estimated after an annealing treatment; these results are shown in Fig. 6. The shaded area represents the expected values for the density distribution when activation energy between 2.08 and 2.10 eV is used.

For r/b greater than 25, the experimental curve falls in the shaded region of the estimated curves, however, for low values of r/b the estimated curve rises above the experimental curve and ends in a region where $r/b\simeq15$. The differences between the experimental and estimated values of size distribution in the region where $r/b<25$ can be ascribed to the experimental difficulty in positively identifying all the small loops. Thus, the measured density values would tend to be below the theoretically estimated values which were derived from the distributions of larger loops. In addition, the theoretical description of the shrinkage of loops predicts that all loops with initial sizes $r/b<26$ will

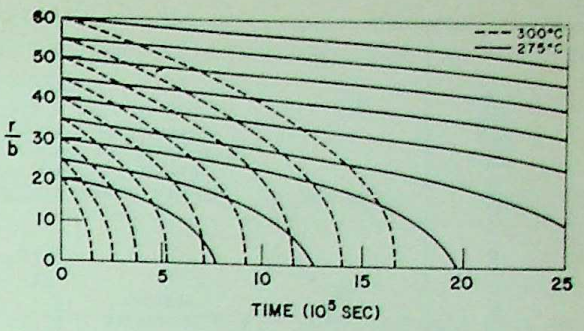

FIG. 5. Shrinkage of loops of size r/b when $E=2.10$ eV at 275 and 300°C.

disappear during the annealing treatment; consequently, the estimated curve results in a sharp cutoff. It is more probable, however, that the curve does not abruptly end, and that a maximum would occur as the measured evidence indicates. Thus, a compromise between the measured data and the calculated data is reasonable. If the same analysis is made for specimen 82 (first annealed at 225°C and then annealed at 300°C), a new distribution can be estimated which is shown in Fig. 7. As in the previous case, the new distribution has the proper form and is a reasonable fit with the actual distribution. These estimated curves of size distribution after annealing are affected greatly by the value of the activation energy E, and the best fit has been found to be between 2.08 and 2.10 eV. Other investigators have found activation energies of this magnitude for annealing irradiated copper in this

temperature range.[18,19] Makin[12] has concluded from recent experiments that the annealing of small spots is associated with an activation energy of 2.0 eV and the annealing of the large spots is associated with an activation energy of 1.0–1.5 eV. His determination was not based on the line-tension-climb relationship described by Eq. (1).

Relationship Between Volume Shrinkage and Dislocation Loops

The specific volume change $\Delta V/V_0$ for isotropic shrinkage is three times the specific length change. Comparisons between the length changes after annealing for the crystals of the orientations shown in Fig. 1 give evidence that $\Delta l/l_0$ is isotropic; hence, the specific volume changes are readily computed.

The relationships between volume change and the removal of dislocation loops from a crystal is illustrated by the schematic diagram in Figs. 8 and 9. In Fig. 8(a) the "plate of atoms" is transported from the dislocation loop to the surface, thus, increasing the volume of the crystal by the extra plate of atoms; a void equal to the

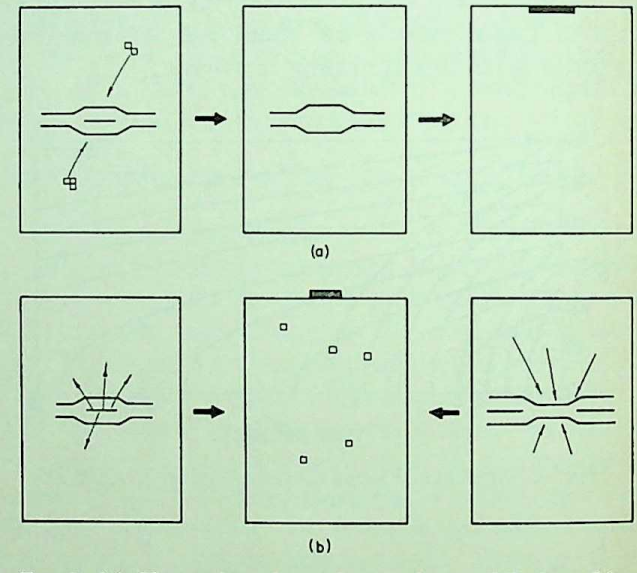

FIG. 9. (a) Change in volume due to the annihilation of interstitial loops by vacancies in the lattice; (b) dissolution of vacancy or interstitial loops.

volume of the atoms transported plus the volume of dislocation of length $2\pi r$ remain in the lattice. After a readjustment of the lattice planes, the differential volume change corresponds to the strain field associated with $2\pi r$ length of dislocation; and, consequently, a small shrinkage occurs [dark areas in Fig. 8(b)]. A similar argument is applicable for a vacancy loop and is diagrammed in Fig. 8(c). Moreover, when both vacancy and interstitial loops co-exist, the "extra plate of atoms" can replace the "plate of vacancies" if the loops are the same size or can replace portions of the vacancy loops if the loops are of different sizes; the decrease in volume is again proportional to the decrease in dislocation length [see Fig. 8(d)]. The same relationship results if loops moved out of the material by slip along the glide cylinder. The volume change due to the annihilation of an interstitial loop by vacancies which are in super-

[a] The value of $\Delta V/V_0$ (1) is based on the volume associated with the dislocation-density change after annealing.
[b] The value of $\Delta V/V_0$ (2) is based on the summation of the specific volume change in column 7 and the specific volume change associated with the reduction of the supersaturation of point defects.

saturation in the lattice is illustrated in Fig. 9(a). The over-all shrinkage is larger than shown in Fig. 8 and depends upon the area enclosed in the loop, the lattice relaxation around the vacancies or clusters of vacancies, and the volume associated with the dislocation loop. A similar analysis for vacancy loops and a supersaturation of interstitial atoms also indicates volume shrinkage. Another possible interaction between loops and point defects is shown in Fig. 9(b). In this case the loops dissolve into point defects which remain in the crystal, and thus, a volume expansion should be found. Experimentally only shrinkage was measured, and the latter process will not be considered.

The dislocation density, ρ_1, is equal to the total dislocation-loop density, ρ_0, times the circumference of an average loop, $2\pi r$. If the change in ρ_1 is compared with the specific volume change after an isothermal annealing treatment, then the volume for a unit length of dislocation can be evaluated. These data are compiled in Table III. Stehle and Seeger[20] have calculated the change in volume associated with a dislocation by applying a nonlinear model to describe the dilation. Their results indicate that the dilation is greatest in the region from one Burgers vector to the center of the core, and the volume associated with a dislocation of length b is about twice the atomic volume. These calculations were applied to straight dislocations. For dislocation loops, however, the volume per unit length of dislocation loop would be somewhat dependent upon the diameter of the loop. If the loops are considered to be prismatic, and if it is assumed that the volume per unit length is the same as in a straight edge dislocation, the specific volume change associated with the loop density change can be calculated for the various annealing treatments. The results are given in Table III. For the annealing treatments at 275 and 300°C the calculated shrinkage is about one-sixth the measure value [see columns (5) and (7)].

If the decrease in density of the loops is a result of the combination of point defects from defect clusters with the loops as shown in Fig. 9(a), then the specific volume change will be the sum of the volume of the dislocation and the volume previously occupied by the clusters. Assuming that a cluster having n point defects has a volume of $n\times$atomic volume (relaxation not considered), the $\Delta V/V_0$ derived from the experimental data of dislocation density is in good agreement with the experimentally measured values [see columns (5) and (8) in Table III].

The present and other annealing experiments[7,11,12] have demonstrated that the dislocation loops in neutron-irradiated copper will decrease in diameter during annealing until they disappear. A similar loop behavior is noted in quenched metals in regions near sinks such as grain boundaries and dislocations that are able to climb.[15] In contrast, when sinks are not available there is a tendency for loops to grow as evidenced in quenched Al–0.5 at.% Mg.[21] Since the loops decrease in size during annealing in irradiated copper, it is assumed that loops are emitting or accepting defects in such a way as to cause loops to shrink. It is expected that the rate-controlling process is diffusion; and, thus, the average distance a vacancy may move during the annealing treatments can be computed. For the 275°C anneal, the vacancy can travel about 1000 Å in 7.9×10^5 sec; this diffusion distance is too small for vacancies to migrate to the surface in bulk material. However, the dislocation loops are on the average 700 Å apart and can serve as sinks for point defects. A direct determination of the intrinsic or extrinsic nature of the dislocation loops in neutron-irradiated copper has not appeared in the literature although loops produced by α-particle[22] bombardment have been found to be interstitial. A recent electron diffraction experiment concerning loops that appear in molybdenum after neutron irradiation at elevated temperatures has shown conclusively that these loops are interstitial.[23] Makin *et al.*, on the bases of annealing experiments in which large and small spots are seen, have concluded that the large spots are interstitial loops and the small are vacancy clusters.[11,12] The nature of the dislocation loops cannot be determined from the present experiment, but the

evidence indicates that both loops and submicroscopic defect clusters exist in these neutron irradiated specimens.

SUMMARY

Copper crystals irradiated with neutrons between 50 and 70°C show the following characteristics when isothermally annealed between 75 and 350°C:

(1) A decrease in volume is detected and is proportional to the neutron exposure. The maximum specific volume changes for 1.14×10^{18} (*nvt* total epicadmium flux) and 0.532×10^{18} (*nvt* total epicadmium flux) are -3.93×10^{-5} and -2.46×10^{-5}, respectively.

(2) Measurable shrinkage of the single crystals takes place between 225 and 325°C, and the temperature where the maximum shrinkage rate occurs appears to be higher for the lower neutron dose.

(3) The change in size distribution of prismatic dislocation loops can be predicted by Eq. (1).

(4) The activation energy for the annealing process corresponds to the activation energy for self-diffusion.

(5) Dislocation loops and submicroscopic point-defect clusters are present in neutron irradiated copper.

Thermal Conductivity of Silicon and Germanium from 3°K to the Melting Point*

C. J. GLASSBRENNER† AND GLEN A. SLACK
General Electric Research Laboratory, Schenectady, New York

(Received 11 December 1963)

The thermal conductivity K of single crystals of silicon has been measured from 3 to 1580°K and of single crystals of germanium from 3 to 1190°K. These measurements have been made using a steady-state, radial heat flow apparatus for $T>300$°K and a steady-state, longitudinal flow apparatus for $T<300$°K to give absolute K values. This radial flow technique eliminates thermal radiation losses at high temperatures. The accuracy of both the low-temperature apparatus and the high-temperature apparatus is approximately ±5%. Some special experimental techniques in using the high-temperature apparatus are briefly considered. At all temperatures the major contribution to K in Si and Ge is produced by phonons. The phonon thermal conductivity has been calculated from a combination of the relaxation times for boundary, isotope, three-phonon, and four-phonon scattering, and was found to agree with the experimental measurements. Above 700°K for Ge and 1000°K for Si an electronic contribution to K occurs, which agrees quite well with the theoretical estimates. At the respective melting points of Si and Ge, electrons and holes are responsible for 40% of the total K and phonons are responsible for 60%. The measured electronic K yields values for the thermal band gap at the melting point of 0.6±0.1 eV for Si and 0.26±0.08 eV for Ge.

INTRODUCTION

IN a semiconductor, various carriers can contribute to the thermal conductivity. These are phonons, photons, electron-hole pairs, and the separate electron and holes. The problem of sorting out the contributions from these processes has been handicapped by the lack of accurate high-temperature measurements. In this paper, we report on measurements of the thermal conductivity K of single crystals of germanium and silicon between 300 and 1580°K taken with an improved cylindrical heat flow apparatus. The measurements of K of silicon below 300°K have been taken with an existing longitudinal heat flow apparatus.[1] Germanium and silicon were measured because they are easily obtained with high purity and known electrical characteristics. As a consequence of this investigation, they could serve as standard materials for K measurements.

The purpose of this investigation was to measure and analyze the K of these materials up to the melting point and, in particular, to unravel the magnitude of the contributions from the various carriers of heat. It was found that the phonon or lattice thermal conductivity is dominant and decreases faster than $1/T$ at high temperatures. The bipolar thermal conductivity, i.e., from electron-hole pairs, is significant at high temperatures and agrees with a simple theory. The polar thermal conductivity, i.e., from the separate electrons and holes, is small, and the photon thermal conductivity is not detectable.

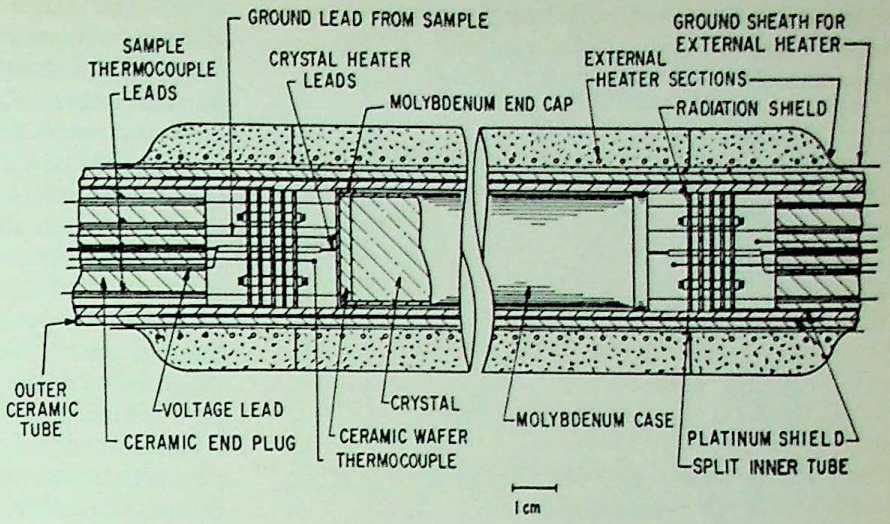

FIG. 1. The high-temperature radial heat flow apparatus showing the crystal sample, heater, thermocouples, and shields.

CRYSTAL SPECIFICATIONS AND PREPARATIONS

A. Low-Temperature Silicon Crystal

The silicon single crystal used for the low-temperature measurements was grown by the pedestal method from a bar of high-purity silicon by W. C. Dash of this laboratory. The growth direction was [111]. It was made with care in order to be oxygen and dislocation free.[2–4] Any vacancy clusters were less than one micron in diameter as determined by etchpit and copper decoration techniques. The pedestal method prevents the silicon from coming in contact with quartz, usually the chief source of oxygen. The crystal was 2 cm long with a geometrical average diameter of 0.44 cm. The diameter varied slightly along the length of the sample. The cross section could be best described as an equilateral triangle with rounded corners, typical of [111] oriented crystals. The room-temperature resistivity was approximately 2000 Ω-cm, and the sample was p type.

B. Crystals Used at High Temperatures

The silicon and germanium samples were both single crystals, cylindrically shaped, approximately 13 cm long by 2.6 cm in diameter. They had on the order of 10^5 dislocations[5] per cm^2. The Ge crystal was grown by the Čzochralski method with a [100] axis from a charge of zone-refined germanium. The room-temperature resistivity of the charge material was greater than 40 Ω-cm which indicates that it was basically intrinsic. The dominant impurity in the charge was specified as antimony. The single crystal of silicon was produced by the floating zone process. The atmosphere was argon and the axis of the cylinder was [111]. The diameter of the "as-received" crystals varied slightly along the axis. Their crystal faces were clearly visible.

A rather elaborate machining operation was used on the crystals in order to insure that the axial heater was exactly in the center of the sample and that the thermocouples were at exactly known positions along the radii. These physical conditions imposed on the heater and thermocouples were solved by cutting the sample into two exactly equal half-cylinders. For this purpose, the original single crystal was centerless, ground to a uniform diameter and carefully cut lengthwise into two approximately equal halves. The flat side of each half-cylinder was given an optically flat polish so that the halves would fit tightly together. Thermocouple grooves were then cut in one of the halves. The nominal radial distances of the center line of the three thermocouple grooves from the axis were: 2.5 and 10 mm on one side of the heater groove, and 6.5 mm on the other side. A heater groove was cut along the axis of each half so that the heater would be in the center of the assembled cylinder. After the grooves were cut, the two halves were temporarily cemented together, but were offset slightly along the longitudinal axis. They were centerless ground a second time so that the interfacial plane and heater wire passed through the center of the cylinder.

After the machining, the sample was assembled and encapsulated in a molybdenum case with a high-purity Al_2O_3 ceramic wafer placed at each end. See Fig. 1. Molybdenum was used because it does not form any low melting alloys with either Si or Ge. Neither the Mo nor the Al_2O_3 contributes electrically active impurities to the Si or Ge in significant amounts during the lengthy, high-temperature runs.

The intrinsic electronic K could be suppressed if, inadvertently, the material became highly doped to a level of about 10^{18} carriers/cc. As a check on the impurity concentration, the electrical conductivity and Hall coefficient of the germanium and silicon samples were measured before and after the high-temperature measurements. Before use the room-temperature resistivity of the germanium crystal was 46.6 Ω-cm, and the

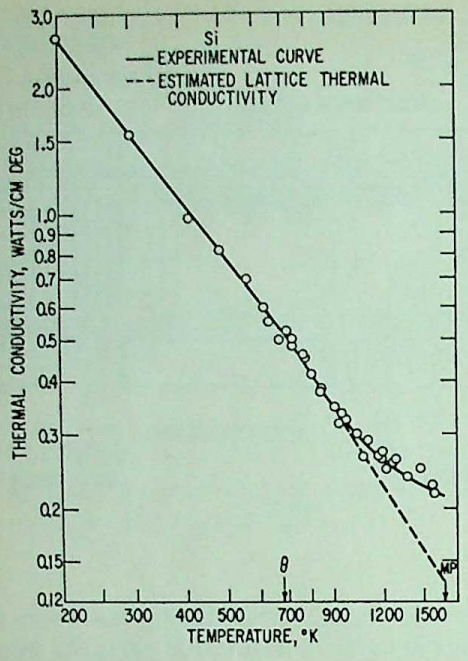

FIG. 2. K versus T for Si showing the experimental points and the extrapolated lattice component K_g. The Debye and melting temperatures are θ and MP, respectively.

net carrier concentration was 2×10^{12}/cm^3. The crystal was so lightly doped that it could not be well characterized as either n- or p-type. After the K had been measured to near the melting point, the electrical resistivity dropped to 4.6 Ω-cm and the crystal was now doped with 8×10^{15} acceptors/cm^3. These acceptors were identified as copper. The copper was probably introduced during the machining of the germanium sample prior to the measurements.

The room-temperature resistivity of the high-temperature silicon sample was 440 Ω-cm with a carrier concentration of 1.27×10^{13}/cm^3 and it was n type. After the K had been measured to near the melting point of silicon, the room-temperature resistivity dropped to 177 Ω-cm, the carrier concentration rose to 2.46×10^{13}, and it was still n type. The specific impurities could not be identified. The important conclusion from these measurements is that neither the germanium nor silicon contained enough electrically active impurities to affect the intrinsic polar or bipolar thermal conductivity in any way.

APPARATUS

The low-temperature measurements were made with a steady-state, longitudinal heat flow apparatus designed by Slack.[1] The final form of the high-temperature, cylindrical-flow thermal conductivity apparatus was obtained after several modifications. Figure 1 shows the details of the sample in the final version of the high-temperature apparatus. A more detailed description of the entire method and apparatus will be published elsewhere later. The central section of the apparatus is shown in Fig. 1. The vacuum plumbing was designed so that the sample chamber could be evacuated to 10^{-6} Torr and then filled with ultra-pure helium. The outer ceramic tube serves as the wall of the vacuum chamber for the sample. The external, 3-section electric heater is wound on this tube, and serves to control the average temperature of the sample. The split inner tube holds the sample and all of the removable parts, i.e., thermocouples, heaters, shields, etc., in place.

The cylindrical geometry for measuring the high-temperature thermal conductivity was chosen for reasons previously stated.[6] In the present, more thorough measurements, certain experimental problems arose which will now be given a cursory examination. Ultra-pure helium gas was used for the atmosphere, because it contained a low oxygen content,[7] and thus there were no oxidation problems at high temperatures. The gas served to provide good thermal contact between the sample and the heater and thermocouple wires. The gas also partially helped to suppress the vapor transport of Si and Ge, which would be appreciable at high temperatures in a vacuum. The molybdenum jacket which encased the germanium and silicon reduced the exposed surface area of the samples and hence further reduced the evaporation. This case also held the halves together. Molybdenum was employed for the jacket, axial heater wire, voltage leads, and heater leads because of its previously mentioned chemical stability. The temperature gradients were measured with platinum versus platinum-10% rhodium because these thermocouples are very stable with time and possess well-

known calibration curves. However, they have a very small emf output and are subject to contamination problems unless carefully used. The thermocouples and axial crystal heater were insulated from the sample by Degussit[8] alumina tubing because it is a very pure ceramic, and is available in very small diameters. It does contain a small amount of iron and silicon, i.e., about 300 ppm. The radiation shields were made from platinum −40% rhodium. These served to keep heat losses from the end of the sample low. They also served as vapor barriers for germanium and silicon vapor coming from the sample. The external heater winding was made in three sections so that both the temperature gradient along the axis of the apparatus near the ends of the sample and the average temperature of the sample could both be controlled. A ground sheath was placed under the external heater to reduce stray electrical leakage currents. The ceramic end plugs were installed to hold the electrical wires in place and to reduce axial heat conduction by the gas. They also helped to protect the thermocouple wires in the temperature gradient from the silicon and germanium vapors.

The electrical heater power to the sample was furnished by either dc or ac. Direct current was used below about 750°K and ac was used (about 435 cycles/sec) at higher temperatures. Due to the lower electrical resistance of the Si, the Ge, and the Al_2O_3 at high temperatures, a small leakage voltage from the crystal heater always appeared in the thermocouples above about 850°K. This leakage was rendered harmless by use of ac since any small 435-cycle ac voltage was not recorded by the thermocouple galvanometer. To insure that the temperature gradient was measured accurately, a few special measuring techniques were employed. Since no two thermocouples are exactly alike, two of the three thermocouples inside the sample were always calibrated in terms of the third when the sample was in an isothermal condition. Checks on the presence of possible thermocouple contamination were made in two ways. First the high-temperature K data points were always followed by a reconfirmation of lower temperature K points at about 400°K. Secondly, variations in the axial temperature gradients in the apparatus at and beyond the radiation shields were intentionally produced by the end windings on the external heater. These variations should not affect the measured K. Any apparent effect meant contaminated thermocouples. Discrepancies of these types resulted in rejection of the high-temperature data, and a reassembly of the entire apparatus with new thermocouples. The final results for both Si and Ge each involved several such reassemblies.

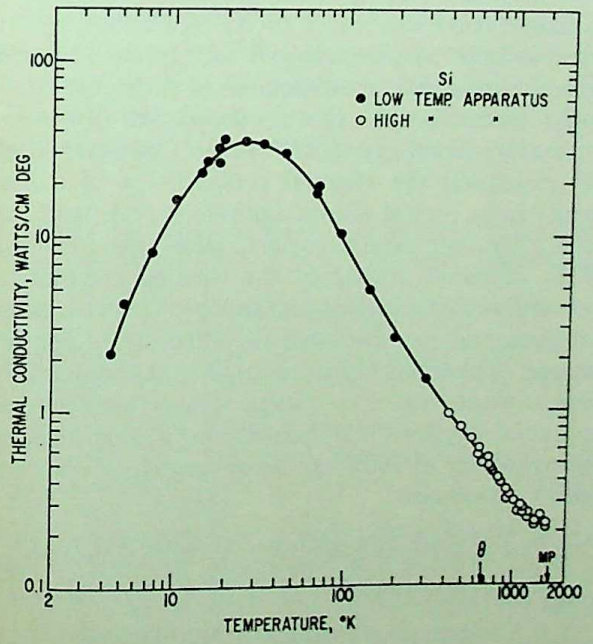

FIG. 4. The low- and high-temperature K versus T results for Si.

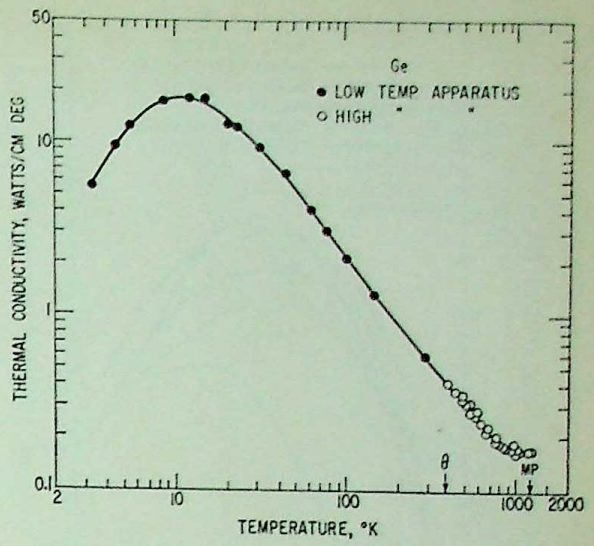

FIG. 5. The low- and high-temperature K versus T results for Ge.

Under steady-state operating conditions between 30 and 50 W of electrical power was furnished to the crystal heater. This is equivalent to about 4 W/cm of sample length. The average temperature differences between the center and surface of the sample ran between 1 and 3°K. The heater wire temperature usually operated between 50 and 100°K above the sample temperature.

RESULTS

The results of the present investigation of the high-temperature K of Si and Ge are shown in Figs. 2 and 3. The composite results for single crystal Si are shown in Fig. 4. Notice that the low-temperature results (solid circles) join on smoothly to the high-temperature results (open circles). Both sets of data were obtained in their respective apparatuses as absolute thermal conductivity values, and neither set of data has been adjusted to match the other. The actual data points in the low-temperature set span the temperature range from 4.3 to 304°K, while the high-temperature points cover the

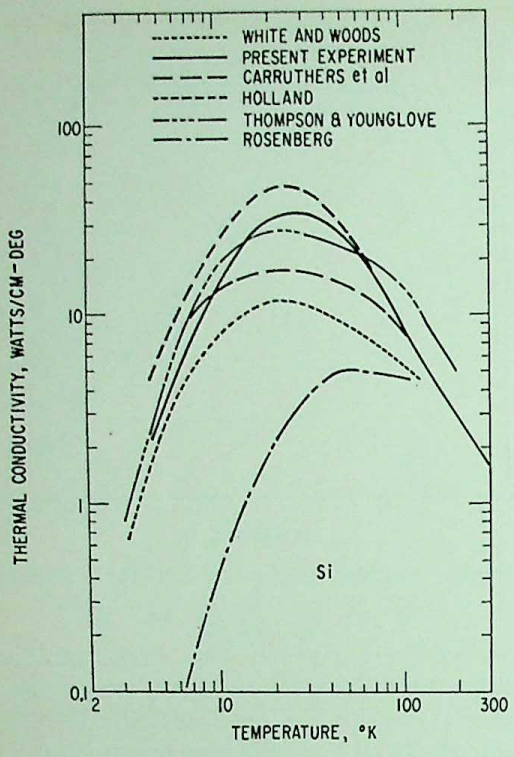

FIG. 6. Comparison of present and previous low-temperature K versus T results for Si.

418 to 1577°K range. The Debye temperature of Si at 674°K is shown for scaling purposes. The melting point, MP, of silicon at 1681°K is only 104°K above the highest point measured.

The results for single crystal Ge are shown in Fig. 5. The points for temperatures between 3.2 and 300°K have been taken from Slack and Glassbrenner.[6] The high-temperature data points between 398 and 1194°K were measured in the present high-temperature apparatus. Neither set of data was adjusted, and again the agreement between the low-temperature and high-temperature data is very good. The Debye temperature θ of Ge is 395°K. These results approach to within 16°K of the melting point, MP, of Ge at 1210°K. The absolute accuracy of both the high- and low-temperature results is computed to be ±5%, while the relative accuracy of any two points measured on the same sample is ±2%. Table I gives smoothed values for the K of Si and Ge. The low-temperature region where K depends on sample size has been excluded.

PREVIOUS DATA

A. Silicon Below 300°K

A comparison of the present and previous low-temperature K measurements of silicon below 300°K is shown in Fig. 6. Except for the measurements by Thompson and Younglove, all of the measurements agree quite well above 100°K. Some of the variation in K below 100°K is accounted for by boundary scattering in different size samples. However most of the variation in Fig. 6 is caused by phonon scattering from impurities and other crystalline defects. The earliest report of thermal conductivity measurements of silicon at low temperatures of which the authors are aware was made by Rosenberg.[9] He measured a polycrystalline silicon sample over the temperature range 2 to 100°K, and employed gas thermometers to measure the temperature gradient during steady-state heat flow. Scattering by the grain boundaries in his polycrystalline sample is probably the reason that Rosenberg's K results are much lower than any of the others. White and Woods[10] have measured a single crystal silicon sample (room-temperature resistivity 6.7 Ω-cm) over a temperature range of 2 to 100°K. The impurities present in this sample were not stated. Thompson and Younglove,[11] in the temperature interval 2 to 200°K, have measured several samples of silicon doped with boron or arsenic. Figure 6 shows their measurement of their most highly doped silicon sample (boron doped with a room-temperature resistivity of 2000 Ω-cm). Carruthers *et al.*[12] have measured the thermal conductivity of a high-purity single crystal silicon sample, n type from 2 to 300°K. The net carrier concentration was 5×10^{14} at 300°K. Holland[13] measured the thermal conductivity of several silicon samples containing different amounts of oxygen and has discussed the effect of oxygen as a scatterer of phonons to reduce the thermal conductivity. His measurements of an n-type sample with the least amount of oxygen ($<10^{16}$ cm^{-3}) and a room-temperature resistivity of 260 Ω-cm agree very closely with the present experiment.

B. Above 300°K

Various previous authors have measured the K of Si and Ge over part of the high-temperature range studied here. Consider Si first. Figure 7 shows how the present results on Si for $T>300$°K compare with some of the better previous data. The earliest K data on Si that has been reported is that of Koenigsberger and Weiss[14] in 1911 who found 0.84 W/cm deg at 290°K for an impure sample. Later authors,[13–24] who have measured K as a function of temperature for $T>300$°K, are listed in Table II. The recent values of K determined by Shanks *et al.*[23] from thermal diffusivity measurements are about 10% lower than the present ones between 300 and 900°K, and 20% higher at 1400°K. The absolute accuracy of the K values in the present experiment is ±5%, and this same limit of error seems to be present in the data of Shanks *et al.*, as judged from the scatter of the points and the size of the samples used. Thus the 10% difference is just within the combined limit of error. The almost temperature-independent K found by Shanks *et al.* for $T>1000$°K, however, is not confirmed. The K of Si continues to decrease with increasing temperature up to 1580°K, The high-temperature heat-capacity data used by Shanks *et al.* is in reasonably good (±2%) agreement with that given by Kelley,[25] so the conversion from thermal diffusivity to K should be accurate. The reason for the discrepancy in K determined by these two different methods is not as yet understood. The K results of Abeles *et al.*[21,22] from 310 to 1200°K, also determined from thermal diffusivity measurements, fall between the present curve and that of Shanks *et al.*

In reviewing the literature on the K of Ge it can be seen that the early measurements on Ge by Greico and Montgomery[26] gave $K=0.59$ W/cm deg at 298°K, in good agreement with the present value of 0.60 W/cm deg at 300°K. The temperature variation of K of Ge for temperatures near or above room temperature has been measured by many investigators. These are listed[6,21,22,26–36] in Table II. Some of these K versus T curves for Ge are shown along with the present results in Fig. 8. The agreement of the older results with the present ones is to within ±20% at 300°K, but becomes increasingly poor at the higher temperatures. The very abrupt rise in K suggested by the authors[6] in 1960 is not confirmed. The change in slope is much more gradual. The large range of values for K of Ge above 700°K found in the other curves in Fig. 8 can be attributed to experimental difficulties in measuring and controlling the thermal radiation losses. The K values deduced from thermal diffusivity measurements by Abeles *et al.*[21,22] are not subject to this source of error, and the agreement of these results with the present ones between 500 and 1070°K is very good. The 10% discrepancy between the present results and those of Abeles *et al.* at 300°K is about at the outer limits of accuracy

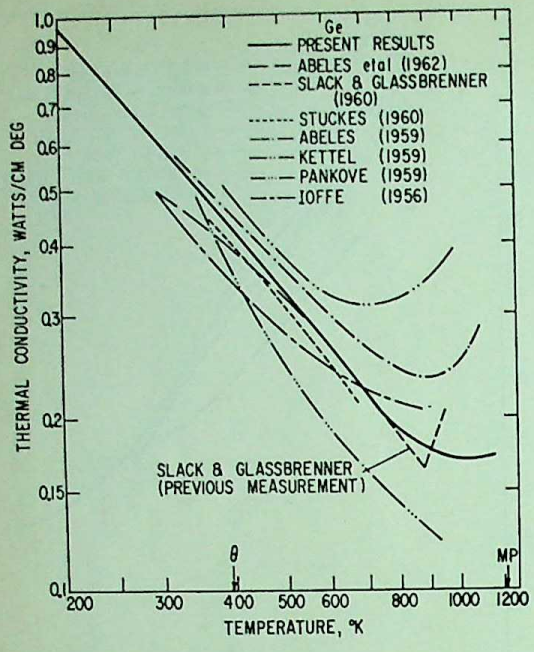

FIG. 8. Comparison of present and previous high-temperature K versus T results for Ge.

of the two experiments. The reason for this probably real discrepancy is not completely understood.

INTERPRETATION OF LOW-TEMPERATURE MEASUREMENTS

In the temperature range below 300°K, the K results on Si and Ge can be interpreted using Callaway's formalism.[37–39] The K due to heat transport by phonons is given by

$$K=\frac{k}{2\pi^2 v}\left(\frac{kT}{\hbar}\right)^3\int_0^{\theta/T}\tau_C(x,T)\frac{x^4e^x}{(e^x-1)^2}dx, \qquad (1)$$

where k = Boltzmann's constant, v = average sound velocity, T = absolute temperature, h = Planck's constant, θ = Debye temperature, $x=(\hbar\omega/kT)$, ω = phonon frequency, and τ_C is a combined relaxation time. The complicating effects[37] of normal phonon scattering have been neglected. The combined relaxation time is thus taken as

$$\tau_C^{-1}=\tau_B^{-1}+\tau_I^{-1}+\tau_U^{-1}, \qquad (2)$$

where τ_B, τ_I, τ_U are the relaxation times for boundary, isotope, and umklapp scattering of the phonons.

The particular form of the relaxation times shall now be examined. Klemens[40,41] has derived a relaxation time for scattering by point imperfections. His results are valid for isotope scattering.

$$\tau_I^{-1}(\omega)=3V_0\Gamma\omega^4/\pi v^3, \qquad (3)$$

where V_0 = average volume per atom in the crystal, and Γ = point impurity scattering parameter.[42] For umklapp scattering the following semiempirical expression[43] will be used:

$$\tau_U^{-1}=B_U\omega^2T. \qquad (4)$$

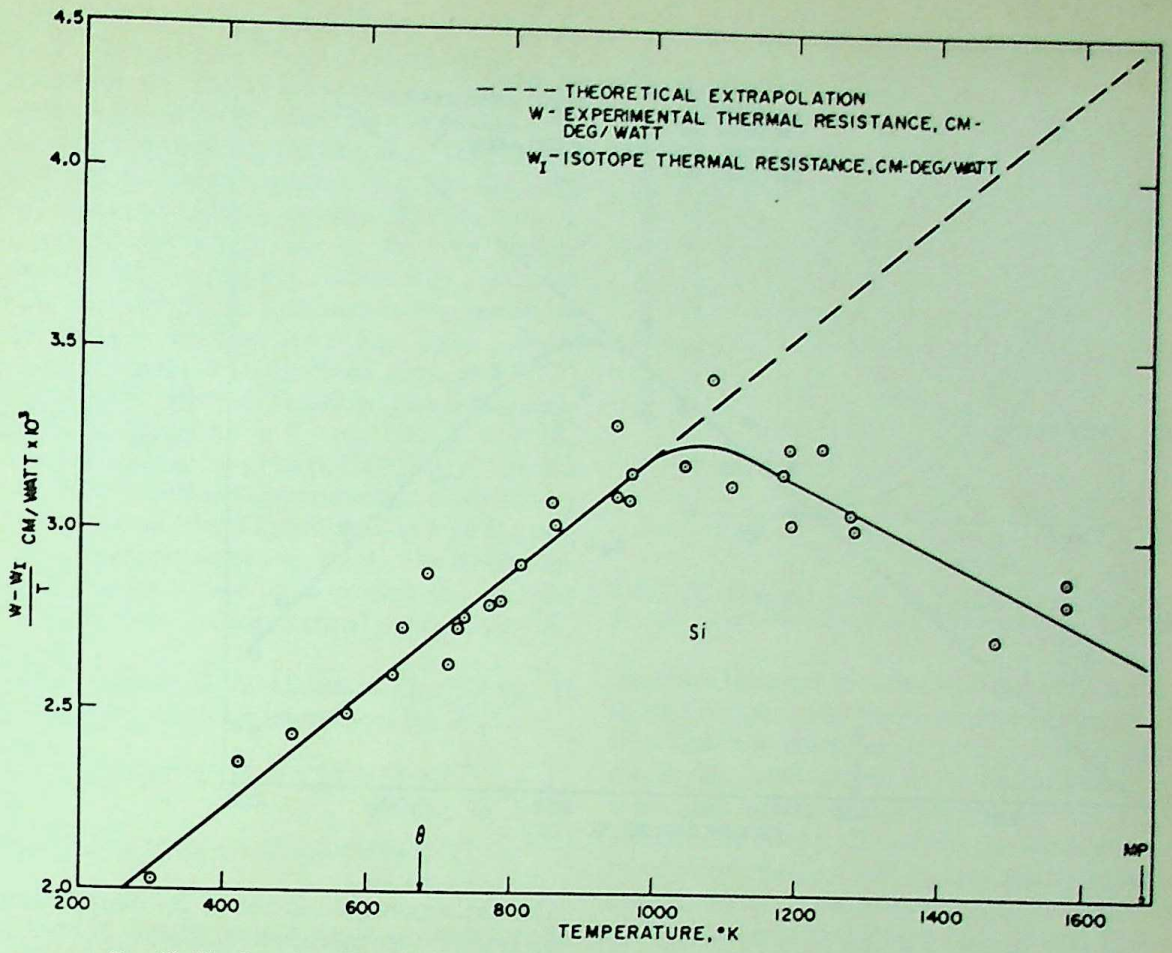

FIG. 10. The function $(W-W_I)T^{-1}$ versus T for Si as a means of determining the extrapolated lattice thermal resistivity at high temperatures.

Here B_U has the approximate value[43] of

$$B_U \sim (h\gamma^2/2\pi m\theta v^2) \exp(-\theta/3T), \quad (5)$$

where γ = Grüneisen's constant assumed to be equal to 2, and m = average mass of a single atom. For boundary scattering the relaxation time for diffuse scattering of the phonons off the walls of the crystal is simply

$$\tau_B^{-1} = v/L, \quad (6)$$

where L is the average diameter of the crystal. For Si these various relaxation times have been included in the K expression given in Eq. (1) using the following values: $v = 6.4\times10^5$ cm/sec, $\theta = 674$°K, $V_0 = 1.99\times10^{-23}$ cm^3, $\Gamma = 1.65\times10^{-5}$, and $L = 0.44$ cm. The results of the calculations for various combinations of relaxation times are shown in Fig. 9 for Si. It can be seen that all three relaxation times must be used in order to obtain agreement between theory and experiment. The theoretical curve with all three scattering processes included gives a maximum K of 56 W/cm deg at 28°K for Si compared to the observed maximum of 39 W/cm deg at 25°K. The fit at lower K values is rather better. In view of the simple model used for deriving Eq. (1) such agreement is considered reasonable. A similar sort of analysis has been carried out by other authors[6,37] for Ge at low temperatures, where the agreement is even better. Some improvement in the fitting of the theory to experiment can be made by including the effects of both the transverse and longitudinal phonon branches and the effects of phonon dispersion.[44] These added complications will not be considered here. The primary conclusion to be drawn from the low-temperature results for $T<300$°K is that phonons are the only significant carriers of the thermal energy, and they are scattered by other phonons, isotopes, and the crystal boundaries. Other carriers of thermal energy do, however, become important for $T>300$°K.

INTERPRETATION OF HIGH-TEMPERATURE MEASUREMENTS

Lattice Thermal Conductivity

In the present context high temperature means $T>300$°K. In this region it is necessary to consider photons and electrons and holes as well as phonons as possible carriers of thermal energy. We shall assume that these various carriers interact only weakly so that their contributions to the thermal conductivity are additive.

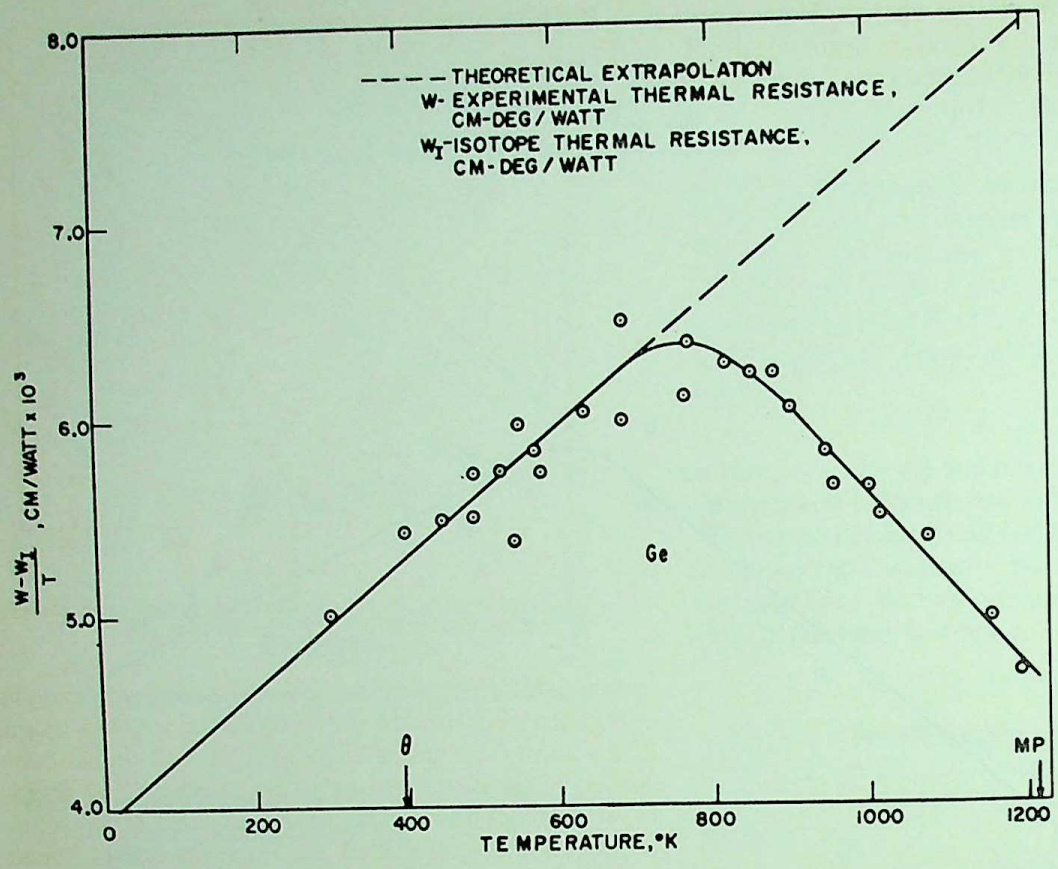

FIG. 11. The function $(W-W_I)T^{-1}$ versus T for Ge as a means of determining the extrapolated lattice thermal resistivity at high temperatures.

Thus

$$K=K_g+K_e+K_r, \tag{7}$$

where K_g is the phonon, K_e is the electronic, and K_r is the radiative or photon contribution to K.

Let us first consider the lattice thermal conductivity K_g. At high temperatures we have to consider the relaxation times τ_I and τ_U given in Eqs. (3) and (4), but we can neglect τ_B in Eq. (6). Equation (4) gives the relaxation time for 3-phonon umklapp processes. However, for $300°K<T<1681°K$, we are in the range of T comparable to or greater than the Debye temperature θ for both Si and Ge. In this range, it may be necessary to consider the relaxation times for four-phonon processes, as Pomeranchuck[45–47] has pointed out. He gives a relaxation time for these higher order (H) processes as:

$$\tau_H^{-1}=B_H\omega^2T^2, \tag{8}$$

with B_H a constant. K_g can be evaluated for $T>\theta$ from Eqs. (1), (3), (4), and (8) if τ_C^{-1} is taken as

$$\tau_C^{-1}=\tau_U^{-1}+\tau_H^{-1}+\tau_I^{-1}.$$

In the region where $T>\theta$ the quantity x in Eq. (1) is small, and the integral simplifies to

$$K=\frac{k}{2\pi^2v}\left(\frac{kT}{\hbar}\right)^3\int_0^{\theta/T}\tau_C x^2dx. \tag{9}$$

Also the exponential factor in B_U disappears to make B_U temperature-independent. Thus

$$\tau_C^{-1}=(B_UT+B_HT^2)\omega^2+A\omega^4. \tag{10}$$

For $T\geq\theta$ the isotope scattering is much less important than the phonon-phonon scattering. In this limit Eqs. (9) and (10) can be reduced by the method used by Ambegaokar,[48] to

$$K_g^{-1}\equiv W_g=W_U+W_H+W_I,$$

where

$$\begin{aligned} W_U&=\pi vhB_UT/\theta k^2,\\ W_H&=\pi vhB_HT^2/\theta k^2,\\ W_I&=4\pi^2V_0\theta\Gamma/hv^2. \end{aligned} \tag{11}$$

This reduction requires $W_g\gg W_I$. This condition is fulfilled for Si and Ge at high temperatures. The only really unknown quantity in Eq. (11) is B_H. The quantities B_U and B_H can be evaluated experimentally from a plot of $(W_g-W_I)T^{-1}$ versus T. The quantity W_I is, except for a difference of a factor of 12 in the definition of Γ, the same as that given by Ambegaokar.[48] For Si one obtains $W_I=0.033$ cm deg/W. For Ge the value is $W_I=0.17$ cm deg/W using $V_0=2.26\times10^{-23}$ cm^3, $\theta=395°K$,[49] $\Gamma=4.90\times10^{-5}$,[50] and $v=3.94\times10^5$ cm/sec.

The determination of W_g is the next problem. Consider Eq. (7). As has been shown,[6] K_r is negligible at all temperatures for Ge. The measurements of Ukhanov[51] on the optical absorption of Si and Ge at elevated temperatures were employed to calculate K_r. This calculation shows that K_r is also negligible (i.e., less than 2% of total K) for Si at all temperatures. The K_e term in Eq. (7) becomes important only at the very highest temperatures when the number of thermally generated carriers becomes very large. This term is responsible for the upturn in the K results shown in Figs. 2 and 3 above 800°K. Thus K_g is the only significant term in Eq. (7) for $T<800$°K in Si and Ge. Therefore, the total measured thermal conductivity is $K=W_g^{-1}$ for $T<800$°K. Figures 10 and 11 show the plots of $(W-W_I)T^{-1}$ versus T for Si and Ge. The linear approximation predicted by Eq. (11) is satisfactory for $T\geq 0.5\theta$ until at high temperatures the K_e term becomes important. The dashed extrapolations in Figs. 10 and 11 show what the behavior would be if only the lattice thermal conductivity K_g were present.

The linear portions of the curves in Figs. 10 and 11 yield the following empirical expressions for W_g:

$$\begin{aligned}&\text{Ge:}\quad W_g=(3.95\times10^{-3}T+3.38\times10^{-6}T^2+0.17)\ \text{cm deg/W},\\&\text{Si:}\quad W_g=(1.56\times10^{-3}T+1.65\times10^{-6}T^2+0.03)\ \text{cm deg/W}.\end{aligned}\tag{12}$$

The first term in these equations yields an experimental value of B_U which agrees with that estimated from Eq. (5) to within a factor of two for both Si and Ge. Such agreement is quite satisfactory. If the very approximate theory used in obtaining Eq. (11) is taken at face value, the results in Eq. (12) for B_H show that the ratio τ_H/τ_U is 3 for Ge and 1 for Si at $T=\theta$. This ratio becomes smaller at higher temperatures. Notice that we have chosen to interpret the observation that K_g for Si and Ge at high temperatures decreases faster than T^{-1} as a sign that 4-phonon processes are taking place. A similar conclusion has been arrived at by Stuckes[19] and by Steigmeier and Kudman[52] for various IV and III-V semiconductors. The result that the 3-phonon and 4-phonon relaxation times, τ_H and τ_U, are nearly equal at $T=\theta$ should, however, be greeted with some caution. The main purpose of the plots in Figs. 10 and 11 is to allow one to make a reasonable extrapolation of K_g in the temperature region where K_e is appreciable.

This extrapolation of K_g from Figs. 10 and 11 has been replotted as the dashed curve in Figs. 2 and 3. The difference between this curve and the experimental results is, from Eq. (7), just K_e. These experimental values of K_e for Si and Ge are plotted in Figs. 12 and 13.

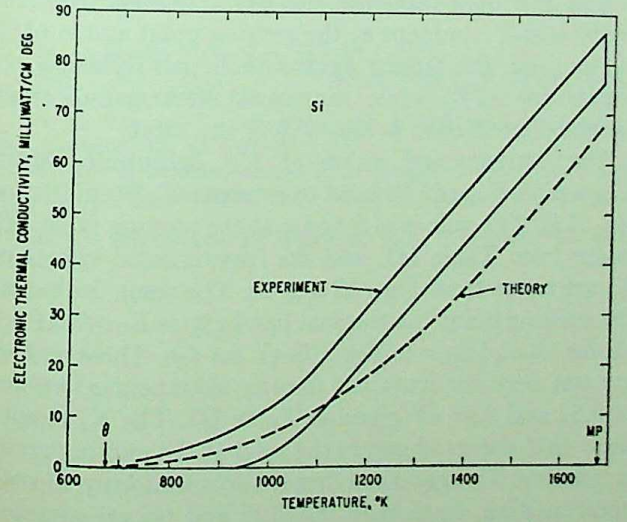

FIG. 12. Comparison of the experimental and theoretical electronic thermal conductivity, K_e versus T, for Si.

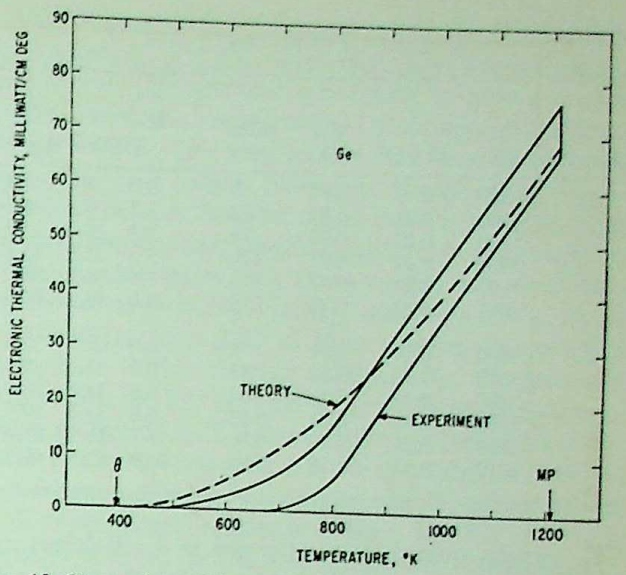

FIG. 13. Comparison of the experimental and theoretical electronic thermal conductivity, K_e versus T, for Ge.

Electronic Thermal Conductivity

The experimental results for K_e can be compared with the theory that has been developed by Davydov and Shmushkevitch,[53] by Price,[54] and by Drabble and Goldsmid.[55] Their results for K_e can be written as the sum of an electronic polar contribution K_{ep}, and an electronic bipolar part K_{eb}.

$$K_e=K_{ep}+K_{eb},$$

where

$$\begin{aligned}K_{ep}&=2\left[\frac{k}{e}\right]^2\sigma T,\\K_{eb}&=\frac{b}{(1+b)^2}\left[\frac{E_G}{kT}+4\right]^2\left[\frac{k}{e}\right]^2\sigma T.\end{aligned}\tag{13}$$

	1210	0.16	0.25	890.	16.0	52.5	68.5

The various quantities are defined as k=Boltzmann's constant, e=electronic charge, σ=total electrical conductivity at T, b=mobility ratio at T, and E_G=indirect energy gap at T. The polar part K_{ep} is the usual Wiedemann-Franz-Lorenz contribution present in metals. The bipolar part K_{eb} is a property of semiconductors, and is caused by electron-hole pairs with energy E_G diffusing down the temperature gradient. Equation (13) has been derived for a very idealized semiconductor which is assumed to be intrinsic, to possess simple parabolic valence and conduction bands, and in which the charge carriers suffer only acoustic mode lattice scattering where the scattering probability varies with the carrier energy e as $\sqrt{e}$. Neither Si nor Ge can be said to fit this model very well since they have multiple minima conduction bands, multiple valence bands, and since both acoustic mode and intervalley scattering occur. An exact calculation of K_e in which all of these effects are considered is not undertaken here. However, as will be seen, Eq. (13) yields predictions which are in reasonable agreement with the experiment.

The experimental parameters that are used in Eq. (13) are σ, b, and E_G. Representative values for these parameters and the calculated values for K_{ep} and K_{eb} are given in Table III. For Si, the $\sigma(T)$ values have been taken from Morin and Maita[56] and Mokrovskii and Regel,[57] and the values of b versus T have been estimated from an extrapolation of the mobility curves of Morin and Maita.[56] The $E_G(T)$ values[56] have been corrected for more recent values of the effective mass, and are taken from Hannay.[58] It has been assumed that E_G varies linearly with temperature and the value of $E_G=(1.21-4.1\times10^{-4}T)$ eV was used.

For Ge the $\sigma(T)$ values have been taken from Morin and Maita,[59] from Epstein,[60] and from the recent compilation of Hamilton and Seidensticker.[61] The values of b versus T have been estimated from an extrapolation of the data given by Morin and Maita.[59] The $E_G(T)$ values[59] have been corrected for better effective mass values.[58] The equation used for Ge was $E_G=(0.785-4.4\times10^{-4}T)$ eV. The computation of K_{ep} depends only on σ and is probably accurate to $\pm5\%$. The computation of K_{eb} depends similarly on σ and is also sensitive to errors in E_G and b. The over-all accuracy in the calculation of K_{eb} is estimated to be $\pm15\%$. Figures 12 and 13 show how the calculated theoretical value of K_e compares with the experimental determination, which is judged to be accurate to within ±5 mW/cm deg. This uncertainty is indicated by the broad band in Figs. 12 and 13. Since the theoretical values of K_e are probably accurate to $\pm15\%$, the agreement with theory is considered quite adequate. In view of the uncertainties in both the calculated and experimental values of K_e it does not seem worthwhile, at present, to undertake a more exact calculation of K_e in which the details of the band structure of Si and Ge are carefully taken into account.

TABLE IV. The experimentally determined contributions to K in solid Si and Ge at their respective melting points.

Quantity	Si 1681°K	Ge 1210°K
K_{ep}/K	5%	9%
K_{eb}/K	32%	32%
K_g/K	63%	59%
K (W/cm deg)	0.22	0.17

The three contributions to the total thermal conductivity, K_{tot}, at the melting point are K_g, K_{ep}, and K_{eb}. Table IV shows the relative contributions of these three terms for Si and Ge. K_g is estimated from the extrapolated dashed curve in Figs. 2 and 3, K_{ep} is calculated form Eq. (13), and K_{eb} is taken to be equal to $K_{tot}-K_g-K_{ep}$. For both materials the lattice thermal conductivity is still dominant at the melting point and is 61% of the total, the bipolar electron-hole pair diffusion accounts for 32%, while the usual Wiedemann-Franz-Lorenz contribution is only 7% of the total.

The experimental value of K_{eb} determined from $K_{tot}-K_g-K_{ep}$ can be used to estimate E_G by means of Eq. (13). The values of b and σ at the melting point are taken from Table III, and the experimental values of K_e are taken from Figs. 12 and 13. The result is that at the melting point the thermal band gap is $E_G=0.6\pm0.1$ eV for Si and $E_G=0.26\pm0.08$ eV for Ge. These values are not very far from the linearly extrapolated values of 0.52 and 0.25 eV given in Table III. The K_e results show that the band gap in the solid at the melting point is nonzero. The gap thus drops discontinuously to zero upon melting, since both liquid Si and Ge are metallic in character.[57,61]

MAGNETIC FIELD EFFECTS

The electronic contribution to the K of Ge is about 40% of the total at 1175°K, a temperature 35°K below the melting point. An attempt was made to alter this electronic contribution by applying a moderate magnetic induction in a direction perpendicular to the axis of the K sample. Magnetic induction strengths (MKS units) up to 0.6 Wb/m² (6000 G) were applied, but no effect on K was observed to within ±2%. Steele[62] found that values up to 1.15 Wb/m² had no effect on the K of Ge at 278°K. Here the estimated $K_e=K_{ep}+K_{eb}$ is only 4×10^{-4}% of the total K for intrinsic Ge. His experiment was not sufficiently sensitive to see changes this small even if the magnetic induction had been sufficiently strong to suppress K_e. Magnetic effects on K have been seen in HgSe,[63] Bi_2Te_3,[64] and InSb.[65,66] The requirement on the magnetic induction is that it must be large enough so that the charge carriers will make about one cyclotron orbit before being scattered. This minimum value,[65] B_m, is approximately

$$B_m=\pi/\mu,$$

where B is in Wb/m², and μ is the carrier mobility in m²/V-sec. The electron mobility in intrinsic Ge at 1175°K is about 0.03 m²/V-sec, the hole mobility is even lower. The minimum magnetic induction is thus about 100 Wb/m² (10^6 G). It is rather clear why no magnetic effects were seen in Ge. No experiments on Si were tried.

CONCLUSIONS

The thermal conductivity K of silicon has been measured from 3 to 300°K using a steady-state, longitudinal heat flow apparatus. By using the relaxation times for umklapp scattering, isotope scattering and boundary scattering, and Callaway's simple model, a theoretical phonon thermal conductivity was calculated and was found to agree with the experimental measurements.

A high-temperature thermal conductivity apparatus employing steady-state, radial heat flow in a cylindrical sample was designed and was found to give accurate (±5%), absolute, measurements at temperatures from 300 to 1600°K. The method does not require any correction for heat loss by radiation. The K values so obtained agree with those found for both Si and Ge using the low-temperature, longitudinal heat flow apparatus.

The results show that phonons are the dominant carriers of heat in high purity, solid Si and Ge at all temperatures from 3°K to their melting points. The phonon or lattice thermal conductivity K_g decreases faster than the T^{-1} law predicted by three phonon umklapp scattering for $T\geq\theta$, where θ is the Debye temperature. For temperatures $T>\theta$, an approximate theoretical formula has been developed for K_g which agrees with experimental results between $0.5\theta<T<1.6\theta$. This formula is based on the assumption that three-phonon, four-phonon, and isotope scattering are important at high temperatures, and it predicts that the thermal resistivities of these three processes are additive. It is suggested that the relaxation times for both three- and four-phonon processes are comparable for $T\geq\theta$.

For temperatures above about 1.6θ an electronic thermal conductivity K_e has been found in both Si and Ge. The theoretical and experimental values of K_e agree quite well. The major part of K_e comes from the bipolar term, with some small contribution from the polar term. At the melting point the phonons contribute an average of 61% to the total K while the bipolar and polar contributions are 32% and 7%, respectively.

The thermal band gaps at the melting points are estimated from K_e as 0.6±0.1 eV for Si and 0.26±0.08 eV for Ge. They are in reasonable agreement with the linear extrapolations from lower temperatures.

ACKNOWLEDGMENTS

The authors wish to thank C. A. Reynolds and F. H. Horn for their interest in this work, and D. Hartman for his aid in obtaining the large single crystals of Si and Ge. The assistance of J. H. McTaggart in many phases of the measurements is greatly appreciated. The authors also thank M. G. Holland for a preprint of his paper on silicon and germanium, and G. C. Danielson and R. W. Powell for several interesting discussions concerning thermal conductivity measurements.

Soft X-Ray Production by 1.5-MeV Protons

W. T. Ogier, G. J. Lucas,* J. S. Murray,* and T. E. Holzer*
Pomona College, Claremont, California
(Received 31 December 1963)

Thick-target yields of x rays with wavelengths from 1.5 to 44 Å have been measured as functions of bombarding proton energy near 1.5 MeV. X-ray production cross sections computed from these yields are in satisfactory agreement with existing theoretical excitation cross-section calculations insofar as current estimates of fluorescence yields permit comparisons to be made. Yields at 1.5 MeV of the ultrasoft x rays measured were, in quanta per proton steradian: Al_K, 3.5×10^{-3}; Cu_L, 9×10^{-4}; C_K, 4.5×10^{-3}.

INTRODUCTION

INTEREST in determination of x-ray yields from proton-bombarded targets revived with the advent of scintillation counting. Extensive early investigations by Lewis, Simmons, and Merzbacher[1] and by Bernstein and Lewis[2] were followed by a number of experimental and theoretical studies. The state of the field was then reviewed and analyzed in a satisfying way for proton energies above one MeV by Merzbacher and Lewis.[3] Subsequent interest has centered on energies below one MeV for which the Born approximation does not yield completely satisfactory results.[4,5] The use of scintillation counters in these modern measurements served to limit observations to x rays with quantum energies of 4.5 keV or more.

The availability of thin-window proportional counter techniques makes possible quantitative study of yields of x rays with quantum energies at least as low as 280 eV.[6] Reports of such proton-yield measurements have only recently begun to appear.[7] In this investigation yields of a number of K and L x-ray bands with quantum energies between 8000 and 280 eV (1.5 to 44.6 Å) were measured for bombarding proton energies between 1.2 and 1.6 MeV. These yield functions are used to calculate cross sections for x-ray production at 1.5 MeV. The ratio of production cross section to excitation cross section is the fluorescence yield. Current estimates of excitation cross section and fluorescence yield both involve uncertainties in the soft x-ray region. These results do not resolve either uncertainty, therefore, but they fit well with reasonable estimates of both parameters.

EXPERIMENTAL PROCEDURE

Targets of the metals investigated were bombarded inside the main tank of the 23-in. cyclotron. This cyclotron, a prototype model, employs radial sector Thomas focusing without the usual tapering of the gap at larger radii to maintain orbit synchronism. Since the sector focusing is strong in the vertical direction for eccentric orbits as well as for symmetric orbits, a target inside the tank is exposed to a considerable spectrum of energies which can be limited somewhat by careful collimating of the incident beam at the target position. Such collimation was provided, and since negligible currents are found in the symmetric orbits at large radii, the angle of collimation was set at approximately 83° with the radial direction in order to select the more energetic eccentric orbits. The proton energy was varied by moving the target assembly radially. In the absence of computed energies, the yield of tantalum L x rays was used to calibrate the beam energy using the data of Bernstein and Lewis[2] extrapolated below 1.5 MeV with the aid of the calculations of Merzbacher and Lewis.[3] The surface of the target was set optically in each case at the angle of specular reflection between the beam direction and the radial direction along which x rays were viewed. The proton and the resulting x ray thus traveled equal distances in the target material.

The x rays were counted outside the magnetic field at the end of a 129-cm evacuated drift path by means of a flow proportional counter of standard design using P-10 gas (10% methane, 90% argon).[8] The window aperture was a single 0.063-in.-diam hole inside the vacuum, which thus subtended a solid angle at the target of 1.21×10^{-6} sr. The window material, 0.00025-in. aluminized Mylar, was bonded with epoxy cement over a slightly larger aperture set just behind the window. One corner of the Mylar was folded under to ground the aluminized surface. This structure gave good counting rates with proton currents smaller than one microampere in all cases except that of tantalum L radiation. Because of the importance of the tantalum data for calibration, it was checked using an aluminum window of larger aperture. The two runs were in very close agreement.

Yields were determined by counting the pulses corresponding to the x-ray band desired with a single-channel pulse-height analyzer while proton current was being monitored with a calibrated galvanometer. The pulses corresponding to a particular band were well resolved, but the structure within bands was not visible. The *bremsstrahlung* background was apparently very small and was ignored. In particular, in the case of carbon-K radiation a clear minimum existed in the pulse-height spectrum between the counting pulses and the amplifier noise. The discrimination level was set just above the noise. The yields reported from the x rays with quantum energy greater than the ionization potential of argon include the attenuated argon-K escape pulses.

Counter efficiencies due to window and gas absorption were computed from the measured geometry of the counter using the mass absorption-coefficient interpolations of the data of Allen by Henke, White, and Lundberg.[9] The path length in the argon was 2.26 cm. The computed efficiencies are recorded in the first column of Table I. The transmission factor of the Mylar for carbon-K radiation was thus estimated to be 0.04. This transmission was checked experimentally by placing a second layer of the same material in the x-ray path in the vacuum. The measured transmission varied from place to place in the film. The value adopted was 0.038 ± 0.01.

EXPERIMENTAL RESULTS

The yields of x rays, Y_μ, in quanta per proton steradian at 1.5-MeV bombarding energy are given in the second column of Table I and the yields as functions of bombarding energy are presented graphically in Fig. 1. Considerable uncertainty lies in the determination of proton energy, since the collimated proton beam had a spread in energy of some 0.2 MeV and the energy calibration below 1.5 MeV is based on extrapolation. The curves for tantalum-L and iron-K radiation both fit well the results of Merzbacher and Lewis,[3] but there is a sizable discrepancy in the data for titanium K. In the preliminary phases of this work the yields from various titanium targets were compared with those from tantalum and iron, always with essentially the results reported.

TABLE I. Data at 1.5 MeV.

	Counter efficiency	Y_μ quanta / proton·sr	μ/ρ	σ_x (1.5 MeV) cm²	Yield factor
C_K	0.038	4.5×10^{-3}	3000	3×10^{-21}	0.007
Al_K	0.45	3.5×10^{-3}	330	1.0×10^{-21}	0.065
Ti_K	0.84	3.2×10^{-4}	114	1.1×10^{-22}	0.24
Fe_K	0.54	1.0×10^{-4}	71.2	3.8×10^{-23}	0.35
Cu_K	0.31	4.5×10^{-5}	50.9	2×10^{-23}	0.4
Cu_L	0.057	9×10^{-4}	1000	1.3×10^{-21}	0.01
Mo_L	0.55	4×10^{-4}	630	6×10^{-22}	0.06

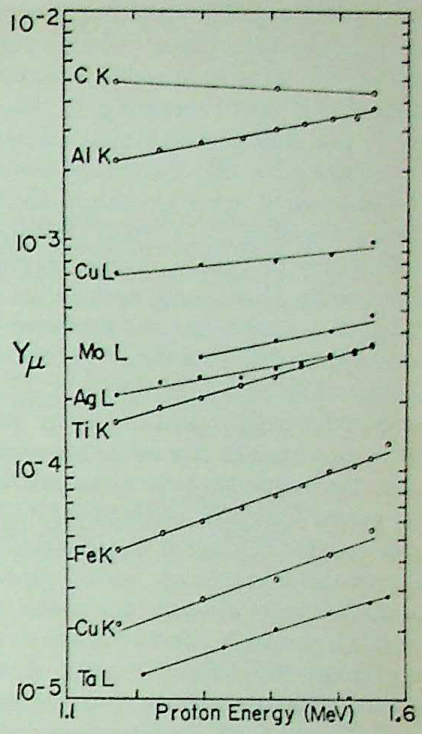

FIG. 1. Thick-target characteristic x-ray yields, Y_μ, in quanta per proton sr as functions of proton bombarding energy. Proton and quantum traveled equal distances in the target material.

The cross section for x-ray production $\sigma_x(E)$ is computed from the yield curve by the familiar formula[3]

$$\sigma_x(E)=\frac{4\pi}{n}\left(\mu Y_\mu+\frac{dY_\mu}{dE}\frac{dE}{dx}\right), \qquad (1)$$

where n is the number of atoms per unit volume and μ the linear absorption coefficient. The stopping powers, dE/dx, are readily available,[10] but the self-absorption coefficients μ are not nearly so easy to obtain, particularly for the L x rays. The K self-absorption coefficients used are based on the Henke, White, and Lundberg interpolation formula[9] and the L coefficients on the Norelco extrapolation of the data of Allen and others.[11] Even the data itself is open to question.[12] The estimated values of μ/ρ used are recorded in the third column of the table, and the resulting calculated x-ray production cross sections in the fourth column.

DISCUSSION

Theoretical excitation cross sections were derived by Bethe and Walske[13] on the basis of screened hydrogenic

wave functions. The resulting integrals depend critically on the minimum energy which must be transferred to the atomic state in question in order to produce excitation. The effect of screening on this energy is expressed by θ, the ratio of the ionization potential of the state in question to the theoretical ionization potential in the absence of outer screening. Merzbacher and Lewis[3] have computed and plotted excitation cross section as a function of proton energy for various values of θ. Comparing their computed curves with experimental data, they found that the predicted cross sections were too large and that the data was consistent with empirical values of θ_K and θ_L of 0.85 and 0.7, respectively, both essentially independent of atomic number. Both values correspond to effective minimum energy transfers higher than the ionization potentials, particularly for the light elements. The extrapolation of this result from the 1.5-Å wavelengths at which it was found to longer wavelengths is a doubtful procedure. Some support may be found in observations of effective thresholds for electron excitation. For example, Dolby[6] observes effective bombarding energy thresholds for strong K x-ray production of about 2200 and 400 eV from aluminum and carbon, respectively. Both correspond roughly to unit values of θ_K. The ionization potential does not appear to be a valid effective minimum for rapid energy transfer.

The ratios of observed x-ray production cross sections to theoretical excitation cross sections obtained from the curves for $\theta_K=0.85$ and $\theta_L=0.7$ plotted by Merzbacher and Lewis[3] are tabulated as yield factors in the last column of the table. To the extent that confidence can be placed in the empirical values of θ these factors are fluorescence yields. Current estimates of soft K-fluorescence yields are classifiable into a low set of values based on extrapolation of measurements with heavier metal targets[14,15] and a considerably higher set of values based on data from argon[16] and a number of theoretical calculations including recently a screened hydrogenic wave function calculation by Callan.[17] The K yield factors in the table from copper through aluminum fit well slightly below Callan's curve. Very little data on L fluorescence yields is available.[18] Since the trajectory of a massive particle in a target is inherently easier to handle theoretically than that of an electron, measurements such as these are a potentially useful way of determining fluorescence yields. They would be worth repeating with more precise apparatus.

The yield of aluminum-K x rays at 1.5 MeV corresponds to a production efficiency of 1.4×10^{10} quanta per joule sr, about the maximum efficiency obtainable. On the other hand, 1.5 MeV is about six times the proton energy required for maximum production efficiency from carbon. The maximum efficiency from carbon is readily estimated with the aid of the measured yield and the excitation cross section curve to be approximately 10^{11} quanta per joule sr. The carbon efficiency is comparable to the efficiency attainable with electron bombardment,[19] but the aluminum efficiency is smaller by a factor of four or more. The proton efficiencies can be raised somewhat by irradiating with protons at grazing incidence. Since the resulting radiation is nearly free of *bremsstrahlung*, it appears that proton excited sources might be superior to filtered electron excited sources in a few applications.

PHYSICAL REVIEW VOLUME 134, NUMBER 4A 18 MAY 1964

Self-Compensation Limited Conductivity in Binary Semiconductors. I. Theory*

G. MANDEL
IBM Watson Research Center, Yorktown Heights, New York
(Received 23 December 1963)

The techniques of Kroger and Vink and Brebrick are extended to allow a calculation of the minimum extent of self-compensation by simple vacancies or interstitial atoms in heavily doped binary semiconductors. The resulting equations are applied to a series of compounds, and it is found that the degree of self-compensation by singly ionizable vacancies varies from essentially complete in KCl (all but $\sim 10^{-9}$ of the impurities compensated) to practically none in GaAs (only $\lesssim 10^{-3}$ of the impurities compensated). The II-VI compounds occupy an intermediate position with about ~ 99 and 99.9% self-compensation in CdTe and ZnTe, respectively. These theoretical conductivity limitations are not sufficient to account for the experimental limitations found in, for example, *n*-ZnTe or *p*-CdS. The above results are extended to include multiply ionizable vacancies, the ionization levels of which fall within the bandgap. It is found that essentially complete self-compensation by a combination of singly and doubly ionized vacancies will occur in the higher bandgap II-VI compounds. As a consequence, for example, the Fermi level in ZnTe cannot be pushed closer to the bottom of the conduction band than half the energy separation between the second ionization level of the acceptor vacancy and the bottom of the conduction band. Some specific implications of the above calculations with respect to CdTe and GaAs are discussed. Finally, certain solubility effects (of impurities) related to stoichiometry and the above calculations are discussed.

I. INTRODUCTION

IT is well known that the introduction of electrically active impurities into a semiconductor host crystal induces the formation of electrically active "natural" defects (vacancies, interstitial atoms, etc.), which tend to at least partially compensate the electrical activity of the impurity. This phenomenon has been considered by a number of workers, particlarly in a review article by Kroger and Vink[1] and, somewhat more rigorously and recently, by Brebrick.[2,3] This self-compensation may be analyzed simply in terms of an energy balance equation, i.e., energy must be supplied by the crystal to produce the "excess" concentration of defect centers while energy is gained by the crystal by the interaction of the defects with the free carriers produced by the added impurity centers. Clearly, if the energy of defect formation is large compared to the energy gained by compensation, very little self-compensation will take place. On the other hand, if the energy of defect formation is small compared to the energy gained by compensation, all free carriers will be compensated by the formation of defects and only insulating crystals will be accessible by equilibrium processes.

The purpose of this paper is the calculation, in terms of the energy parameters of the host crystals, of the minimum extent of self-compensation by simple vacancies in a series of binary compounds, i.e., KCl, ZnTe, CdTe, and GaAs. Qualitatively, we expect to observe a trend in this series due to the fact that the more ionic compounds, e.g., KCl, have electronic bandgaps which are large compared to their cohesive energies while the reverse is true for the more covalent compounds, e.g., GaAs. Roughly speaking, the energy gained by the system upon "recombination" of a free carrier at a vacancy is expected to correlate with the bandgap, while the energy required to generate a vacancy, i.e., the energy required to remove an atom from the lattice, is expected to correlate with the cohesive energy.

The possibility of obtaining appreciable *n*- and *p*-type conductivity in the II-VI compounds, e.g., CdTe and ZnTe, is a question of increasing technological importance because of possible application toward an injection luminescence device operating in the visible region of the spectrum. These compounds appear to be an intermediate case requiring somewhat more careful analysis.

In Sec. II, we calculate the degree of self-compensation by simple singly ionizable acceptor vacancies in a binary semiconductor *MN*, into which we have introduced a large concentration of shallow donors, *D*. (A precisely analogous situation will exist for acceptors.) This calculation is based essentially upon the equation for charge neutrality and Fermi statistics as applied to a nondegenerate semiconductor.[1–3]

In Sec. III, we apply the resulting equations to the series of compounds under consideration and find the expected trend in the results. Of particular interest are the results for CdTe and ZnTe, which indicate that the degree of self-compensation by singly ionizable vacancies calculated theoretically is *not* sufficient to account for the observed conductivity limitations in the II-VI compounds, ZnTe being a particularly appropriate example.

In Sec. IV, we generalize the results of Sec. II to in-

clude multiply ionizable vacancies, in particular, doubly ionizable vacancies, such as might be expected to be important in the II-VI compounds. It is demonstrated that multiply ionizable vacancies can be of critical importance in determining the degree of self-compensation under certain circumstances, these circumstances being most probably appropriate to the II-VI compounds. In particular, under these circumstances, we find that the Fermi level cannot be pushed appreciably closer to the bottom of the conduction band than half the energy separation between the second ionization level of a simple doubly ionizable acceptor vacancy and the bottom of the conduction band.

Some specific implications of Secs. II and IV are discussed with respect to GaAs and CdTe in Sec. V. In particular, it is predicted that the concentration of simple vacancies in GaAs must be small, and certain experimental evidence supporting this view is cited. With respect to CdTe, it is pointed out that the assignment of a level much below the conduction band to the second ionization of a Cd vacancy cannot be correct.

Finally, in Sec. VI, we discuss certain effects of vacancies on the solubility of impurities, in view of the above calculations.

II. SINGLY IONIZABLE VACANCIES

Let us consider a binary compound semiconductor, MN, into which we have introduced a large concentration of donors, D, at the temperature T. The pressures of the various species in the vapor phase are fixed, particularly the pressures of $M_{(g)}$ and $N_{(g)}$, p_M and p_N. The only defects in the host crystal which we consider are simple singly ionizable vacancies, an M atom vacancy being assumed to be an acceptor while an N atom vacancy is assumed to be a donor. For simplicity, we will analyze only the case of *heavy* doping in which the concentration of ionized donors, D^+, is large compared to the concentration of ionized N vacancies, V_N^+, or holes in the valence band, p. [The calculations can easily be extended to include V_N^+ by simply writing $(D^+ + V_N^+)$ in place of D^+ throughout.]

It will be shown in Sec. III that self-compensation by interstitial atoms rather than vacancies is essentially equivalent and leads to similar results.

The charge conservation equation, which is sufficient to describe the system[1–3] is given by

$$D^+ = n + V_M^-, \tag{1}$$

where n is the concentration of electrons in the conduction band and V_M^- is the concentration of ionized M vacancies. The competition between n and V_M^- in maintaining charge neutrality is clearly the question at hand.

The interactions between defects in equilibrium in a nondegenerate semiconductor are given by the equations of Fermi statistics

$$n = N_c \exp(E_F - E_c/kT), \tag{2}$$

$$V_M^-/V_M = g_M \exp(E_F - E_A/kT), \tag{3}$$

where N_c is the density of states near the bottom of the conduction band (given in terms of the electronic effective mass and T), E_F is the Fermi level, E_c is the energy at the bottom of the conduction band, V_M is the concentration of neutral M vacancies, E_A is the acceptor energy level associated with an M vacancy, and g_M is a degeneracy factor (generally we assume $g_M = 2$ for a singly ionizable level). An equivalent description is given by the mass action formalism.[1–3]

$$nV_M/N_c V_M^- = 1/g_M \exp(E_A - E_c/kT), \tag{4}$$

where the right-hand side of Eq. (4) is an equilibrium constant describing the ionization of an ionized M vacancy to yield a neutral M vacancy and an electron in the conduction band.

Combining Eqs. (1) and (4), we obtain immediately

$$n/D^+ = 1/1+Q, \tag{5}$$

$$Q = g_M V_M/N_c \exp(E_c - E_A)/kT = g_M V_M/N_c \times \exp(E_g - E_A')/kT, \tag{6}$$

where E_g is the electronic bandgap and E_A' is the acceptor level of the M vacancy relative to the valence band.

Equations (5) and (6) are our central result. All the quantities in Eq. (6) except V_M, the concentration of neutral M vacancies, are generally known with sufficient accuracy (with the possible exception of E_A' in some cases). We note that, except for the temperature, T, only V_M is under experimental control. V_M will be determined by the pressure of $M_{(g)}$ in the system, p_M, which can take on a range of values. The connection between V_M and p_M is written[1–3]

$$p_M V_M/N_M = \exp \Delta S_M/k \exp(-\Delta H_M/kT), \tag{7}$$

where N_M is the concentration of M sites in the lattice, and where the right-hand side of Eq. (7) is an equilibrium constant referring to the process in which an atom of M is removed from the MN lattice and placed into the vapor, the pressure of $M_{(g)}$ being maintained at 1 atm (standard state), leaving behind an M vacancy in the lattice. The quantities ΔS_M and ΔH_M are defined as the entropy and enthalpy of M vacancy formation, respectively. Note that we have not assumed that $M_{(g)}$ is the only species in the vapor phase but are simply using p_M as a convenient measure of the chemical potential of M in the system.

Inasmuch as we wish to calculate the minimum extent of self-compensation, we must estimate the minimum value of V_M and, therefore, the maximum value of p_M. Clearly p_M must always be less than the value associated with the presence of a pure condensed phase of M (generally $M_{(l)}$ in cases of interest).[3] For temperatures

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

several hundred degrees centigrade below the maximum melting point of MN, or lower, the maximum achievable value of p_M is fairly well approximated by that associated with $M_{(l)}$, $p_M{}^{\text{vap}}$, for most cases of interest. We will confine our calculations to such temperatures that $p_M \cong p_M{}^{\text{vap}}$ and simply point out that the results will represent a lower bound to the degree of self-compensation at other temperatures where $p_M < p_M{}^{\text{vap}}$, e.g., the maximum melting point. We write,

$$p_M{}^{\text{vap}} = \exp \Delta S_M{}^{\text{vap}}/k \exp(-\Delta H_M{}^{\text{vap}}/kT), \quad (8)$$

and obtain, finally, from Eqs. (6)–(8),

$$kT \ln Q^{\min} = E_g - E_A' - \Delta H_M + \Delta H_M{}^{\text{vap}} + T(\Delta S_M - \Delta S_M{}^{\text{vap}}) + kT \ln(g_M N_M/N_c). \quad (9)$$

Thus, with Eqs. (5) and (9) we can calculate the maximum relative concentration of free carriers that we can introduce into $MN_{(s)}$ at the temperature T. If T is sufficiently large, these carriers will be equal in concentration to the "uncompensated" donor impurities present. If the temperature at which we measure the conductivity is much less than T, some of these carriers may "freeze out." The extent of this "freeze-out" is determined largely by the energy level associated with the donor impurity (for the case of singly ionizable vacancies only). We will not be concerned with this "impurity limitation" on the accessable carrier concentration and conductivity but merely state that Eqs. (5) and (9) allow us to calculate the maximum relative concentration of uncompensated shallow impurities (virtually all ionized at temperature T) that can be introduced into $MN_{(s)}$.

III. CALCULATION OF RESULTS; KCl, ZnTe, CdTe, AND GaAs

We now apply Eqs. (5) and (9) to p-KCl, n-ZnTe, n- and p-CdTe, and n-GaAs. The energy bandgaps, E_g, are available in the literature.[4–9] The energy levels of the compensating vacancies, E_A' are available for p-KCl (F center),[10] n-ZnTe,[11] n-CdTe,[8] and p-CdTe.[8,12] No data are available on E_A' in GaAs and we will simply assume $E_A' = 0$ in this case to put an upper bound on the extent of self-compensation.

The enthalpy of compensating vacancy formation, ΔH_M, is available as such only for n-CdTe.[8] The enthalpy of formation of interstitial Cd atoms in p-CdTe is reported,[8] however, according to the equation

$$I_{\text{Cd}}/N_{\text{Cd}} p_{\text{Cd}} = \exp - \Delta S_{\text{Cd}}{}^I/k \exp \Delta H_{\text{Cd}}{}^I/kT, \quad (10)$$

where I_{Cd} is the concentration of interstitial Cd atoms. It is, in practice, impossible to distinguish between interstitial Cd atoms and Te vacancies by electrical measurements.[1] If we reinterpret the data in terms of Te vacancies and use Eq. (7) (with M = Te) in place of Eq. (10), it is easy to demonstrate that the "equivalent" enthalpy of Te vacancy formation is given as

$$\Delta H_{\text{Te}} = \Delta H_{\text{CdTe}} - \Delta H_{\text{Cd}}{}^I, \quad (11)$$

where ΔH_{CdTe} is the standard molar enthalpy change for the reaction

$$\text{CdTe}_{(s)} = \text{Cd}_{(g)} + \text{Te}_{(g)}. \quad (12)$$

ΔH_{CdTe} is essentially twice the cohesive energy per gram-atom of $\text{CdTe}_{(s)}$ and is available in the literature.[13,14] On the basis of such reinterpretation, we have obtained ΔH_{Te} for the calculation appropriate to p-CdTe. It is apparent that, for our purposes, no significant difference exists between interstitial atoms and vacancies and that the available data can always be interpreted without error in terms of vacancies, as above.

The enthalpy of vacancy (F center) formation in KCl has not been reported. Data are available, however, as to the concentration of F centers as a function of potassium pressure, p_{K}, at one temperature (697°C).[15] In particular, the concentration of F centers is reported to be proportional to $p_{\text{K}}{}^{0.85}$, rather than the expected linear dependence. We may handle these data in several ways, with slight variation in the calculated results. Firstly, we arrive at the minimum value of V_{Cl} by extrapolating the reported data to a value of p_{K} consistent with the highest possible value of p_{Cl} ($p_{\text{Cl}}{}^{\text{vap}}$), an extrapolation of perhaps a factor of 10^{20}, and use Eq. (6). Secondly, we may assume a linear dependence and carry out the same extrapolation with a resultant difference of a factor of 10^3 (fewer vacancies). Finally, in a fashion equivalent to the linear extrapolation, we may estimate the standard molar entropy change appropriate to the removal of a Cl atom to the vapor as half the standard molar entropy change of the reaction.

$$\text{KCl}_{(s)} = \text{K}_{(g)} + \text{Cl}_{(g)}, \quad (13)$$

plus a small contribution due to the presence of the vacancies,[2,3,16] which we somewhat arbitrarily estimate as ~4 e.u.[16] On the basis of our estimate of the total entropy change, we use Eq. (7) and the data mentioned above to calculate ΔH_{Cl}. Use of this calculated value in Eq. (9) leads, as expected, to essentially the same result

as the linear extrapolation, and is probably the most reliable method.

No thermodynamic data on vacancy formation is available for either ZnTe or GaAs. We may, however, follow Swalin[16] and write

$$\Delta H_M = \Delta H_{MN} - E_r \simeq 2E_{\text{coh}} - E_r, \qquad (14)$$

where ΔH_{MN} is the standard molar enthalpy change for the reaction

$$MN_{(s)} = M_{(g)} + N_{(g)}. \qquad (15)$$

E_{coh} is the cohesive energy per gram-atom and E_r is a "relaxation" energy associated with the vacancy. Eq. (14) is based on the assumption of constancy of bond energy and may be expected to apply to covalent crystals. An equation of the same form can actually also be derived for ionic crystals.[17] If we put the data for n-CdTe[8] into the form of Eq. (14), we find $E_r/\Delta H_{MN} = 0.24$. Similarly, for Ge,[15] $E_r/\Delta H_{MN} = E_r/2E_{\text{coh}} = 0.19$. We will assume that Eq. (14) applies to both ZnTe and GaAs. Further, we will assume that $E_r/\Delta H_{MN}$ has the same value for ZnTe as for CdTe. For GaAs, we will assume a value of $E_r/\Delta H_{MN}$ midway between that of CdTe and Ge, i.e., $E_r/\Delta H_{MN} = 0.21$, and use the data of ΔH_{GaAs}.[18]

The enthalpies and entropies of vaporization [Eq. (8)], are available for all the elements involved.[14]

For each case, we take the temperature, T, to be several hundred degrees centigrade below the maximum melting point of the host crystal in order that the maximum value of p_M be reasonably accurately described by $p_M{}^{\text{vap}}$.

The entropies of vacancy formation, ΔS_M, are generally unknown. The over-all entropy term in Eq. (9), $(\Delta S_M - \Delta S_M{}^{\text{vap}})$, is clearly the standard molar entropy change that occurs upon transfer of one mole of M atoms from $MN_{(s)}$ to $M_{(l)}$, leaving M vacancies in the crystal. This must be given by approximately minus half the standard molar entropy of formation of $MN_{(s)}$ from the solid elements ($\sim$2 e.u.) plus the standard molar entropy of fusion of $M_{(s)}$ ($\sim$3 e.u. for most elements) plus a contribution due to the "excess" entropy of the vacancies[2,3,16] (which is $\sim$4 e.u.).[15] We therefore take $(\Delta S_M - \Delta S_M{}^{\text{vap}})$ as $\sim$9 e.u. in each case.

The degeneracy factor, g_M, is taken as 2 for all cases and the concentration of available M sites, N_M, is calculated from the densities of the host crystals, which are easily available.

The density of states, N_c, is calculated from the temperature, T, and the appropriate effective mass, m^*, which is available for n-CdTe,[19,20,8] p-CdTe[8] (with some uncertainty) and n-GaAs.[21] We will take m^* for n-ZnTe as identical to that of n-CdTe and that for p-KCl as equal to the free-electron mass.

Finally, the only implicit temperature dependence in Eq. (9) that we consider is that of the bandgap, E_g. Estimates of this dependence are available for CdTe[8,22] and CdAs.[22] The value for ZnTe is interpolated from data for CdTe, CdSe, and ZnSe.[22] The value of $(\partial E_g/\partial T)$ for KCl is arbitrarily estimated as -10^{-3} eV/°C.

The inputs for Eq. (9) are given in Table I, excluding $(\Delta S_M - \Delta S_M{}^{\text{vap}}) = 9$ e.u. $= 3.9\times10^{-4}$ eV/°C and $g_M = 2$.

The results of the calculation based on Eq. (9) and the data in Table I are presented in Table II, along with data on E_g and E_{coh}. It is clear from the above discussion relating to the data in Table I that the results in the second and third columns in Table II are reliable only as to order of magnitude. Nevertheless, we may draw certain firm conclusions from these results:

1. There does exist a self-compensation "boundary" such that certain compounds, falling beyond the "boundary," cannot be doped by any equilibrium process to have appreciable electronic conductivity, e.g., the alkali halides. A rough rule of thumb for determining the position of the self-compensation "boundary" is given by the ratio of the bandgap, E_g, to the cohesive energy per gram-atom, E_{coh}; essentially complete self-compensation occurring for values of this ratio much above unity while little self-compensation occurs for values below 0.5. The expected trend from ionic to covalent compounds is observed.

2. The II-VI compounds constitute a class in which considerable self-compensation may be expected to occur ($E_g/E_{\text{coh}} \approx 1$). Nevertheless, the calculated degree of self-compensation by singly ionizable vacancies for these compounds is *not* sufficient to explain the well-known difficulty of obtaining, for example, appreciable conductivity in n-ZnTe or p-CdS. Similar results are expected for compensation by simple singly ionizable interstitial atoms [see discussion of data in Table I for p-CdTe and Eq. (14)]. We conclude, therefore, that some other limitation on the accessible carrier concentration and conductivity in II-VI compounds must be involved. There may, of course, be *impurity* limitations related to solubility or position of energy levels within the electronic bandgap. There may also be other "natural defects" involved, e.g., impurity-vacancy pairs, etc. A particular possibility that we will consider in more detail is the presence of doubly ionizable vacancies, of which both ionization levels fall within the electronic bandgap.

IV. MULTIPLY IONIZABLE VACANCIES

In the general case, we designate the concentration of M vacancies, which have been ionized to a charge of

$-i$ as $V_M{}^{-i}$ and follow Sec. II in writing a charge neutrality equation,

$$n+\sum_{i=1}^{N} iV_M{}^{-i}=D^+, \tag{16}$$

where N is the highest charge state to fall within the bandgap. We also write an equilibrium constant for ionization of a vacancy in the ith charge state,

$$nV_M{}^{-i+1}/N_cV_M{}^{-i}=g_{i-1}/g_i\exp(E_{A_i}-E_c/kT), \tag{17}$$

where g_i is a degeneracy factor and E_{A_i} is an energy level describing the ith charge state of the vacancy. As before, E_c is the energy at the bottom of the conduction band. It follows from use of Eq. (17) in Eq. (16) that Eq. (5) still applies, with Q given by

$$Q=Q_1\left\{1+\sum_{i=2}^{N}(ig_i/g_1)\left(\frac{n}{N_c}\right)^{i-1}\times\exp\left[(1/kT)\sum_{j=2}^{i}(E_c-E_{A_j})\right]\right\}, \tag{18}$$

where

$$Q_1=g_1V_M/N_c\exp(E_c-E_{A_1})/kT, \tag{19}$$

as in Eq. (6).

For the II-VI compounds, it is believed that $N=2$ and we write, for these compounds,

$$Q=Q_1\{1+(2g_2/g_1)(n/N_c)\exp(E_c-E_{A_2}/kT)\}. \tag{20}$$

Certain general features of Eqs. (18) and (20) should be noted. We see that the effect of the second ionization level of the vacancy only becomes significant in Eq. (20) if the doping level is such that the Fermi level rises above the second ionization energy level [see Eq. (2)]. If we attempt to dope the host crystal so heavily that the Fermi level does rise above the second ionization level of the acceptor vacancy, we see from Eqs. (1) and (20) that the situation is soon reached in which

$$n/N_c=\exp(E_F-E_c)/kT=(g_1D^+/2g_2Q_1N_c)^{1/2}\times\exp(E_{A_2}-E_c/2kT). \tag{21}$$

It is clear that $Q_1\gg1$ for the higher bandgap II-VI compounds (see Table II). Further $(g_1D^+/2g_2Q_1N_c)^{1/2}\lesssim1$. It follows that the Fermi level in the II-VI compounds cannot be pushed closer to the bottom of the conduction band than half the energy separation between the second ionization level of the acceptor vacancy and the bottom of the conduction band. In other words, shallow impurities will be completely compensated by a combination of singly and doubly ionized vacancies in a II-VI compound if the second ionization level of the compensating vacancy falls within the bandgap.

Even if the Fermi level does not rise above the second ionization level of the acceptor vacancies, these levels will still contribute to the temperature dependence of the carrier concentration. If the donor impurities are sufficiently shallow, the position of these second ionization levels will entirely determine this temperature dependence. However, as long as $Q_1\gg1$, "freeze-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

out" of carriers onto these levels cannot push the Fermi level higher than the maximum value discussed above. Complete compensation of impurities by a combination of singly and doubly ionized vacancies will then always occur as long as the energy level of the added donor impurities is shallower (closer to the conduction band) than the second ionization level of the vacancies. If the energy level of the donor impurity is sufficiently deep, the donors will not be completely compensated, but cannot then contribute appreciable conductivity.

V. SPECIFIC IMPLICATIONS: GaAs, CdTe

The magnitude of the concentrations of vacancies in GaAs is of interest because it has been suggested that the concentration of some natural defects can be quite high ($\sim 10^{19}/\text{cm}^3$).[23] The estimated value of the energy of vacancy formation used in Sec. III, however, leads to the conclusion that the total concentration of simple vacancies, neutral or ionized, must be low. In particular, the maximum concentration of neutral Ga vacancies (under the maximum pressure of As) is calculated to be $\sim 10^{14}/\text{cm}^3$. If the Ga vacancies were *shallow* acceptors, the total concentration of Ga vacancies could hardly exceed $10^{18}/\text{cm}^3$ in a crystal of GaAs grown from an As-rich melt and doped to be degenerately n-type (at the growth or equilibration temperature). This view is supported by the well-known fact that GaAs can be prepared either n- or p-type at the $10^{17}/\text{cm}^3$ level without appreciable compensation. Thus under "normal" preparation conditions, the concentrations of electrically active natural defects must be low, i.e., $\lesssim 10^{15}/\text{cm}^3$.

As regards CdTe, it has been suggested that the second ionization level of the acceptor Cd vacancy is 0.6 eV below the conduction band.[8,12] It is, however, well known that CdTe can be doped degenerately n-type.[8,20] From the results of Sec. IV, it is clear that this contradicts the assignment of the 0.6-eV level to the second ionization level of the isolated Cd vacancy. This conclusion does not depend on the results of Sec. III but simply requires that Q_1 not be much smaller than unity. The experimental observation that substantial self-compensation is observed in n-CdTe[8] demonstrates that this requirement is met. There is, in fact, some support for the estimated energy of vacancy formation in CdTe used in Sec. III in that large concentrations of singly ionized Cd vacancies can be introduced into p-CdTe.[12]

It would thus appear that the 0.6-eV level must be assigned to some other center, possibly some complex involving a doubly ionized Cd vacancy.[12] The second ionization level of the isolated Cd vacancy in CdTe must, in fact, be much closer to the conduction band and may be the level recently observed by Lorenz *et al.*[24,25] in CdTe and some other II-VI compounds (all of which can be doped heavily n type). The exclusion of ZnTe (which apparently cannot be doped n type) from this group is significant.

VI. SOLUBILITY EFFECTS

Inasmuch as an impurity must reside on either an M site or an N site in $MN_{(s)}$, we expect that the solubility of impurities in binary compounds must, in general, be a function of the stoichiometry of the system, i.e., the concentration of vacancies. In Sec. II, we have a situation in which the concentration of added donor impurities in $MN_{(s)}$ is held fixed. Under these circumstances, it was pointed out, the maximum *relative* amount of uncompensated donor impurities will occur in a system in which the concentration of compensating acceptor vacancies is a minimum. What is generally held constant in the laboratory, however, is, to a first approximation, the thermodynamic activity of the added donor impurities. As a consequence of the dependence of the solubility of the impurities on the vacancy concentration, it is not necessarily true, then, that the maximum *total* concentration of uncompensated impurities will occur in a system in which the concentration of acceptor vacancies is a minimum.

For, example, let us consider a compound semiconductor $MN_{(s)}$, which is brought into equilibrium at the temperature T with a total constant activity of added donor impurities, i.e., the partial pressure of atomic $D_{(g)}$ is held constant at a value p_D. These impurities are presumed to reside on M sites in the host crystal for this system. The pressure of $M_{(g)}$ is again designated p_M and we assume, as in Sec. II, that only singly ionizable acceptor M vacancies need be taken into account.

The concentration of neutral donors, D, in the host crystal is determined by the equilibrium constant.[1–3]

$$D/p_D V_M = K(T), \tag{22}$$

which refers to the process in which an atom of $D_{(g)}$ "fills" an M vacancy to yield a neutral donor impurity in the lattice.

The concentration of ionized impurity atoms in the crystal, D^+, is determined by the equilibrium constant for the ionization of a neutral impurity to yield a free electron.

$$nD^+/N_c D = (1/g_D)\exp(E_D - E_c/kT), \tag{23}$$

where g_D is a degeneracy factor and E_D is the energy level associated with the donor impurity.

It follows, from Eqs. (5) and (23), that

$$n^2 = [1/(1+Q)](N_c D/g_D)\exp(E_D - E_c)/kT). \tag{24}$$

At constant p_D and T, D is proportional to V_M according to Eq. (22). On the other hand, according to

Eq. (6), Q is also proportional to V_M at constant T. We see, therefore, that the total concentration of free carriers, n, is a maximum when V_M is a *maximum*, despite the fact that the relative amount of uncompensated donors, n/D^+, is a minimum under the same conditions. When $Q \gg 1$, as in the II-VI compounds (see Sec. III), the *total* concentration of free carriers is essentially independent of V_M. Thus, as p_M is varied in these systems, only the concentration of compensated donors varies.

It should be noted that the situation is entirely different if the donor impurities reside on N sites rather than M sites. Under such circumstances, the solubility of the impurities is maximized and the degree of self-compensation minimized when V_M is minimized, i.e., when p_M is maximized.

Theory of the Optical and Magnetic Properties of the Self-Trapped Hole in Lithium Fluoride*

T. P. Das and A. N. Jette
University of California, Riverside, California

and

R. S. Knox
University of Rochester, Rochester, New York

(Received 23 September 1963)

Using a semiphenomenological method, the energy and wave functions of a self-trapped hole (V_k center) in LiF are obtained as a function of the separation between the two F^- ions at which the hole is assumed trapped. The lattice distortion energy due to the changes in Madelung, repulsive, and polarization energies is calculated as a function of the totally symmetric displacement of the two participating F^- ions and six positive ions adjacent to the F^- ions. This lattice energy is combined with the calculated energy for the F_2^- molecule to obtain the total energy as a function of the distance between the participating F^- ions for both the symmetric (Σ_g) and antisymmetric (Σ_u) states of the hole on the V_k center. Only the energy curve for the ground (Σ_u) state exhibits a minimum in the expected region of F^--ion separation. From the resulting configurational coordinate curves, the optical absorption energy and width are computed and found to be in order-of-magnitude agreement with experiment. Computed values of the experimentally known isotropic and anisotropic hyperfine constants are used to assess the validity of our molecular wave functions, which were obtained in a one-electron approximation.

I. INTRODUCTION

In recent years, a fairly detailed understanding of the F center in alkali halides has been achieved by concerted theoretical and experimental studies of its electronic structure.[1] The F center consists of an electron bound to a negative-ion vacancy, and is the simplest of several "electron" color centers such as the M, R, and F' centers.[2] A series of "hole" color centers also exists (V_1,H,V_k); these are characterized by optical absorption bands lying at somewhat higher energies than those of electron centers, are generally stable only at low temperatures, and must be formed by high-energy irradiation. The best understood of these, a center which consists of a self-trapped hole, has been studied elaborately by Castner and Känzig.[3] Electron resonance data have conclusively shown that this center is not associated with a vacancy but instead resembles a negative halogen molecule-ion with a hole shared between two adjacent negative ions. Two previous theoretical attempts[4,5] have been made to explain the stability of this self-trapped holes. Yamashita[4] tried to calculate the energy of the hole in KCl as a function of the displacement of the Cl^- ions which trap it. He could not obtain a minimum in the energy as a function of this displacement but suggested that the repulsion between the core electrons of the Cl^- ions, which he had neglected, might provide a minimum in the energy curve at half the usual distance between the ions in the crystal. A subsequent attempt by Nettel[5] gave the result that the energy of a hole trapped as a Cl_2^- ion in the crystal had higher energy than a chlorine atom

at a cubic site. It appears that Nettel had not employed adequate variational functions for the hole to take account of the relatively strong distortion of the wave function of one of the trapping ions by the other.

In the present paper we attempt to obtain the energy of the LiF crystal containing a hole relative to that of the perfect crystal. The hole is assumed to be shared between two F^- ions so that we have in effect a F_2^- molecule. The energies of the three σ electrons are calculated as a function of the distance between the ions in the two cases corresponding to the unpaired electron being in a symmetric or antisymmetric state. For each distance between the ions, the repulsive, Madelung, and polarization energies are also calculated allowing for relaxation and electronic polarization of six positive ions in the plane of the F_2^- molecule, which are the nearest neighbors to the two F^- ions forming the molecule. The minimum in the total energy curve plotted as a function of the distance between the fluorine nuclei of the F_2^- molecule then gives the equilibrium configuration of the crystal.

In Sec. II, the various contributions to the energy are discussed qualitatively. In Sec. III, the calculation of the lattice energy change is described and in Sec. IV, the computations for obtaining the electronic energies and wave function of the F_2^- molecule are described. In Sec. V, the configuration coordinate curves for the crystal are presented and the optical absorption energy and width and hyperfine constants are calculated and compared with experiment. The nature of the agreement between theoretical and experimental results is then analyzed. In the last section, limitations of the present work are discussed and suggestions for improvement are listed.

II. ANALYSIS OF THE VARIOUS TERMS IN THE ENERGY OF THE CRYSTAL

Our calculation is based on the variation principle. The energy of the crystal containing the hole is calculated as a function of several variation parameters. Some of these parameters may be regarded as equivalent to the configuration coordinates in calculations on luminescent centers, while others are variation parameters that occur in the electronic wave functions. With respect to the former, our calculation resembles that of Williams,[6] with at least one major exception. He was able to use experimental values of the excitation energy of free Tl^+ ion in constructing his excited state configurational coordinate curves, whereas we must rely on computations of this quantity.

Before we describe our variation parameters in detail, we will list and explain the various terms in the total crystal energy E when a hole is present

$$E=E_0+E_A+(\alpha_M e^2/a)+E_E+\Delta E_M+\Delta E_R+\Delta E_P. \quad (1)$$

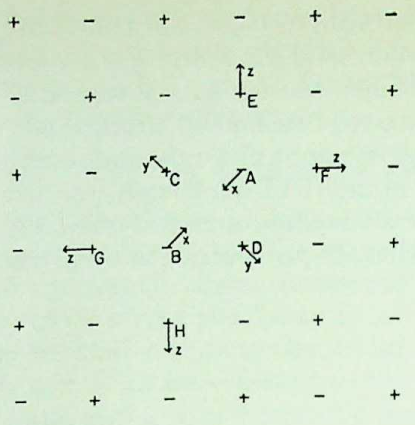

FIG. 1. Diagram showing the ions $A, B, \cdots, H$ which we allow to displace and their directions of displacement.

These terms may be understood in terms of a sequence of events occurring during the removal of an electron from the crystal. E_0 is the energy of the perfect crystal; the next two terms represent the energy required to remove an electron from an F^- ion and place it at infinity; E_A is the electron affinity (work done in taking the electron from F^- itself) and $\alpha_M e^2/a$ is the Madelung energy (work done taking the electron out of the electrostatic potential of the crystal). Here a is the nearest-neighbor distance and α_M the corresponding Madelung constant. Up to this point we have regarded the lattice and remaining electrons as stationary; now let us assume that the hole becomes shared with a nearest neighboring F^- ion so that a molecule F_2^- is formed (see ions A and B in Fig. 1). This will "require" an energy E_E, a quantity which is negative and which will certainly depend on R, the nuclear separation of A and B. The redistribution of charge on the two F^- ions, as well as their relaxation toward each other, will cause a further change in electrostatic energy of the crystal which is included in ΔE_M. In this term is also included the change of electrostatic energy due to the relaxation of neighboring positive ions which will now occur as explained in detail below. Finally, ΔE_R and ΔE_P are the analogous changes in repulsive and polarization energies, respectively, occasioned by the redistribution of charge and motion of the ions.

Of the six terms in (1) which represent the change in the energy of the crystal due to the creation and capture of a hole, the last three and $\alpha_M e^2/a$ may be considered as constituting a change in lattice energy $\Delta E_L=\Delta E_M+\Delta E_P+\Delta E_R+(\alpha_M e^2/a)$. These three contributions are calculated as a function of the fractional displacements (in terms of nearest-neighbor distance in the lattice) x, y, and z of the ions of types A, C, and E shown in Fig. 1. The type-A ions are the two F^- ions (A,B) which share the hole, type C are the two Li^+ ions (C,D) which are the nearest neighbors of A and B. The type E ions are the four Li^+ ions (E,F,G,H) which are the nearest neighbors of the A and B ions. They lie on the same plane as the A- and C-type ions. The relaxation of the four Li^+ ions, which are nearest neighbors of the A and B ions but which do not lie on the plane of the A- and C-type ions, is neglected. Because of the geometry of

[6] F. E. Williams, J. Chem. Phys. 19, 457 (1951).

Digitized by Arya Samaj Foundation Chennai and eGangotri

the location of these ions, they are an order of magnitude less effective in influencing the lattice energy than the ions C, D, E, F, G, and H. In calculating the repulsive energy change ΔE_R, only nearest-neighbor interactions are considered. The polarization energy of the rest of the lattice as well as of the ions $A, \cdots, F$ is calculated following Mott and Littleton's procedure.[7] The net lattice energy is thus obtained as a function $\Delta E_L(x,y,z)$. Since x represents the major relaxation, $\Delta E_L(x,y,z)$ is minimized with respect to y and z to obtain $\Delta E_L(x,y_0,z_0)$ which is a function of x alone. The details and results of the lattice energy calculation are presented in Sec. III.

The terms E_A and E_E represent the electronic energy changes associated with the creation and capture of the hole. The electron-affinity E_A of the F^- ion is taken as 0.363 eV, from Hartree-Fock calculations[8] on the F^- ion. The F_2^- binding energy E_E is obtained by calculating the energy of three σ electrons in the molecule (two electrons in σ_g state and one in σ_u when the hole is in the antisymmetric state Σ_u, and two electrons in σ_u state and one in σ_g state for the hole in the symmetric state Σ_g) and taking the difference between this energy and the energy of three $2p$ electrons on the F^- ion. The details of the calculation of E_E as a function of the distance between A and B, that is, $E_E(x)$, as well as the potential and the variational form of the wave function employed will be discussed in Sec. IV. $E_E(x)$ is then combined with $\Delta E_L(x)$ to obtain the variation of the total energy of the crystal with x; the position of its minimum gives the equilibrium configuration of the crystal. It will be seen later that a minimum is found only when the hole is in the Σ_u and not in the state Σ_g.

III. CALCULATION OF LATTICE ENERGY CHANGES

We shall first consider the change in the Madelung energy of the lattice due to the presence of the hole. For this calculation, we shall assume that the hole is equally divided between the two F^- ions. This is a fairly good approximation if the bonding between A and B is not too strong so that there is not much migration of charge to the region between the two ions. The general expression for the difference in Madelung energies of the crystal between the two situations in which the ions $A, B, C, \cdots, H$ are displaced, $E_M(x,y,z)$, and undisplaced, $E_M(0,0,0)$, can be shown to be given by

$$E_M(x,y,z)-E_M(0,0,0)$$
$$=\sum_{L=A}^{H}\sum_{M\neq A,\cdots,H}^{\infty}\zeta_L\zeta_M\left(\frac{1}{r_{LM_0}}-\frac{1}{r_{L_0M_0}}\right)$$
$$+\sum_{L=A}^{M-1}\sum_{M=A}^{H}\zeta_L\zeta_M\left(\frac{1}{r_{LM}}-\frac{1}{r_{L_0M_0}}\right). \quad (2)$$

Here ζ_L and ζ_M are the charges on the lattice points L and M, and L_0 and L represent, respectively, the undisplaced and displaced positions of the point L. Thus, for example, r_{LM_0} represents the distance between the displaced position of the point L and undisplaced position of M. If we are interested in an expansion of (2) in powers of x, y, and z correct to second order, we may take

$$\sum_{M\neq L}^{\infty}\frac{\zeta_L\zeta_M}{r_{LM_0}}=\sum_{M\neq L}^{\infty}\frac{\zeta_L\zeta_M}{r_{L_0M_0}}, \quad (3)$$

provided that all ζ_M are equal to $\pm e$ and are situated on a regular cubic lattice. Equation (3) is a result of the fact that in regular cubic crystals, the next multipole interaction between ions after the monopole corresponds to $l=4$. Hence only quartic and higher terms in x, y, or z are to be expected from the summation in (3). It follows that

$$\sum_{M\neq A\cdots H}^{\infty}\frac{\zeta_L\zeta_M}{r_{LM_0}}=\sum_{M\neq L}^{\infty}\frac{\zeta_L\zeta_M}{r_{L_0M_0}}-\sum_{\substack{M=A\\M\neq L}}^{H}\frac{\zeta_L\zeta_M}{r_{LM_0}}, \quad (4)$$

which may be used to simplify Eq. (2) to the following form:

$$E_M(x,y,z)-E_M(0,0,0)$$
$$=\frac{1}{2}\sum_{\substack{M=A\\M\neq L}}^{H}\sum_{L=A}^{H}\zeta_L\zeta_M\left(\frac{1}{r_{LM}}-\frac{2}{r_{LM_0}}+\frac{1}{r_{L_0M_0}}\right). \quad (5)$$

If the charges on the A and B ions are $-qe$ and the charges on the rest of the lattice points are the same as in the perfect lattice, then the above calculation must be modified in an obvious way, and one obtains

$$E_M(x,y,z)-E_M(0,0,0)$$
$$=\sum_{L=A}^{M-1}\sum_{M=A}^{H}\zeta_L\zeta_M\left(\frac{1}{r_{LM}}+\frac{1}{r_{L_0M_0}}-\frac{1}{r_{LM_0}}-\frac{1}{r_{L_0M}}\right)$$
$$+2(q^2-q)\left(\frac{1}{r_{AB_0}}-\frac{1}{r_{A_0B_0}}\right)$$
$$-2(q-1)\sum_{L=C}^{H}\left(\frac{1}{r_{LA_0}}-\frac{1}{r_{L_0A_0}}\right). \quad (6)$$

In the present case we are assuming that $q=\frac{1}{2}$. Also, ζ_L is $+e$ for a positive ion and $-e$ for a negative ion. With the help of Fig. 1, one can calculate the various distances involved in Eq. (6) correct to terms quadratic in x, y, and z. Thus, for example,

$$\frac{1}{r_{AE}}+\frac{1}{r_{A_0E_0}}-\frac{1}{r_{AE_0}}-\frac{1}{r_{A_0E}}=-\frac{\sqrt{2}}{a}xz. \quad (7)$$

Equation (6) includes the repulsive energy between charges $-e/2$ on the ions A and B. This is a spurious

term introduced by our assumption that the hole is equally distributed between the two F^- ions, and must be excluded because all such intramolecular interactions are contained in E_E. We therefore obtain the following expression for ΔE_M:

$$\Delta E_M(x,y,z)=E_M(x,y,z)-E_M(0,0,0)-[e^2/4\sqrt{2}a(1-\sqrt{2}x)]. \quad (8)$$

Using equations like (7), Eqs. (6) and (8) may be expanded in powers of x, y, and z, and after a lengthy calculation one obtains

$$\Delta E_M=(e^2/a)(-0.177-0.500x-0.354x^2-1.414y+1.207y^2+2.358z+3.426z^2+3.000xy+2.500zx-1.707yz). \quad (9)$$

It should be emphasized that this equation has been derived for a particular (fcc) lattice.

Next, we consider ΔE_R. In keeping with our earlier assumptions for the Madelung energy change we shall not consider the repulsion between the ions A and B. This latter repulsive energy, when it becomes appreciable, will be included in the electronic energy terms. Also, we shall consider repulsion between nearest neighbors alone. There are several choices that one can make for the repulsive interaction energy between the positive and negative ions. One possible choice is the Born-Mayer potential,[9] which has the form

$$V(r)=Be^{-r/\rho}, \quad (10)$$

with B and ρ obtained from the observed compressibility and lattice constant of the crystal. In the determination of B and ρ in the Born-Mayer formula from the perfect crystal, Van der Waals forces were neglected, i.e., their effect is assumed to be adequately included in the exponential parameters. Therefore in using this formula for the imperfect crystal, we should ignore Van der Waals forces for the sake of consistency. Huggins and Mayer[10] have also obtained B and ρ from data on the perfect crystal, but including Van der Waals forces separately. We shall also make use of these constants to test the sensitiveness of the calculated lattice energy to the choice of force constants. Another form for the repulsive energy has been proposed by Pauling,[11] namely

$$V(r)=0.0485e^2r_0{}^{n-1}/r^n, \quad (11)$$

where r_0 is the sum of the ionic radii of the positive and negative ions and n depends on the nature of the positive and negative ion pair. For LiF one can take $n=6$ so that for the repulsive potential between Li^+ and F^- ion we can rewrite (11) as

$$V(r)=Ae^2/r^6, \quad (12)$$

where $A=0.0485r_0{}^5$. Using the form in Eq. (10) for the repulsive energy, the expression for $\Delta E_R(x,y,z)$ is given by Eq. (13):

$$\Delta E_R(x,y,z)=4Be^{-a/\rho}\left[\frac{a}{\rho}\left\{\left(-x^2-y^2-2z^2-\frac{xy}{2}\right)+\frac{a}{2\rho}(x^2+y^2+2z^2-xy-\sqrt{2}xz)\right\}\right]. \quad (13)$$

In obtaining Eq. (13), the energy differences between a pair of ions L and M is calculated using the relation

$$\Delta E_R(L,M)=B[e^{-r_{LM}/\rho}-e^{-r_{L_0M_0}/\rho}], \quad (14)$$

where r_{LM} and $r_{L_0M_0}$ have the same meaning as in Eq. (6). The distances r_{LM} between the displaced ions and their nearest neighbors are calculated up to quadratic terms in x, y, and z as before.

Using the Pauling expression (12) for the force law, Eq. (15) is obtained for the change in the repulsive energy as a function of x, y, z:

$$\Delta E_R(x,y,z)=(Ae^2/a^6)[60x^2+60y^2+120z^2-96xy-84\sqrt{2}xz]. \quad (15)$$

In Table I are tabulated the constants B and ρ both in the Born-Mayer and Huggins-Mayer approximations as well as the value of A in the Pauling approximation. In obtaining A, a value of $r_0=1.95$ Å was used in Eq. (12), this value of r_0 being the sum of the ionic radii of Li^+ and F^- ions. The lattice constant a for LiF is 2.01 Å, only slightly different from r_0. On introducing the values of B, ρ, and A in Eqs. (14) and (15), we get the following equations for $\Delta E_R(x,y,z)$ in the three cases.

Huggins-Mayer:

$$\Delta E_R(x,y,z)=\frac{e^2}{a}[1.664x^2+1.664y^2+3.328z^2-3.031xy-3.642xz], \quad (16a)$$

Born-Mayer:

$$\Delta E_R(x,y,z)=\frac{e^2}{a}[2.482x^2+2.482y^2+4.964z^2-3.675xy-4.635xz], \quad (16b)$$

Pauling:

$$\Delta E_R(x,y,z)=\frac{e^2}{a}[2.910x^2+2.910y^2+5.820z^2-4.656xy-5.762xz]. \quad (16c)$$

The difference between Eqs. (16a) and (16b) which use the same force law but different force constants B and ρ could partly be ascribed to the neglect of the effect of the Van der Waals forces in using the Huggins-Mayer formula. In order to get an expression for

[9] M. Born and J. E. Mayer, Z. Physik. 75, 1 (1932); we will use the simple theory given by M. Born and K. Huang, *Dynamics of Crystal Lattices* (Oxford University Press, New York, 1955), p. 26.

Pauling			1.368×10^{-40}

$\Delta E_R(x,y,z)$ which would be comparable to (16b) one would have to include in $\Delta E_R(x,y,z)$ the contribution from the change in Van der Waals energy due to the displacement of the lattice points. We shall not do this but instead use the differences between the lattice energy changes with Huggins-Mayer and Born-Mayer formulas as a measure of the importance of Van der Waals forces. Equations (16a) and (16b) indicate that while the Van der Waals contribution to the lattice energy is significant, it is definitely less important than the repulsive energy change. The difference between the energy expressions in (16b) and (16c) is due to the different formulas [Eqs. (10) and (12)] employed. It is encouraging that the difference between Eqs. (16b) and (16c) is less than that between (16a) and (16b) since both Born-Mayer and Pauling formulas include the effect of the Van der Waals forces indirectly. One last comment about the repulsive energy calculation. We have used Eqs. (10) and (12) together with the constants in Table I which refer to the energy of repulsion between Li^+ and F^- ions. Actually ions A and B are somewhat different from the regular F^- ion because they each contain a total charge $-e/2$, which is less than that of a regular F^- ion. Our belief that the use of Eqs. (10) and (12) does not lead to significant error is based on two considerations. First, that the charge distribution of five and one-half $2p$ electrons is probably not too different from what it would be for six. Secondly, at least in the Σ_u state, the hole probably affects only the charge distribution in the region between the two ions A and B. Hence, to the nearest-neighbor positive ions, $C, D, \cdots, H$, the A and B ions do not "look" very different from perfect F^- ions.

We shall finally consider ΔE_P, the energy associated with the polarization of the lattice due both to the two holes on ions A and B and the displacements of the neighboring points $C, D, \cdots, H$. The polarization energy due to a point charge at a lattice site has been considered in detail by Mott and Littleton.[12] In the zeroth-order approximation, where one considers the crystal as a dielectric continuum in calculating local fields at the ions, the dipole moments on the positive and negative ions are given by

$$N_\pm = \frac{M_\pm a^3 e}{r^2}, \tag{17}$$

with the dipoles directed outwards in the direction of $\mathbf{r}$, the radius vector joining the impurity charge ζ_i and the ion under consideration.

$$M_\pm = \frac{\zeta_i(1-1/K_S)(e^2/A+\alpha_\pm)}{4\pi[(e^2/A)+\frac{1}{2}(\alpha_+ +\alpha_-)]}, \tag{18}$$

where α_+ and α_- are the electronic polarizabilities of the positive and negative ions on the lattice, K_S is the static dielectric constant and $A = 6a/\theta$ is the spring constant with the compressibility $1/\theta$ given by

$$\frac{1}{\theta} = \frac{1}{3a}\left[\frac{1}{\rho^2} - \frac{2}{a\rho}\right] B e^{-a/\rho}. \tag{19}$$

We however follow the first-order approximation of Mott and Littleton in that we permit the nearest-neighbor ions ($B, C, \cdots, H$ in the case of the hole on A) to move discretely and determine their displacements by a detailed consideration of the various terms in the lattice energy. So we have to allow for this difference in nature between the ions $A, \cdots, H$ and the ions in the rest of the crystal. We shall do this by taking into account only the electronic polarization of ions A to H, since their ionic polarizations have already been considered by calculating their electrostatic and repulsive interactions with other ions in the crystal in their displaced positions.

Our polarization energy calculation is also somewhat more involved than the calculation of the polarization energy due to single point charges such as single vacancies and interstitials in a lattice. The ions A and B carry only charges $-e/2$ and are in displaced positions as compared to their original positions A_0 and B_0 in the lattice. Therefore, in the calculation of polarization effects we have in effect to consider four charges, namely $-\frac{1}{2}e$ each at A and B, and $+e$ each at the points A_0 and B_0. The latter two represent the effective charges the vacancies would have if the charges $-\frac{1}{2}e$ were *entirely* removed. Each of these four charges polarizes the ions in the rest of the lattice and the dipole moment on the polarized ion not only interacts with the polarizing charge (direct polarization energy) but also with the other three charges (indirect polarization energy). We shall consider the four ions in six pairs, namely (A_0B_0), (AB), $(AB_0)(A_0B)$, (AA_0), and (BB_0). To avoid counting the direct polarization energy for each of the four charges twice, we shall include the direct polarization energies only while considering the first two pairs (A_0B_0) and (AB). Strictly speaking, one should consider similar pairs for the ions C, D, E, F, G, H because they are also displaced from their original equilibrium positions. A consideration of such effects is equivalent to considering the polarization of the lattice due to the dipoles produced by the displacements of $C, \cdots, H$ from their original positions. Since the displacements of the ions $C, \cdots, H$ are expected to be less important than those of A and B, we shall neglect the

[12] See Ref. 7; B. G. Dick (private communication).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

effects of the dipoles at $C, \cdots, H$ on the polarization energy. Thus we have

$$\Delta E_P = \Delta E_p(A_0B_0)+\Delta E_p(AB)+\Delta E_p(AB_0)+\Delta E_p(A_0B)+\Delta E_p(AA_0)+\Delta E_p(BB_0). \tag{20}$$

$$\Delta E_p(A_0B_0) = -\frac{e^2}{a}\Bigg[M_1\sum_i \frac{1}{r_{A_0i}^4}+M_2\sum_j \frac{1}{r_{A_0j}^4}+M_1\sum_i \frac{\cos\theta_{A_0iB_0}}{r_{A_0i}^2 r_{B_0i}^2}+M_2\sum_j \frac{\cos\theta_{A_0jB_0}}{r_{A_0j}^2 r_{B_0j}^2}-\frac{M_2}{r_{A_0B_0}^4}-2\left(\frac{M_1}{r_{A_0C_0}^4}-\frac{M_1'}{r_{A_0C}^4}\right)$$
$$-2\left(\frac{M_1\cos\theta_{A_0C_0B_0}}{r_{A_0C_0}^2 r_{B_0C_0}^2}-\frac{M_1'\cos\theta_{A_0CB_0}}{r_{A_0C}^2 r_{B_0C}^2}\right)-2\left(\frac{M_1}{r_{A_0E_0}^4}-\frac{M_1'}{r_{A_0E}^4}\right)$$
$$-2\left(\frac{M_1}{r_{A_0G_0}^4}-\frac{M_1'}{r_{A_0G}^4}\right)-4\left(\frac{M_1\cos\theta_{A_0E_0B_0}}{r_{A_0E_0}^2 r_{B_0E_0}^2}-\frac{M_1'\cos\theta_{A_0EB_0}}{r_{A_0E}^2 r_{B_0E}^2}\right)\Bigg], \tag{21}$$

where

$$M_1=\frac{[1-(1/K_S)][(e^2/A)+\alpha_+]}{4\pi[(e^2/A)+\frac{1}{2}(\alpha_++\alpha_-)]}, \quad M_1'=\frac{\alpha_+}{a^3},$$
$$M_2=\frac{[1-(1/K_S)][(e^2/A)+\alpha_-]}{4\pi[(e^2/A)+\frac{1}{2}(\alpha_++\alpha_-)]}, \quad M_2'=\frac{\alpha_-}{a^3}. \tag{22}$$

The summation in i in the first and third terms of (21) runs over the positive ions in the lattice while the summation over j in the second and fourth terms runs over the negative ions except that in the fourth term the points $j=A_0$ and $j=B_0$ are excluded. The fifth term arises because (when considering the effect of the charge $+e$ at A_0) we do not have an ion at the B_0 site and vice versa for the charge $+e$ at B_0. The sixth, seventh, eighth, ninth, and tenth terms in (21) take account of the correction to be introduced because we have to consider only the electronic polarization of the displaced ions C, D, E, F, G, and H. The angles like $\theta_{A_0jB_0}$ stand for the angle subtended by the points A_0 and B_0 at the lattice point j.

$$\Delta E_p(AB) = -\frac{e^2}{4a}\Bigg[M_1\sum_i \frac{1}{r_{A_i}^4}+M_2\sum_j \frac{1}{r_{A_j}^4}+M_1\sum_i \frac{\cos\theta_{A_iB}}{r_{A_i}^2 r_{B_i}^2}+M_2\sum_j \frac{\cos\theta_{A_jB}}{r_{A_j}^2 r_{B_j}^2}-(M_2-M_2'')\frac{1}{r_{AB}^4}$$
$$-2\left(\frac{M_1}{r_{AC_0}^4}-\frac{M_1'}{r_{AC}^4}\right)-2\left(\frac{M_1\cos\theta_{AC_0B}}{r_{AC_0}^2 r_{BC_0}^2}-\frac{M_1'\cos\theta_{ACB}}{r_{AC}^2 r_{BC}^2}\right)-2\left(\frac{M_1}{r_{AE_0}^4}-\frac{M_1'}{r_{AE}^4}\right)-2\left(\frac{M_1}{r_{AG_0}^4}-\frac{M_1'}{r_{AG}^4}\right)$$
$$-4\left(\frac{M_1\cos\theta_{AE_0B}}{r_{AE_0}^2 r_{BE_0}^2}-\frac{M_1'\cos\theta_{AEB}}{r_{AE}^2 r_{BE}^2}\right)\Bigg], \tag{23}$$

where M_1, M_2, and M_1' are defined in Eq. (22) and

$$M_2''=\frac{\alpha_-'}{a^3}. \tag{24}$$

The quantity α_-' represents the polarizability of the π electrons on the F^- ion. The fifth term is introduced to take account of the fact that only the polarization of the π electrons on A and B ions has to be considered; the polarization of the σ electrons will be taken care of indirectly in the electronic energy. The summations in the first and third terms again run over the positive ions alone and those in the second and fourth terms over the negative ions alone, the points $j\neq A, B$ are again excluded from the fourth summation. The rest of the terms are introduced to avoid introducing the ionic polarization of the ions $C, D, \cdots, H$ in ΔE_P.

$$\Delta E_p(AB_0)+\Delta E_p(A_0B) = \frac{e^2}{a}\Bigg[M_1\sum_i \frac{\cos\theta_{A_0jB}}{r_{A_0i}^2 r_{Bi}^2}+M_2\sum_j \frac{\cos\theta_{A_0jB}}{r_{A_0j}^2 r_{Bj}^2}-2\left(\frac{M_1\cos\theta_{A_0C_0B}}{r_{A_0C_0}^2 r_{BC_0}^2}-\frac{M_1'\cos\theta_{A_0CB}}{r_{A_0C}^2 r_{BC}^2}\right)$$
$$-2\left(\frac{M_1\cos\theta_{A_0E_0B}}{r_{A_0E_0}^2 r_{BE_0}^2}-\frac{M_1'\cos\theta_{A_0EB}}{r_{A_0E}^2 r_{BE}^2}\right)-2\left(\frac{M_1\cos\theta_{A_0G_0B}}{r_{A_0G_0}^2 r_{BG_0}^2}-\frac{M_1'\cos\theta_{A_0GB}}{r_{A_0G}^2 r_{BG}^2}\right)\Bigg]. \tag{25}$$

In Eq. (25) also, the summation indices (in the first and second terms) refer to positive and negative ions, re-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

spectively, the ion B being left out of the summation in j. Finally, we have

$$\Delta E_p(AA_0)+\Delta E_p(BB_0)=-\frac{e^2}{a}\Bigg[M_1\sum_i\frac{\cos\theta_{A_0iA}}{r_{A_0i}^2r_{Ai}^2}+M_2\sum_j\frac{\cos\theta_{A_0jA}}{r_{A_0j}^2r_{Aj}^2}-2\left(\frac{M_1\cos\theta_{A_0C_0A}}{r_{A_0C_0}^2r_{AC_0}^2}-\frac{M_1'\cos\theta_{A_0CA}}{r_{A_0C}^2r_{AC}^2}\right)$$
$$-2\left(\frac{M_1\cos\theta_{A_0E_0A}}{r_{A_0E_0}^2r_{AE_0}^2}-\frac{M_1'\cos\theta_{A_0EA}}{r_{A_0E}^2r_{AE}^2}\right)-2\left(\frac{M_1\cos\theta_{A_0G_0A}}{r_{A_0G_0}^2r_{AG_0}^2}-\frac{M_1'\cos\theta_{A_0GA}}{r_{A_0G}^2r_{AG}^2}\right)\Bigg]. \quad (26)$$

We can combine Eqs. (21), (23), (25), and (26) to obtain the net polarization energy of the lattice given by Eq. (20). Since we require the energy only up to quadratic terms we have to express the polarization energy in terms of linear and quadratic terms in x, y, and z only. This can be done with the help of Fig. 1 and expressing the distances and angles involving the displaced ions A, B, $\cdots$, H in terms of linear and quadratic terms in x, y, and z. The detailed evaluation of the coefficients of these terms requires several lattice summations, some of them about the single center A and some involving the two centers A and B. A few of these summations were available from the work of earlier authors,[7,13] namely

$$\sum_i\frac{1}{r_{A_0i}^4}=10.1977,$$
$$\sum_i\frac{1}{r_{A_0j}^4}=6.3346,$$
$$\sum_i\frac{1}{r_{A_0i}r_{B_0i}^3}-\sum_i\frac{1}{r_{A_0i}^3r_{B_0i}^3}=5.036, \quad (27)$$
$$\sum_i\frac{1}{r_{A_0j}r_{B_0j}^3}-\sum_i\frac{1}{r_{A_0j}^3r_{B_0j}^3}=4.152.$$

These summations are the least convergent of the various sums needed. The rest of the sums have the general form

$$\sum\frac{x_{A_0i}^{\alpha}x_{B_0i}^{\beta}y_{A_0i}^{\gamma}y_{B0i}^{\delta}}{r_{A_0i}^{\sigma}r_{B_0^{\sigma}i}^{\tau}}, \quad (28)$$

with similar expressions involving j. x_{A_0i}, y_{A_0i}, and z_{A_0i} represent coordinates of the ith ion in terms of the crystal axes with respect to the undisplaced position of A. These were performed on the Illiac at the University of Illinois computing center and checked on the IBM-1620 at the computing center of the Riverside campus of the University of California. Their values are presented in Table II. The sums were carried out in all cases up to the eleventh neighbors of the relevant type (positive or negative ion), and the convergence was tested by finding the additional contribution in going to the thirteenth neighbors. The convergence in all cases was better than 0.1%.

Next we have to consider the values of the quantities M_1, M_2, M_1', M_2'' to be used in the calculation. The expressions for these are given in terms of K_S, α_+, α_-, α_-', and the spring constant A in Eqs. (22) and (24). In Table III the values of these quantities are tabulated together with the source from which they were obtained.

TABLE II. Lattice sums involved in the calculation of ΔE_p. The sums and notation are defined in the text [see Eq. (28)].

Using these values, we obtain

$$\begin{aligned} M_1&=0.0624,\\ M_1'&=0.0036,\\ M_2&=0.0796,\\ M_2'&=0.0482. \end{aligned} \tag{29}$$

The result of our expansion and substitution is finally,

$$\begin{aligned}\Delta E_P(x,y,z)=-(e^2/4a)[&1.416-0.505x+0.702x^2\\ &-0.010y-0.007y^2+0.089xy+0.037z\\ &+0.087z^2+0.106xz]. \end{aligned}\tag{30}$$

It is understandable why in the expression for the polarization energy the coefficients of the terms that do not involve x are small. These terms arise out of the electronic polarization of the positive ions which have rather small polarizability. Combining Eqs. (9), (16), and (30) we get the following equation for the net change in the lattice energy, namely,

$$\begin{aligned}\Delta E_L(x,y,z)=(\alpha_M e^2/a)+(e^2/a)[&-0.538-0.374x\\ &-1.416y+2.348z+\alpha x^2+\beta y^2+\gamma z^2\\ &+\lambda xy+\mu yz+\nu xz], \end{aligned}\tag{31}$$

where the coefficients α, β, γ, λ, μ, and ν depend on our choice of the repulsive energy formula. In Table IV, the values of these coefficients are tabulated when the Born-Mayer, Huggins-Mayer, and Pauling repulsive energy formulas are used. The coefficients in the lattice-energy expression are seen to be sensitive to the choice of the repulsive energy formula, as discussed above.

From Eq. (31), one obtains the energy of the lattice as a function of x alone by minimizing the lattice energy with respect to y and z. This leads to the equations

$$\begin{aligned} 2\beta y+\mu z&=1.416-\lambda x,\\ \mu y+2\gamma z&=-2.348-\nu x. \end{aligned}\tag{32}$$

One can now solve Eqs. (32) in terms of x and substitute the following expressions (33) obtained for $y(x)$ and $z(x)$ in Eqs. (31) and hence express the lattice energy in terms of x alone, as in (34):

$$\begin{aligned} y_0(x)&=b+cx,\\ z_0(x)&=d+ex, \end{aligned}\tag{33}$$

and

$$\Delta E_L(x)=A+Bx+Cx^2. \tag{34}$$

From Eq. (34), one can obtain a plot of the lattice energy as a function of x or of R, the distance between the ions A and B, the relation between R and x being given by

$$R=\sqrt{2}a(1-\sqrt{2}x). \tag{35}$$

In Table V, the values of b, c, d, and e in Eq. (33) and A, B, and C in Eq. (34) are tabulated for our three different repulsive force laws. In Fig. 2, we have plotted $\Delta E_L(R)$ as a function of R and as expected there is great similarity between the Born-Mayer and Pauling curves, there being a minimum in the lattice energy curve in each case. The positions of the minima can be expressed either in terms of x or in terms of R, using Eq. (35). In Table VI, we have tabulated for the cases of the three repulsive formulas employed, the values of x_0, R_0, and $\Delta E_L(R_0)$, the lattice energy at the position of the minimum in $\Delta E_L(R)$. The minimum in the lattice energy curve is rather significant and arises out of a compromise between the energy of interaction between the ions A and B with the ions C, D, E, F, G, H. Thus, the distance between the ions A and C decreases as x increases while the distances between ion A and ions E and F increases as x increases. The fact that we get a minimum in the lattice energy curve indicates that there is self-trapping of the hole even in the absence of appreciable electronic conjugation between the ions A and B leading to the F_2^- molecule ion. As we shall see in the next section, there is also a stable state for the free F_2^- ion. The relative depths and shapes of the lattice energy and electronic energy curves are important in determining the nature of the total energy curve for the crystal. We shall discuss this point further in Secs. IV and V after describing the electronic energy calculation.

TABLE IV. Values of coefficients in lattice energy expressions.

Coefficient	Born-Mayer	Huggins-Mayer	Pauling
α	1.953	1.135	2.381
β	3.691	2.873	4.119
γ	8.368	6.732	9.224
λ	−0.698	−0.053	−1.678
μ	−1.707	−1.707	−1.707
ν	−2.162	−1.169	−3.288

IV. ELECTRONIC ENERGY CALCULATIONS

The next quantities that we have to calculate are the energies and wave functions for a F_2^- ion as a function of internuclear separation. There are various standard methods in molecular physics to accomplish this, broadly divided into molecular orbital and valence-

TABLE V. Coefficients b, c, d, e, A, B, and C in Eqs. (34) and (35) for the different choices of repulsive energy formula. A, B, and C are in Ry ($e^2/2a_0$).

Coefficient	Born-Mayer	Huggins-Mayer	Pauling
b	0.163	0.202	0.148

bond methods.[14] Both these methods in their improved forms, including configuration interaction in the molecular orbital approach and ionic character in the valence bond approach, are essentially equivalent. In their improved forms they are comparable to variational approaches in the self-consistent procedure for atoms including configuration interaction. In our calculations, we have not attempted to include any configuration interaction or self-consistency requirements, but have adopted a simple molecular orbital procedure. In the usual molecular orbital method, as in the Hartree-Fock approach for atoms, one generally starts from the following many-electron Hamiltonian and computes from it a one-electron Hamiltonian for each state:

$$\mathcal{H}=-\sum_i \nabla_i^2+\sum_i \frac{2z}{r_i}+\sum_{i>j} \frac{2}{r_{ij}}. \tag{36}$$

For simplicity, we have adopted the following approximate one-electron Hamiltonian for the three $2p$ electrons which take part in the σ bond for the F_2^- molecule:

$$\mathcal{H}=-\nabla_i^2+V_A(\mathbf{r}_{Ai})+V_B(\mathbf{r}_{Bi}). \tag{37}$$

The potentials $V_A(\mathbf{r}_{Ai})$ and $V_B(\mathbf{r}_{Bi})$ both represent the one-electron potentials seen by a $2p$ electron on a F^- ion. The justification for choosing (37) is the following. When the unpaired electron in the molecule is in the neighborhood of ion A, then as far as the ion A is concerned, it sees the potential that a $2p$ electron on an F^- ion would see. In the same situation, as far as ion B is concerned, the charge distribution on it looks like a neutral atom to the unpaired electron on A and therefore the electron again experiences the same potential from ion B as a $2p$ electron on an F^- ion would. These arguments are valid when the cores of the F^- are not too distorted by the presence of the hole. This would be true if the distance between the fluorine nuclei in the molecule is not very greatly different from the distance in the perfect crystal.

As basis functions for our determination of the σ_g and σ_u functions for the F_2^- molecule, we have selected the following linear combinations:

$$\Phi_g=\sum_i c_i\phi_{ig}, \qquad \Phi_u=\sum_i d_i\phi_{iu}, \tag{38}$$

where

$$\begin{aligned} &\phi_{1g}=\phi_{1A}-\phi_{1B}, \quad \phi_{1u}=\phi_{1A}+\phi_{1B}, \\ &\phi_{2g}=\phi_{2A}-\phi_{2B}, \quad \phi_{2u}=\phi_{2A}+\phi_{2B}, \\ &\phi_{3g}=\phi_{3A}+\phi_{3B}, \quad \phi_{3u}=\phi_{3A}-\phi_{3B}, \\ &\phi_{4g}=\phi_{4A}+\phi_{4B}, \quad \phi_{4u}=\phi_{4A}-\phi_{4B}, \end{aligned} \tag{39}$$

with

$$\begin{aligned} &\phi_{1A}=\frac{P_{2p}(r_A)}{r_A}Y_1^0(\theta_A,\phi_A), \quad \phi_{3A}=\frac{P_{2p}(r_A)}{r_A^2}Y_0^0(\theta_A,\phi_A), \\ &\phi_{2A}=P_{2p}(r_A)Y_1^0(\theta_A,\phi_A), \quad \phi_{4A}=\frac{P_{2p}(r_A)}{r_A}Y_0^0(\theta_A,\phi_A). \end{aligned} \tag{40}$$

The function $P_{2p}(r_A)$ is taken to be the radial part of the $2p$ wave function of the F^- ion. Ideally one should have used in addition to ϕ_{1A} and ϕ_{2A}, functions whose radial parts are $r_AP_{2p}(r_A)$, $r_A^2P_{2p}(r_A)$, $\cdots$ to include a complete set. We have chosen only two functions out of the complete set as a compromise to reduce the work involved. The same remark applies to the choice of the functions ϕ_{3A} and ϕ_{4A}. Taking the radial parts of all the functions as being related to $P_{2p}(r_A)$ enables us to make use of the known integral and differential properties [Eq. (43)] of this function, especially as they relate to the effective potentials V_A and V_B and the atomic eigenvalues $\mathcal{E}_{2p}$.

To set up secular equations to obtain the coefficients c_i and d_i in Eq. (38), we have to compute matrix ele-

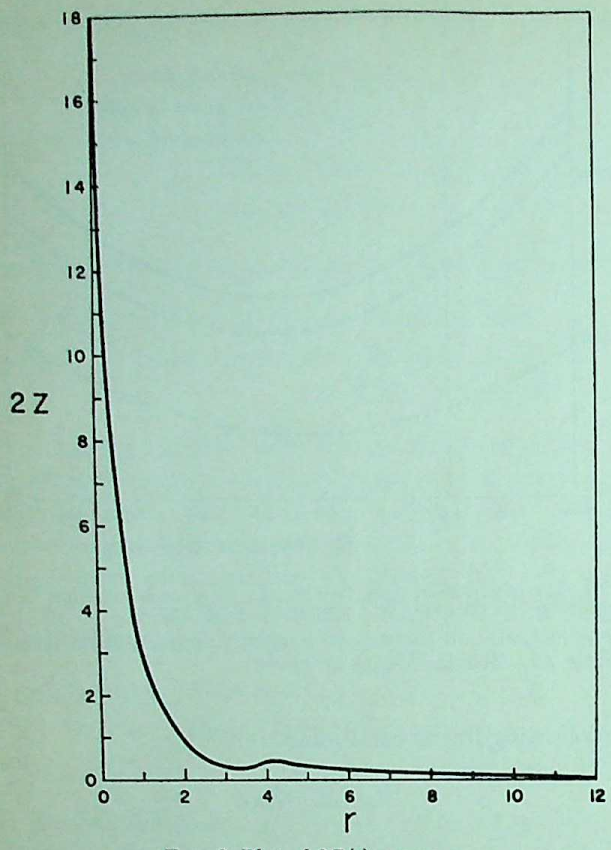

FIG. 3. Plot of $2Z(r)$ versus r.

ments $\mathcal{H}_{ij}=\langle\phi_i|\mathcal{H}|\phi_j\rangle$ for both u and g states. These matrix elements $\mathcal{H}_{ij}$ involve integrals over the orbitals in Eq. (39). Examples of the various types of integrals

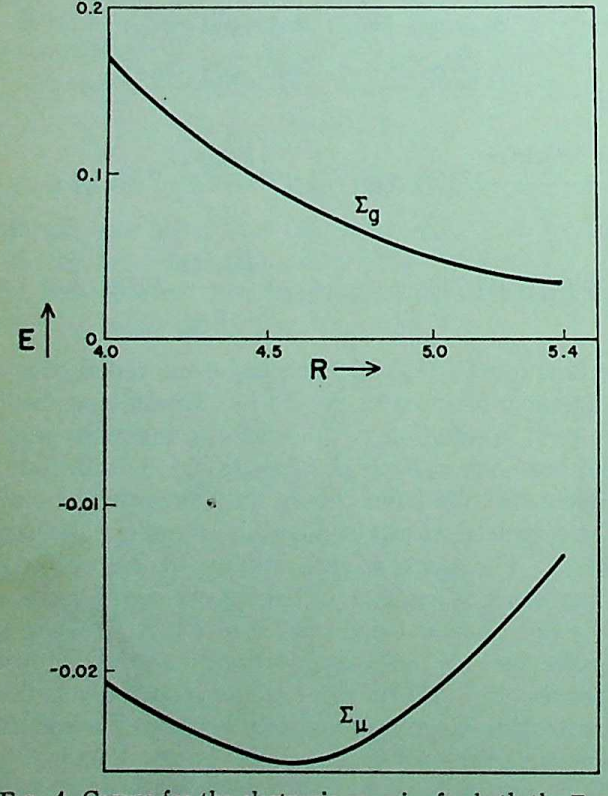

FIG. 4. Curves for the electronic energies for both the Σ_g and Σ_u states of the hole as a function of R, the distance between ions A and B.

that have to be calculated are

$$\langle\phi_{iA}|-\nabla^2|\phi_{iA}\rangle,\quad \langle\phi_{iA}|V_A|\phi_{iA}\rangle,\quad \text{and}$$
$$\langle\phi_{iA}|V_B|\phi_{iA}\rangle,\quad \langle\phi_{iB}|-\nabla^2|\phi_{iA}\rangle,\quad \langle\phi_{iA}|V_A|\phi_{iB}\rangle.$$

Of these integrals only the first two are one-center integrals, the other three are two-center integrals. The one-center integrals can be obtained by direct numerical integration. For example, we have

$$\langle\phi_{1A}|-\nabla^2|\phi_{1A}\rangle=\int_0^\infty\left(\frac{dP_{2p}}{dr}\right)^2dr+2\int_0^\infty\frac{P_{2p}^2}{r^2}dr,$$
$$\langle\phi_{1A}|V_A|\phi_{1A}\rangle=-\int_0^\infty\frac{P_{2p}^2}{r}2Z(r)dr, \tag{41}$$

where the potential $V_A(r)$ has been expressed as

$$V_A(r)\equiv-2Z(r)/r. \tag{42}$$

We obtain $V_A(r)$ directly from its definition by the one-electron Hartree-Fock equation:

$$V_A(r)=+\mathcal{E}_{2p}-\frac{P_{2p}''}{P_{2p}}-\frac{2}{r}, \tag{43}$$

where $\mathcal{E}_{2p}$ is the one-electron energy for the $2p$ state and $P''=d^2P/dr^2$. The function P_{2p} and the energy parameter $\mathcal{E}_{2p}$ are taken from Froese's calculations.[8] In Fig. 3 we have plotted the values of $2Z(r)$ as a function of r. For the two-center integrals we employ Löwdin's α-function method.[15] The α functions and the integrals involving them that were required [to determine the matrix elements of the Hamiltonian $\mathcal{H}$, Eq. (37)], were obtained at the computing centers of the University of Rochester and Argonne National Laboratory. Since we require the electronic energy as a function of the distance between the ions A and B we have to compute the matrix elements for different values of R. These computations were done for six values of R, namely $4.0a_0$, $4.4a_0$, $4.8a_0$, $5.0a_0$, $5.2a_0$, and $5.4a_0$. Since the functions ϕ_i do not form an orthonormal set, we must take account of the integrals $S_{ij}=\langle\phi_i|\phi_j\rangle$ for both the σ_g and σ_u states and the eigenvalue secular equation then takes the form:

$$\mathrm{Det}|\mathcal{H}_{ij}-S_{ij}E|=0 \tag{44}$$

for both σ_g and σ_u states. The eigenvalues $\mathcal{E}_g$ and $\mathcal{E}_u$ for the six values of R considered are tabulated in Table VII. Also tabulated in Table VII are the quantities

$$E_u=\mathcal{E}_u+2\mathcal{E}_g+(2/R)-3\mathcal{E}_{2p} \tag{45}$$

and

$$E_g=2\mathcal{E}_u+\mathcal{E}_g+(2/R)-3\mathcal{E}_{2p}. \tag{46}$$

The quantity E_u represents the decrease in energy of the three σ electrons due to bonding between the ions

A and B, when the hole is in the Σ_u state; E_g represents the corresponding energy decrease of the three σ electrons for the Σ_g state of the hole. The term $2/R$ represents the Coulomb energy of repulsion between the effective unit positive charges at the A and B ions about which the three σ electrons of the F_2^- molecule can be considered as moving. Thus E_u and E_g give the values of the term E_E in Eq. (1) for the Σ_u and Σ_g states of the hole, respectively. The variations of E_u and E_g with R are shown in Fig. 4. It is seen that while E_u has a minimum at $R=4.56a_0$, E_g has no such minimum. This result indicates that while the Σ_u state for the hole in the free F_2^- molecule is stable, the Σ_g state is not, as expected. Finally, to obtain the variation in total energies of the hole states Σ_u and Σ_g in the crystal with the distance R between A and B, we have to combine the energies plotted in Figs. 2 and 4 which will give us the variation with R of the total energy of the crystal in the presence of the hole.

V. TOTAL ENERGY OF CRYSTAL AND INTERPRETATION OF VARIOUS EXPERIMENTALLY STUDIED PROPERTIES OF THE HOLE

In Table VIII, we tabulate $E-E_0$ of Eq. (1) as a function of R. In addition to the lattice energy calculated from Eq. (34) and the electronic energy tabulated in Table VIII we have added the electronic affinity E_A which we have taken as 0.363 Ry from Froese's calculations.[8] For the lattice energy, in view of the inaccuracy in principle in the use of the Huggins-Mayer expression, as mentioned earlier, we have only used the Born-Mayer and Pauling expressions. Also tabulated is δE which is the difference between E and the quantity

$$\frac{\alpha_m e^2}{a}+E_A=1.283\ \text{Ry}, \tag{47}$$

representing the increase in energy of a crystal when an electron leaves the crystal (or a hole is produced in the crystal) excluding the energy change due to relaxation of the ions of the lattice and the electronic binding between the ions A and B. The suffixes g and u to δE and E are added in Table VIII to indicate the corresponding states Σ_g and Σ_u of the hole. The negative values of δE_u and δE_g indicate that the combined effects of the lattice distortion and electronic conjugation between A and B ions is to stabilize the hole center. In the case of the Σ_u state both the lattice distortion and electronic conjugation lead to stabilization. For the Σ_g state, the lattice distortion leads to stabilization while the presence of two antibonding σ_u electrons and only one bonding σ_g electron leads to destabilization. In Fig. 5 the energies δE_u and δE_g are plotted as functions of R for both the Pauling and Born-Mayer approximations. The zero ordinate on this plot would represent the energy of the undisturbed crystal after the hole has been removed, while the energy of the perfect crystal E_0 lies at −1.283 Ry. As was found in Fig. 4 with the electronic energy, again we have a minimum only in the Σ_u state and none in the Σ_g state suggesting that only the Σ_u state for the hole has a stable minimum. This result cannot be taken too literally, however, because we must realize that when R corresponds to the normal lattice distance or greater distances, our de-

TABLE VIII. Energy in Ry of the crystal due to the presence of the hole.

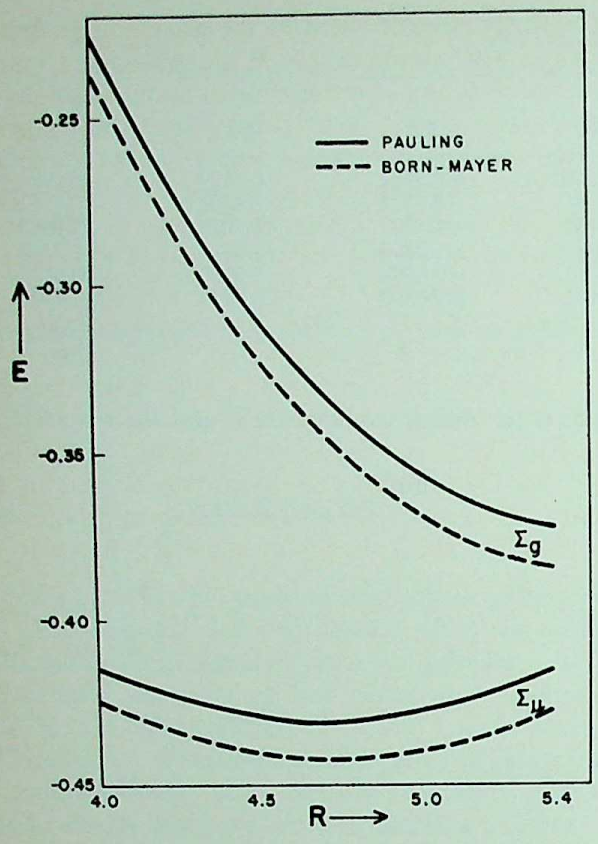

FIG. 5. Curves for the total energies δE_u and δE_g for the Σ_u and Σ_g states, respectively, of the hole as a function of R.

scription is not a complete one. In that case, there is high probability of the hole hopping to a new pair of F^- ions.

A comparison of Figs. 2, 4, and 5 indicates that the depths and rates of variation around the minimum of the Born-Mayer and Pauling curves are comparable. Also it is seen that the minima of the lattice energy curves for the Pauling and Born-Mayer approximations are at $R=4.89a_0$ and $4.92a_0$, respectively, while the minimum in the E_u curve for the electronic energy occurs at about $4.56a_0$. In comparison, the minimum in the δE_u curves for the total energy occurs at about $4.72a_0$ for both the Pauling and Born-Mayer approximations. These considerations indicate that according to our calculations, the lattice distortion around the V_k center and the electronic binding within the F_2^- molecule are comparable in importance in contributing to the stabilization of the V_k center.

From Fig. 4 one can also obtain the absorption energy for transitions between the Σ_u and Σ_g hole states. By the Franck-Condon principle, we expect the transition energy to be obtained vertically from the minimum in the E_u curve. From Fig. 5, the absorption energy for both the Born-Mayer and Pauling approximations is 0.097 Ry, which corresponds to 1.32 eV. This is to be compared with the experimentally observed[16] position of the absorption peak at 3.54 eV. We thus obtain only order-of-magnitude agreement with experiment. There are two possible sources of error which might be responsible for the disagreement between theoretical and experimental absorption energies. Our molecular calculations are approximate and perhaps a better calculation would lead to a stronger binding that is, a deeper energy curve for the Σ_u state of the hole and move the Σ_g state correspondingly upwards in energy.[14] The other possibility is the lack of self-consistency in our calculation which is implied by the direct addition of E_E and ΔE_L.

From the ground state and excited state curves for the energy as a function of R, we can also obtain the width of the absorption band. Assuming a linear dependence on the excited state configuration coordinate (R in our case)[17] one obtains the following expression for the width at an intensity equal to one half of that at the maximum, namely:

$$\Delta W = 27A\,(\mu K)^{-1/4}\ \text{eV}, \tag{48}$$

where A is the excited state slope in Ry/a_0, μ is the effective mass of the oscillator in units of the electron mass, and K is the ground-state force constant in Ry/a_0^2. Properly, one should use not only the reduced mass of the two F atoms A and B but include a small correction from the ions $C, D, \cdots, H$ which relax. However this last correction is rather difficult to calculate and is not warranted because of the various approximations that we have made so far in our calculations. So we take

$$\mu = 9.5m_e \times 1837,$$

where the electron mass, $m_e = 9.11\times10^{-28}$ g. From the Born-Mayer curve in Fig. 5, we get $K=0.1\ \text{Ry}/a_0^2$, $A=0.1\ \text{Ry}/a_0$. Substituting these numbers in (48) we have

$$\Delta W = 0.58\ \text{eV} \tag{49}$$

as compared to the experimental value of 0.95 eV found by Delbecq *et al.*[16] So the calculated value of the half-width is about a factor of 2 less than experiment. An improved electronic energy calculation would lead to a deeper potential well for the Σ_u state implying an increase in K, while the Σ_g state would get steeper leading to an increase in A. These two consequences are opposite in their influence on ΔW but perhaps their combined effect would lead to better agreement with experiment. Another quantity that can be derived from Fig. 5 from the ground-state curve is the half-width of the lowest vibrational state. One can deduce the following expression for this latter half-width, namely

$$(\Delta R)_{1/2} = (0.996)\,(\mu K)^{-1/4} a_0. \tag{50}$$

Using the values of μ and K for the Born-Mayer curve

we get $(\Delta R)_{1/2}=0.015a_0$. The Pauling curves in Fig. 5 yield almost exactly the same values for ΔW and $(\Delta R)_{1/2}$ as the Born-Mayer curves. This small value of $(\Delta R)_{1/2}$ assures us that the actual inter-nuclear distance in the F_2^- molecule is always well within the region in which our calculation is valid.

With the wave functions that we have obtained for the V_k center, we can make an approximate calculation of the hyperfine coupling constants between the unpaired electron spin and the F^{19} nucleus. The Hamiltonian describing the magnetic hyperfine interaction between a nucleus and the spins of the orbital electrons is given by

$$\mathcal{H}=\mathcal{H}_{\rm dip}+\mathcal{H}_F, \tag{51}$$

where

$$\mathcal{H}_{\rm dip}=\frac{2\mu_N\mu_B}{I}\sum_i\left[\frac{\mathbf{S}_i\cdot\mathbf{I}}{r_i^3}+\frac{3(\mathbf{S}_i\cdot\mathbf{r}_i)(\mathbf{I}\cdot\mathbf{r}_i)}{r_i^5}\right] \tag{52a}$$

and

$$\mathcal{H}_F=(16\pi/3)(\mu_N\mu_B/I)\sum_i\mathbf{S}_i\cdot\mathbf{I}\delta(\mathbf{r}_i). \tag{52b}$$

In Eqs. (52), μ_N and $\mathbf{I}$ are, respectively, the magnetic moment and spin of the nucleus, μ_B is the Bohr magneton, $\mathbf{S}_i$ and $\mathbf{r}_i$ are, respectively, the spin and position vectors of the ith electron. The summation in i runs over all the electron spins in the atomic or molecular system under consideration. When we have a system with one unpaired electron and the wave functions for the various electronic states of the system are orthogonal we can drop the summation over i in Eqs. (52a) and (52b) and take expectation values over the orbital corresponding to the single unpaired electron. However, when the wave function for the orbital of the unpaired electron is not orthogonal to the wave functions for other states one has to take the expectation values of the summations in (52a) and (52b) over the entire determinantal wave function involving both the outer unpaired electronic state and all other paired states of the molecule. It can be shown[18] however, that in such cases, one can simplify the calculation by making the unpaired electron wave function orthogonal to the wave functions for the paired states by the Schmidt orthogonalization procedure. One then has to take the expectation value of only one term out of the summations in (52a) and (52b) over the orthogonalized wave function. For the ground state Σ_u of the hole, the unpaired electron will be in a σ_u state. The orthogonalized wave function for the unpaired electron will therefore be of the form:

$$\psi=\frac{\psi_u-S_1(\psi_{1SA}+\psi_{1SB})-S_2(\psi_{2SA}+\psi_{2SB})}{N[1+2S_1^2\langle\psi_{1SA}|\psi_{1SB}\rangle+2S_2^2\langle\psi_{2SA}|\psi_{2SB}\rangle+4S_1S_2\langle\psi_{1SA}|\psi_{2SB}\rangle]^{1/2}}, \tag{53}$$

where

$$S_1=\langle\psi_u|\psi_{1SA}\rangle=-\langle\psi_u|\psi_{1SB}\rangle,$$
$$S_2=\langle\psi_u|\psi_{2SA}\rangle=-\langle\psi_u|\psi_{2SB}\rangle,$$
$$N^2=\langle\psi_u|\psi_u\rangle.$$

The overlap integrals $\langle\psi_{1SA}|\psi_{1SB}\rangle$, $\langle\psi_{1SA}|\psi_{2SB}\rangle$, and $\langle\psi_{2SA}|\psi_{2SB}\rangle$ are all one order of magnitude less than the overlap integrals S_1 and S_2, so we shall neglect them. Using Eq. (53) for the wave function ψ of the unpaired electron and Eq. (52a) for $\mathcal{H}_{\rm dip}$, we obtain Eq. (54) for the hyperfine constant "b". Since we want to express "b" in Oersteds we have divided the hyperfine constant in energy units (ergs) by $2\mu_B$.

$$\begin{aligned}b=(3\mu_N/2IN^2)[&\langle\psi_u|0|\psi_u\rangle+S_1^2\langle\psi_{1SA}|0|\psi_{1SA}\rangle\\&+S_2^2\langle\psi_{2SA}|0|\psi_{2SA}\rangle-2S_1\langle\psi_u|0|\psi_{1SA}\rangle\\&-2S_2\langle\psi_u|0|\psi_{2SA}\rangle+2S_1S_2\langle\psi_{1SA}|0|\psi_{2SA}\rangle],\end{aligned} \tag{54}$$

with

$$0=(3\cos^2\theta_A-1)/r_A^3,$$

where r_A and θ_A refer to the polar coordinates of the electron with respect to A and with the AB direction as the Z axis. Equation (54) is approximate because a number of cross terms, involving $1S$ and $2S$ orbitals on atom B have been dropped. These terms are three orders of magnitude less than the leading term $\langle\psi_u|0|\psi_u\rangle$. Furthermore it is clear that the second, third, and sixth terms in (54) are identically zero. The fourth and fifth terms are two orders of magnitude smaller than the leading term. Therefore we can write, using (38) and (39),

$$\begin{aligned}b=(3\mu_N/2IN^2)[&\sum_{ij}d_id_j\{\langle\phi_{iA}|0|\phi_{jA}\rangle\\&+\langle\phi_{iA}|0|\phi_{jB}\rangle+\langle\phi_{iB}|0|\phi_{jA}\rangle+\langle\phi_{iB}|0|\phi_{jB}\rangle\}].\end{aligned} \tag{55}$$

In Eq. (55) the fourth term in brackets is two orders of magnitude smaller than the contribution from the first term while the second and third terms are each more than one order of magnitude smaller. Also, when either i or j is three or four, the contribution to the first term is identically zero. We thus have finally,

$$\begin{aligned}b=(6\mu_N/5IN^2)[&d_1^2\langle\phi_{1A}|r_A^{-3}|\phi_{1A}\rangle+d_2^2\langle\phi_{2A}|r_A^{-3}|\phi_{2A}\rangle\\&+2d_1d_2\langle\phi_{1A}|r_A^{-3}|\phi_{2A}\rangle].\end{aligned} \tag{56}$$

Using Eq. (39) for ϕ_{1A} and ϕ_{2A} we then obtain for b the value 747.3 Oe for both the Pauling and Born-Mayer approximations. More than 99% of the contribution to b comes from the first term in (56). Since our wave functions were tabulated for the points listed in Table VIII, we had to interpolate the coefficients d_i in Eq. (55) at R equal to $4.72a_0$. The calculated value

TABLE IX. Contributions from the various terms in Eq. (57) to the isotropic hyperfine interaction constant for F^{19} nucleus in the V_k center. The wave function densities are in units of a_0^{-3} and the contributions to a_F in Oe.

Term in Eq. (57)	Wave function density	Contribution to hyperfine constant a_F
First	0.00012	0.175
Second	0.00684	10.317
Third	0.00604	9.099
Fourth	−0.00178	−2.679
Fifth	−0.00167	−2.516
Sixth	0.01288	19.384
Total	0.02243	33.780

of the hyperfine constant b is in fair agreement, certainly in much better agreement, with experiment than the optical absorption frequency and width. The experimental value of b is not known unambiguously[3] because it depends on the sign of a which is not known. If the sign of a is assumed negative, the experimental value of b would be 946 Oe while for a positive the value would be 828 Oe. The hyperfine constant a is given by

$$a=a_F-(b/3), \tag{57}$$

where

$$a_F=(8\pi\mu_N/3IN^2)[\psi_u^2(A)+S_1^2\psi_{1SA}^2(A)+S_2^2\psi_{2SA}^2(A)-2S_1\psi_u(A)\psi_{1S}(A)-2S_2\psi_u(A)\psi_{2S}(A)+2S_1S_2\psi_{1S}(A)\psi_{2S}(A)].$$

The term a_F arises from the Fermi contact term $\mathcal{H}_F$ in the Hamiltonian and $-b/3$ from $\mathcal{H}_{\rm dip}$. In Eq. (57) we have neglected all the terms that involve $\psi_{1SB}(A)$ and $\psi_{2SB}(A)$. We have done this because the terms involving $\psi_{1SB}(A)$ and $\psi_{2SB}(A)$ are an order of magnitude smaller than the smallest of the terms in Eq. (54). This approximation is in line with our assumption concerning the smallness of the overlaps between the $1S$ and $2S$ orbitals about the two centers. To emphasize the importance of the overlap terms which may also be referred to as the Pauli correlation terms,[19] we have tabulated in Table IX the values of the various terms in the brackets of Eq. (57) in units of a_0^{-3} as well as the value of a_F in Oersteds for $R=4.72a_0$, the equilibrium distances for both the Pauling and Born-Mayer cases.

Combining a_F and $-b/3$ we get for a the value -215.3 Oe. It appears that the constant b is in much better agreement with experiment than the costant a. The reason for this can be gauged by examining Table IX. From Table IX it appears that the major contribution to a comes from the second, third, and sixth terms in Eq. (57). All these terms depend bilinearly on the overlap integrals S_1 and S_2. A stronger conjugation between the two ions A and B, as expected from earlier considerations of the optical data, would reduce the distance corresponding to the minimum in the total energy curve in Fig. 4 and would therefore increase S_1 and S_2 significantly. Such an increase would enhance a_F and therefore cause a greater cancellation between a_F and $-b/3$ leading to a smaller theoretical value of a. The value of b on the other hand, as seen from Eq. (56) does not depend sensitively on R and should therefore be relatively unaffected by a stronger conjugation. This stronger conjugation would also make the electronic energy curve deeper than the lattice energy curve and therefore make the properties of the V_k center less sensitively independent on the lattice potential. Evidence that this is the case has been obtained by Twidell and Hayes[20] in recent work on CaF_2. It should be mentioned here that in addition to the Pauli correlation effect there will be a contribution to a_F from the exchange polarization effect[21] which arises out of the difference in the potentials experienced by electrons in the two spin states of the $1S$ and $2S$ shells. For an order of magnitude estimate of the exchange polarization one could use as a criterion the results from the nitrogen atom. Thus, noting that there are three unpaired $2p$ electrons in the nitrogen atom as compared to approximately one-half of a $2p$ electron per fluorine atom in the present case, one would expect the exchange polarization contribution to a to be about a sixth of the 10 Mc result found for the nitrogen atom. This would correspond to only about 0.25 Oe. While this result is probably an underestimate because the $1S$ and $2S$ wave functions in fluorine atom are more strongly bound than in nitrogen, it is however clear that a consideration of exchange polarization effect alone cannot explain the difference between our calculated values of a and experiment.

VI. CONCLUSION

From the calculations in the previous sections it appears that both the distortion of the lattice around the V_k center and the electronic binding of the σ electrons play important roles in determining the properties of the V_k center. The relative importance of the lattice and electronic energies would of course determine how the properties of the V_k center will vary from one crystal to another. Recent work of Twidell and Hayes,[20] however, indicates that the electronic properties of the V_k center in CaF_2 are almost the same as in LiF. This could be explained either if the electronic binding energy of the F_2^- molecule and the lattice energy are as comparable with each other in importance as in LiF or if the electronic binding energy has been underestimated by us and really involves a curve with a steeper minimum than we have calculated and the lattice effect is of minor importance in determining the equilibrium

configuration. The latter possibility seems somewhat more probable, from our considerations of optical and hyperfine data in the last section. Also, we have made an approximate calculation of the energy of a trapped fluorine atom at a F^- site using the Born-Mayer approximation and allowing for displacements of the nearest neighbor Li^+ ions. The procedure employed in the calculations is analogous to that used by Dick[22] in recent work on alkali halide solid solutions. The energy of the trapped fluorine atom relative to the undisturbed crystal after the hole is removed is then found to be -0.441 Ry. Comparing this with the corresponding energy, -0.443 Ry for the V_k center for the Born-Mayer approximation, it is noticed that they are almost equal, although one would expect the V_k center to be lower in energy from a consideration of relative stability. This result seems to substantiate our conclusion that we have underestimated the electronic binding energy of the V_k center and should have a curve with a steeper minimum for the ground state in Figs. 4 and 5.

It would be useful to combine the results of a careful recalculation[23] of the electronic energy of the F_2^- molecule with the results of our lattice energy calculations in Sec. III to obtain a better total energy curve for the V_k center. It would also be interesting to find out if the recalculated wave function for the electronic σ_u state gives better agreement with the experimental value of the hyperfine constant a. It is encouraging that the results of the lattice energy calculations in Sec. III with two widely different repulsive energy formulas, such as the Born-Mayer and Pauling expressions (10) and (12), are not very different from one another and especially that the curves in Figs. 2 and 5 are so similar in shape. This is a very significant result because the effects of such widely different force laws have not been extensively compared in imperfect crystals. In future calculations one could therefore use either the Born-Mayer or Pauling repulsive formula with equal confidence.

One possible source of error in the calculation of the absorption energy should be mentioned here. When we consider the Hartree-Fock approximation for an atomic or molecular system, the net energy of the system is not just the sum of the one-electron energies for the individual states because then the Coulomb and exchange interaction energies get counted twice. One has therefore to subtract off the Coulomb and exchange energies from the sum of one-electron energies for the various states. The difference in E_u and E_g, which are tabulated in the last column of Table VII, is therefore likely to differ from the $\Sigma_u \rightarrow \Sigma_g$ excitation energy for the hole if there is appreciable difference in the exchange and Coulomb integrals occurring in the energy expressions for the σ_g and σ_u states of the electrons. We have not made any estimates of the correction due to this source of error because such a refinement would be inconsistent with the approximations we have already made in our electronic energy calculations in Sec. IV.

There is one other correction that has to be considered in any improved calculations in future. In Sec. IV and in Fig. 5 we have directly added the electronic and lattice energies associated with the V_k center which amounts to a neglect of self-consistency requirements. To be entirely self-consistent, one should consider the change in the potential seen by the electrons due to the distortion and polarization of the lattice. Correspondingly, one has also to consider the change in lattice energy produced by the redistribution of the electron density on the F_2^- molecule due to electronic binding. However, if it turns out in a refined calculation that the electronic binding is much more important than the lattice distortion in determining the equilibrium situation for the V_k center, one would expect the consistency condition involving interaction between lattice and electronic potentials to be correspondingly less important.

ACKNOWLEDGMENTS

This work was initiated when two of the authors (T. P. Das and R. S. Knox) were at the University of Illinois. We are grateful to Professor F. Seitz for his hospitality and his interest in this work. We are also grateful to Professor B. G. Dick of the University of Utah and Dr. T. Gilbert and many other colleagues at Argonne National Laboratory and the University of Rochester for valuable discussions. Dr. Yamashita kindly communicated to us his earlier unpublished work in this field which was rather helpful to us.

Electron Tunneling Through Thin Aluminum Oxide Films*

THOMAS E. HARTMAN AND JAY S. CHIVIAN
Texas Instruments Incorporated, Dallas, Texas
(Received 13 December 1963)

The thin-film Al-Al_2O_3-Al system is studied. The current density as a function of temperature and voltage through aluminum oxide less than 30 Å thick is analyzed using the theory of Stratton. The charge transport mechanism is established as tunneling by the functional form of the small temperature dependence. By fitting the current density data to the temperature dependence for $79°K < T < 300°K$ and $0 \leq V \leq 1.0$ V, the integrals arising from the WKB approximation are evaluated for an arbitrary barrier shape. The region of applied voltage for which quadratic power series expansions in V of these integrals are valid is established as $0.0 \leq V \leq 0.3$ V. Assuming a trapezoidal barrier shape, approximate values for the barrier heights of 0.89 and 0.78 eV and an electron effective mass of $m^*/m = 1$ are deduced. Comparisons are drawn between the more general forms of Stratton's and Simmons' theories.

I. INTRODUCTION

THE flow of electrons through a sufficiently thin insulating film will occur by the quantum mechanical mechanism of tunneling.[1] Barrier layers thicker than a few tens of angstroms are nearly impenetrable to tunneling electrons, as the transmission probability falls off exponentially with thickness, except where the tunnel distance is shortened by the application of a sufficiently large voltage (i.e., Fowler-Nordheim[2,3] region). For diminishingly small applied voltages, the electronic conductivity of films a few tens of angstroms thick may arise from thermionic or Schottky emission over the barrier,[4] tunneling through the barrier, space-charge limited current,[5] or a combination of these mechanisms with traps in the forbidden gap of the insulator participating as an intermediary.[6]

At temperautres below the superconducting transition for the aluminum films in the Al-Al_2O_3-Al system, the electron current through an aluminum oxide film a few tens of angstroms thick has been shown to result from tunneling.[7] The thermionic or Schottky contribution to the current is clearly negligible at these temperatures.

Emtage and Tantraporn[4] have reported that for the Al-Al_2O_3-Al system the entire current through a 50-Å-thick oxide film at room temperature appears to come from Schottky emission. Whether thermionic emission or tunneling dominates the zero-voltage conductivity depends very strongly on the thickness of the oxide film. For sufficiently thin oxide films tunneling will be the dominant conduction mechanism. It is easy to show for the Al-Al_2O_3-Al system, assuming a rectangular barrier 0.85 eV high and an effective mass $m^*/m = 1$, that at room temperature the critical thickness is 35 Å (or thinner), tunneling will dominate almost exclusively. For oxide films thicker than 35 Å, thermionic or Schottky emision will dominate and the conductivity will be highly temperature-dependent.

The current density through aluminum oxide films less than 30 Å thick, sandwiched between two aluminum films, was measured as a function of temperature and voltage. The conduction mechanism, even for diminishingly small applied voltages, is shown to be tunneling by the functional form of relatively small temperature dependence. The data are analyzed using the theory of Stratton.[8] Using the barrier height and thickness deduced from the data the Schottky current was calculated and found to be more than two orders of magnitude less than the measured current at room temperature. The integrals arising from the WKB approximation in the theory are evaluated for an arbitrary potential barrier shape by fitting the current density data to the temperature dependence. Finally, the theory of Stratton is modified to take more accurate account of the back current, which is the current that flows in the direction opposite to the current which is aided by the applied potential. The resulting equation can be reduced to either Stratton's or Simmons' theory depending on the approximations employed.

II. EXPERIMENTAL TECHNIQUE

A. Sample Preparation

The configuration of the aluminum-aluminum oxide-aluminum thin-film sandwiches employed in these experiments is shown schematically in Fig. 1. The substrate is a glass microscope slide cleaned by a technique similar to that of Lowe.[9] The slide is subsequently ion bombarded in the manner described by Holland.[10]

The metal layers are deposited on an unheated substrate in a vacuum-evaporation system at a pressure of less than 1×10^{-6} Torr. The composition of the resi-

TABLE I. Residual gas analysis.[a]

Gas or vapor	Partial pressure, % of total pressure
Water vapor	89
Carbon monoxide	8
Nitrogen	1
Oxygen	1
dc 704 (pump oil)	<1

[a] The residual gas analysis was made with a mass-spectrometer similar to the one described by W. D. Davis and T. A. Vanderslice, *Vacuum Symposium Transactions*, edited by C. R. Meissner (Pergamon Press, Inc., London, 1960), p. 417.

dual gasses in the system at its ultimate pressure of 3×10^{-8} Torr are shown in Table I. The silver used for contacts and interferometry gauges is vaporized from a molybdenum Knudsen surface emitting source[11] and the 99.999+% pure aluminum is vaporized from a tungsten hairpin filament source.[12]

First the lower aluminum layer is deposited on aluminum contacts. The slide is then removed from the vacuum system, and placed in a preheated furnace of dry air at atmospheric pressure and a temperature of 300°C for two to four hours.[13] The slide is then vapor degreased in isopropyl alcohol, replaced in the vacuum system, ion bombarded, and the remaining metal layers are deposited.

The metal films are each approximately 1000 Å thick. The junction area is 10^{-2} cm^2, and is coated with a protective layer of silicon monoxide 2000 to 3000 Å thick (not shown in Fig. 1) using a tantalum perforated chimney source similar to the one described by Drumheller.[14] The samples are stored in a vacuum desiccator at room temperature.

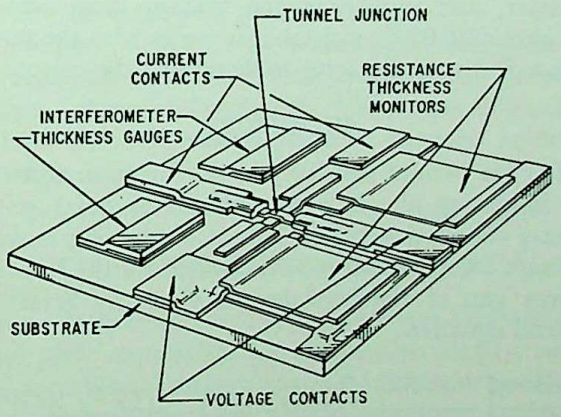

FIG. 1. Sample configuration.

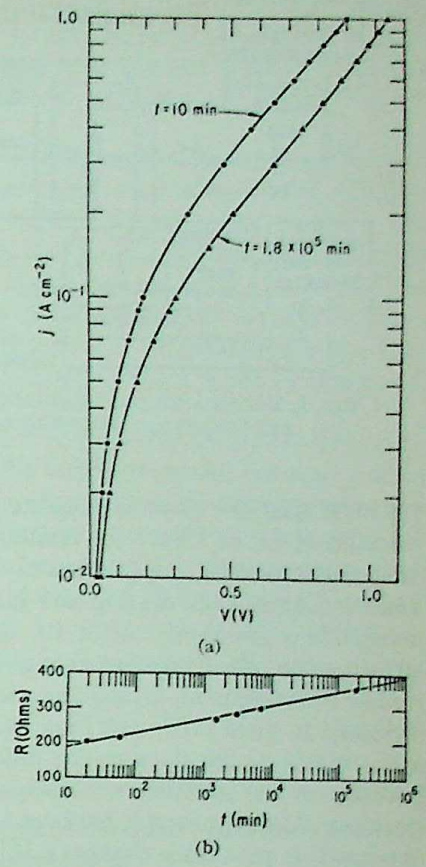

FIG. 2. Electrical characteristics of a typical sample as a function of time. (a) Initial and final plot of the current density as a function of the applied voltage. (b) Plot of the zero bias junction resistance as a function of time.

B. Sample Characteristics

For applied voltages less than 90 mV, the electrical characteristics of the samples are Ohmic (see Fig. 7). The resistance and capacitance of the samples are measured using a low-frequency-transformer ratio arm bridge which impresses 90 mV rms (or less) upon the sample, hence the values obtained correspond essentially to the zero-applied-voltage condition. All other electrical measurements are made using four-terminal methods, so that lead and contact resistance errors are avoided. The resistance of the samples range from 100 to 400 ohms and their capacitance is about 0.022 to 0.028 μF. The zero-applied-voltage resistance R and the j versus V characteristics for a typical sample are shown in Fig. 2, where j is the current density, V is the applied voltage, and t is the time ($t=0$ is the time when the sample fabrication was completed).

An increase in the junction resistance of the same general form as that reported by Handy[15] is observed. As shown in Fig. 2(b) the junction resistance increases approximately as the logarithm of the time. Extrapolating this plot the junction resistance would be expected to be double its initial (i.e., $t=20$ min) value at $t=1.6\times10^6$ min (or in about three years). The slope of the junction resistance versus $\log t$ is similar to that reported by Handy for unprotected junctions within 2 to 3 min after deposition of the second aluminum layer. Handy

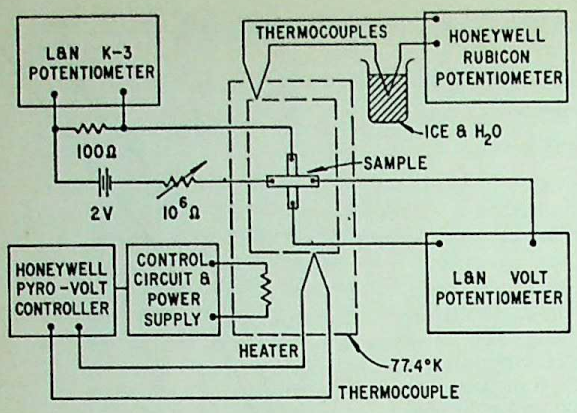

FIG. 3. Schematic diagram of electrical measurement and temperature controlling apparatus.

reported that the slope is pressure sensitive and in a vacuum of 5×10^{-2} Torr the resistance doubled in less than 3000 min (i.e., approximately two days). These results suggest that coating the junction with silicon monoxide immediately after its formation tends to preserve the initial junction characteristics.[16]

The measurement techniques described below are designed to yield 0.1% precision, which is required for the analysis of the data in the following section. The stability of the junction is consequently of prime importance. After the sample has been aged for four months the junction resistance changes 0.1% in about 3000 min which is approximately the time required to take the data for the volt-current characteristics analyzed in Sec. IV.

The change in the zero-applied-voltage resistance is accompanied by a shift in the volt-current characteristics. After storing the samples for four months, the electrical characteristics up to 1.0 V are quite stable with time. The initial plot of log j versus V and the plot after aging for four months are shown in Fig. 2(a). The final plot is reproducible to within 0.1% at a constant temperature even when the sample has been cycled to liquid-nitrogen temperature between measurements. No shorting,[17] hysteresis,[17] long time constant,[17] forming,[18,19] negative dynamic resistance,[18,20] or change in the direction or rectification with temperature[15] effects were observed. A small rectification effect is observed and is discussed in Sec. IV.

Aluminum oxide films formed by a number of different techniques have been investigated in this laboratory. Only the oxides gfown thermally, as described above, were used in the experiments reported here. However, the results are considered to apply to almost all aluminum oxide films of less than 30 Å thickness grown on the surface of vacuum deposited aluminum films, provided the applied voltage is less than 0.2 V. The shape of the log j versus V plot can be correlated with the oxidation technique.[21] However, the characteristic shapes for each oxidation technique are nearly identical for applied voltage less than 0.2 V, aside from a multiplicative constant which arises from small differences in the oxide film thickness.

C. Measurement Techniques

A schematic diagram of the electrical measurement and temperature controlling apparatus is shown in Fig. 3. The apparatus is designed to maintain the sample inside a temperature-controlled light-tight chamber at any temperature between the boiling point of liquid nitrogen and room temperature. Since the substrate is a relatively poor heat conductor, it is necessary to enclose the sample in a constant temperature chamber, because the sample tends to come to radiation equilibrium with the temperature of its surroundings. The apparatus is similar to that of Ure[22] with the addition of a proportional temperature controller which regulates the dc heater power. With this apparatus the temperature can be maintained within ±0.2°K during the time required to measure the volt-current characteristics. The controlled temperature is measured with a copper-constantan thermocouple.

The dc volt-current characteristics at constant temperature are measured by setting a predetermined voltage across the junction, as compared with a volt potentiometer, and measuring the voltage drop across a 100 ohm ($\pm0.05\%$) resistance in series with the sample with a K-3 potentiometer to determine the current.

III. THEORY

The net current density j in the direction normal to the insulating film in a metal-insulator-metal system, from a conducting region 1 to a conducting region 2, through the potential barrier formed by the forbidden energy gap of the insulator, is given by Stratton's[8] general equation

$$j=\frac{4\pi mq}{c_1^2h^3}\left[\frac{\pi c_1kT}{\sin(\pi c_1kT)}\right]\exp(-b_1)[1-\exp(-c_1qV)], \quad (1)$$

where

$$b_1=\alpha\int_{x_{11}}^{x_{21}}(\varphi-\zeta_1)^{1/2}dx; \quad c_1=\frac{\alpha}{2}\int_{x_{11}}^{x_{21}}(\varphi-\zeta_1)^{-1/2}dx,$$

which are functions of the applied voltage V that arise

[16] This result is in disagreement with the results of J. Penley, J. Appl. Phys. 33, 1623 (1962), but suggests that the pressure sensitive resistance change may be due to diffusion through the unprotected top metal layer, see J. J. Wortman and R. M. Burger, Second Annual Symposium on the Physics of Failure in Electronics, 1963 (unpublished).

Digitized by Arya Samaj Foundation Chennai and eGangotri

from the WKB approximation and can be computed for a given barrier $\varphi(x,V)$. The limits x_{11} and x_{21} are the classical turning points given by the values of x for which $\varphi(x,V)=\zeta_1$, ζ is the Fermi energy, x is the direction normal to the insulating film, q is the charge and m the mass of the electron, h is Planck's constant, T is the absolute temperature and $\alpha=4\pi(2m)^{1/2}/h$.

Equation (1) is derived assuming a parabolic energy-momentum relation with the same electron mass in each of the three regions. Stratton[8] has shown that the equation is still valid when the effective mass in the insulator is less than the mass in either conducting region. It is found that the more general form of Stratton's equation for a nonparabolic energy-momentum relation in the insulator is not required to explain the results in Sec. IV. This presumably arises because the barrier heights deduced in Sec. IV are a small fraction of the energy gap. Other conditions on the range of application of Eq. (1) are discussed by Stratton.

The last term in brackets in Eq. (1) represents the back current, or electrons tunneling from the conducting region 2 to conducting region 1 against the applied electric field. This term diminishes in importance rapidly with increasing applied voltage. The voltage dependence of the forward current results predominantly from $b_1(V)$ in the exponential.

In deriving the equation it is assumed that the current is largely due to electrons whose energies are close to the Fermi energy in the conducting region 1. As a result an expansion with respect to energy near ζ_1 is employed. The result of this procedure is to assume that most of the current is forward current, and that even the back current arises from electrons whose energies are close to ζ_1. This is a very good approximation for all but the very small applied voltages.

The back current is more accurately represented by an expansion about the Fermi energy in the conducting region 2 given by $\zeta_2=\zeta_1-qV$.[23] From the symmetry it follows that the current density is more accurately given by

$$j=\frac{4\pi mq}{h^3}\left\{\frac{e^{-b_1}}{c_1^2}\left[\frac{\pi c_1 kT}{\sin(\pi c_1 kT)}\right]-\frac{e^{-b_2}}{c_2^2}\left[\frac{\pi c_2 kT}{\sin(\pi c_2 kT)}\right]\right\}. \quad (2)$$

From this more accurate expression both Stratton's and Simmons'[24] expressions for the current density, assuming an arbitrary barrier shape $\varphi(x,V)$, can be derived depending on the particular assumptions employed.[25] Both Eq. (2) and Simmons'[24] Eq. (20) are intractable to experimental analysis.

The difficulty in arriving at any straightforward solution for the current density, where an arbitrary (or unknown) barrier shape $\varphi(x,V)$ is involved, is the evaluation of the integrals arising from the WKB approximation. Stratton expands the functions around energies near the Fermi level to avoid the difficulty, whereas Simmons employs an approximate value for the integrals.

The advantage of Stratton's theory is that it holds for nonzero temperatures and in the form given in Eq. (1) it is tractable to experimental analysis. The unknown functions $b_1(V)$ and $c_1(V)$ can be deduced by fitting the experimental current-density data, as functions of temperature and voltage, to Eq. (1) as shown in the following section. The disadvantage is the inaccuracy in the back current, which is not serious as will be indicated.

The disadvantages to Simmons' theory are the restriction to absolute zero temperature and the experimental intractability. The advantage is that since electrons of all energies are taken into account the back current is more accurate. By combining the two approaches, some of the advantages of both can be retained. In particular, the average barrier height as defined by Simmons and the tunnel path length can be given by

$$\bar{\varphi}-\zeta_1=b_1/(2c_1), \quad (3)$$

and

$$(\Delta x)^2=2b_1c_1/\alpha^2, \quad (4)$$

respectively, in terms of Stratton's functions which can be deduced from experiment.

Finally, it is easy to show from Eq. (2) (using the values of the functions b_1 and c_1 deduced in the following section) that at a given temperature the current does not rise as rapidly with increasing voltage as implied by Eq. (1). The error decreases monotonically with increasing voltage and at 0.10 V the correction attenuates the tunnel current only about 3%. For diminishingly small applied voltages Simmons' and Stratton's expressions (at $T=0$) are equivalent. At a constant voltage, the current is less than that predicted by Eq. (1). The error decreases monotonically from a maximum of about 2% to about 1% at room temperature. The corrections to Eq. (1) stemming from the more accurate account of the back current are seen to be small.

IV. EXPERIMENTAL RESULTS

A. Temperature Dependence

It will now be shown that the experimental current density data as a function of temperature and voltage can be fitted to the functional form of the temperature dependence in Eq. (1). The temperature dependence is given by

$$j(T)\propto[\pi c_1 kT/\sin(\pi c_1 kT)]. \quad (5)$$

The functional form of Eq. (5) arises from the Fermi distribution of electrons in the metal layers and will not fit unless the electrons tunnel directly from the metal on one side to the metal on the other side (since voltages

[23] The authors are indebted to R. Stratton for pointing out this correction to the theory.

[24] J. G. Simmons, J. Appl. Phys. 34, 1793 (1963).

[25] In deriving Simmons' (Ref. 24) Eq. (20) some differences in the β factors from those of Simmons arise; however, in practice $\beta\approx 1$ over the range of interest.

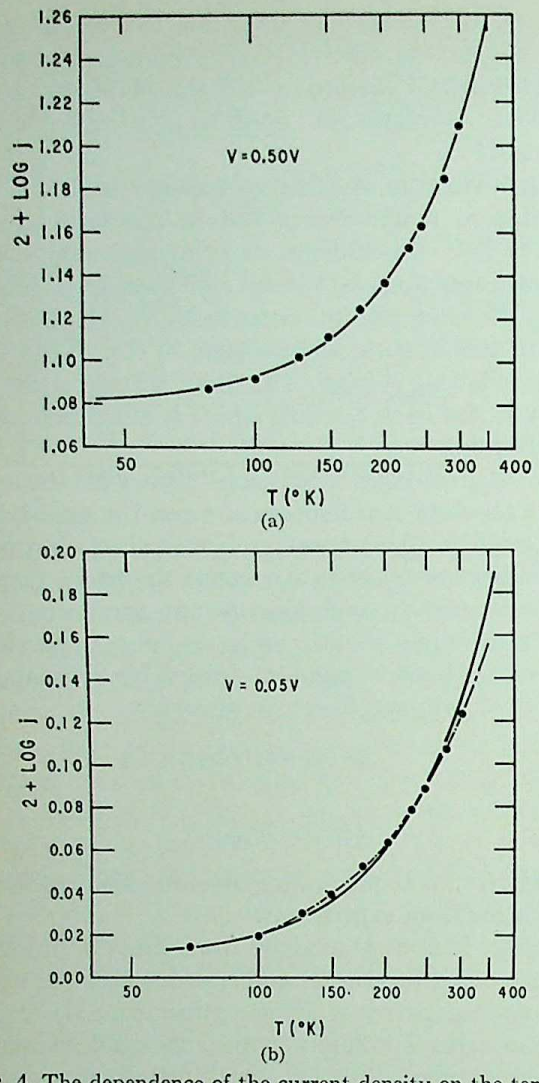

FIG. 4. The dependence of the current density on the temperature at (a) 0.50 V and (b) 0.05 V. The points are experimental data, and the curve, which is theoretical, corresponds to Eq. (1) [or the expression in (5)].

less than those required for Fowler-Nordhiem emission are employed).

The coefficients b_1 and c_1 are determined, at any particular voltage, by fitting the experimental plot of $\log_{10} j(T)$ versus $\log_{10} T$ to the theoretical plot of Eq. (5) which is $\log_{10}[\pi c_1 kT/\sin(\pi c_1 kT)]$ versus $\log_{10}(\pi c_1 kT)$. A typical example is shown in Fig. (4a). The value of c_1 is deduced from the temperature corresponding to $\pi c_1 kT=1$. Using Eq. (1), b_1 can be calculated from $j(0)$, which is deduced from the current density extraploated to absolute zero temperature corresponding to $[\pi c_1 kT/\sin(\pi c_1 kT)]=1$. The quality of the fit shown in Fig. 4(a) for 0.50 V applied potential is characteristic for all voltages between 0.10 and 0.90 V. It should be noted that the scale of the ordinate axis has been expanded greatly compared to the abscissa in order that the relatively small (e.g., compared to Schottky) temperature dependence (between 30 to 50% change in going from liquid nitrogen to room temperature) can be compared accurately with the theoretical form.

The quality of the fit of the experimental current-density data, as functions of temperature and voltage, to the functional form of the theoretical temperature dependence establishes that tunneling directly between the two aluminum layers is the predominant mechanism for the electronic conduction through the aluminum oxide film.

A typical example of the fit of the data to the expression (5) for $V<0.10$ V is shown in Fig. 4(b). The deviations may arise from small thermal emf's which can produce internal voltages, but do not appear to be due to the back current [i.e., fit the transcendental temperature dependence given in Eq. (2)]. The form of the experimental curve, shown as the dashed curve in Fig. 4(b), is characteristic of all the samples investigated at very small applied voltages.

The temperature dependence in Eq. (1) can be expanded for small temperatures in a binomial series with respect to $\pi c_1 kT$ which gives[8]

$$\Delta j = j(T) - j(0) = \frac{j(0)}{6}(\pi c_1 kT)^2 + \frac{7j(0)}{360}(\pi c_1 kT)^4 + \cdots . \quad (6)$$

Chow[26] has analyzed the temperature dependence of the current density in the Be-BeO-Au system by fitting the data to the quadratic dependence given in Eq. (6) and neglecting the higher order terms. The $j(0)$ was calculated, assuming the quadratic dependence, using two of the data points. The result of plotting $\log_{10} \Delta j = \log_{10}[j(T)-j(0)]$ versus $\log_{10} T$ is a straight line of slope 2.04 up to 300°K. Similar results for the Al-Al_2O_3-Al system have also be reported.[17] Analyzing the temperature dependence data in this way is subject

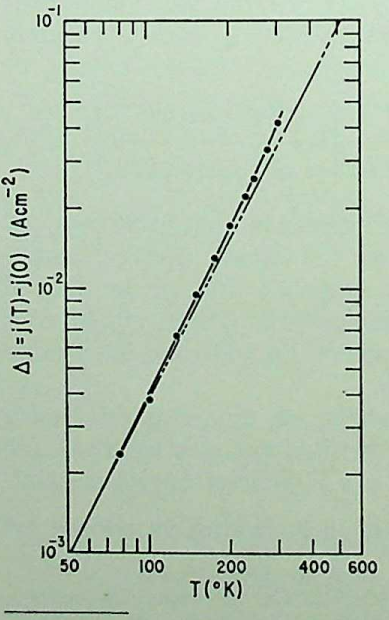

FIG. 5. The dependence of the change in the current density at 0.50 V on the temperature. The points are experimental data, the dashed line is the T^2 approximation, and the curve, which is theoretical, corresponds to Eq. (6) and includes the T^4 term.

[26] C. K. Chow, J. Appl. Phys. 34, 2919 (1963).

Digitized by Arya Samaj Foundation Chennai and eGangotri

to considerable error. In order that the quadratic approximation hold, $j(0)$ must be determined from the data over a small range of temperatures usually between 78 and 150°K. This may result in some inaccuracy in $j(0)$ and considerable deviation of $\Delta j(T)$ from the T^2 line over the range of temperatures where the T^2 approximation is valid (cf. Chow's[26] Fig. 1). However, $j(0)$ can be determined with good accuracy using the technique described above. Using the $j(0)$ determined from Fig. 4(a), a plot of $\log_{10}\Delta j$ versus $\log_{10}T$ is shown in Fig. 5 for the experimental data shown in Fig. 4(a). Results quite similar to those of Chow are obtained except that good agreement with the T^2 linear approximation (shown as the dashed line in Fig. 5) is obtained for temperatures less than 100°K. The solid curve is a plot of the theoretical temperature dependence as given by Eq. (6) including the T^4 term, using the value of $c_1=16.0$ eV^{-1} determined from Fig. 4(a). A straight line of slope slightly greater than two can be fitted to the data in Fig. 5, but in fact it is seen that the deviation of the experimental data from the T^2 line is due to the T^4 term in Eq. (6).

B. Functions $b_1(V)$ and $c_1(V)$

The coefficients b_1 and c_1 are functions of voltage and arise from the WKB approximation. The specific volt-current characteristic for a given barrier potential $\varphi(x,V)$ can be given from Eq. (1) by evaluating b_1 and c_1 as functions of V. Stratton[8] has developed Eq. (1) further for small applied voltages, while maintaining an arbitrary barrier shape, by expanding b_1 and c_1 as the following quadratic power series in qV

$$b_1=b_{10}-b_{11}(qV)+b_{12}(qV)^2, \tag{7}$$

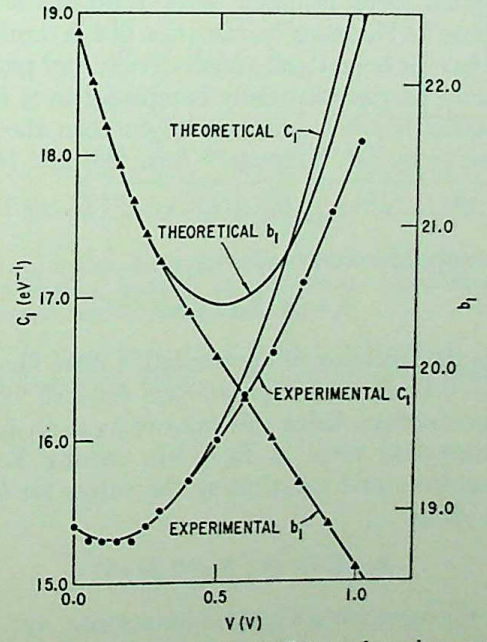

FIG. 6. The dependence of the coefficients b_1 and c_1 on voltage. The points are deduced from the experimental data by fitting the temperature dependence. The theoretical curves are quadratic power-series expansions corresponding to Eqs. (7) and (8).

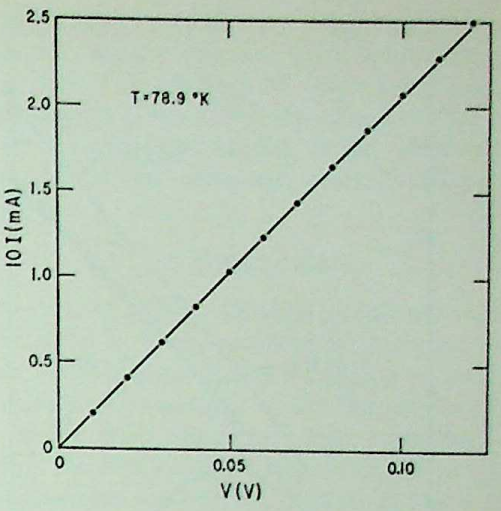

FIG. 7. Low-voltage Ohmic region. The current as a function of small applied voltage at $T=78.9$°K.

and

$$c_1=c_{10}-c_{11}(qV)+c_{12}(qV)^2. \tag{8}$$

By fitting the experimental current density data to the theoretical temperature dependence for a set of applied voltages in the range $0\leq V\leq 1.0$ V, b_1 and c_1 can be deduced as functions of V. The results are shown in Fig. 6. The experimental curves are plots of b_1 and c_1 deduced from the experimental data. The theoretical curves are the quadratic power-series expansions given in Eqs. (7) and (8) which have been fitted to the experimental curves for small applied voltages. The coefficients for the power series are listed in Table II. The region of applied voltage for which the quadratic power-series expansions in V, of the integrals arising from the WKB approximation, are valid, is seen to be $0.0\leq V\leq 0.3$ V.

Although c_1 can be represented approximately by the low-voltage quadratic over a substantially larger range of applied voltage, b_1 cannot. A plot of the current density as a function of voltage [cf. Fig. 2(a)] suggests a nearly linear approximation for b_1 in the range $0.2<V<1.0$ V, preceded by an Ohmic region (cf. Fig. 7). Stratton,[8] in analyzing the earlier data of Fischer and Giaever[27] and Pimbley,[28] fitted the quadratic power series for b_1 out to about 1.4 V. This procedure is equivalent essentially to fitting a parabola to the lower part of the experimental curve for b_1 shown in Fig. 6, which does not converge to the experimental curve for b_1 for

TABLE II. Quadratic power-series coefficients.

b_1	c_1 (eV)$^{-1}$

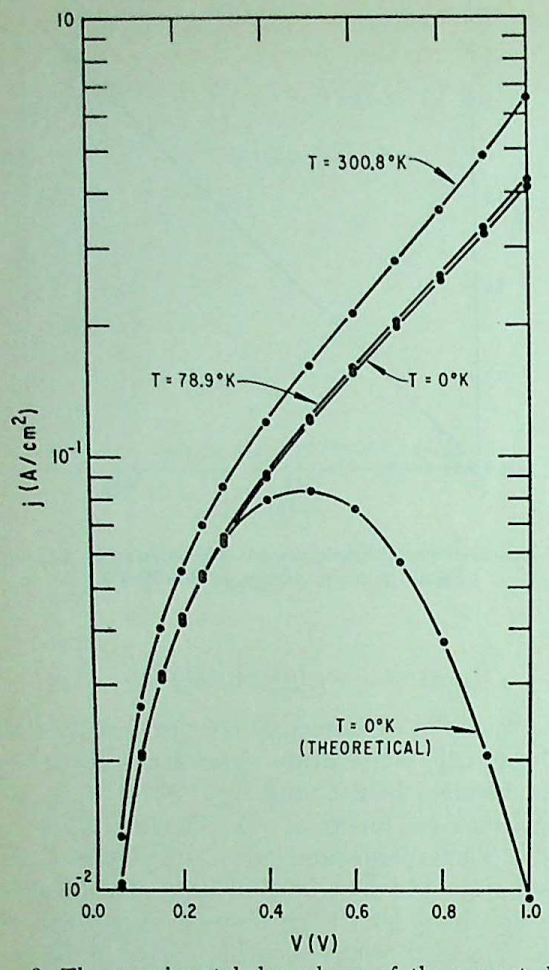

FIG. 8. The experimental dependence of the current density on the voltage at room, liquid nitrogen and extrapolated to absolute zero temperature. The theoretical curve was calculated, assuming the quadratic power-series approximations for b_1 and c_1, using Eq. (1).

small V. The coefficients of the quadratic expansions are related to physical properties of the potential barrier.[8] The numerical values for the physical properties reported by Stratton, therefore, are in error.

The low-voltage quadratic expansions given in Eqs. (7) and (8) using the coefficients in Table II were used to calculate the theoretical volt-current characteristic for $T=0$°K shown in Fig. 8. The experimental characteristics for room, liquid nitrogen and extrapolated to absolute zero temperature are also shown. It is apparent that the theoretical curve is a good representation for $0\leq V\leq 0.3$ V, which is the range of voltage for which the quadratic power-series expansion for b_1 is valid, and that the divergence between the theoretical and experimental curve for $T=0$°K results from the functional form of b_1 shown in Fig. 6.

The functional form of b_1 and c_1 shown in Fig. 6 for $V>0.3$ V is not expected to be universal. In particular, the functional form shown here pertains to an oxide grown by the technique described in Sec. IIA.

C. Physical Properties of the Barrier Layer

The numerical values of the coefficients in Table II can be related to the physical properties of the barrier when a particular barrier shape is assumed. Using Simmons' expression for the tunnel path length given in Eq. (4), b_1 and c_1 given by Eqs. (7) and (8), and the coefficients from Table II, it is easy to show that Δx is approximately constant over the range $0.2<V<0.6$ V which is consistent with a trapezoidal (or rectangular) barrier shape.

Using the asymmetry in the experimental current density with respect to the polarity of the applied potential, and the relation for asymmetrical barriers that[8]

$$b_{11}+b_{21}=c_{10}$$

a value of $b_{21}=7.82$ (eV)$^{-1}$ is obtained.

Assuming a trapezoidal barrier shape for $\varphi(x,V)$, integrating, carrying out the Taylor expansions with respect to energy and the binomial expansion in Eq. (7) (and assuming a corresponding series for b_2) leads to the following relationships between the physical parameters and the coefficients:

$$\left.\begin{aligned} b_{10}&=\frac{2\alpha L}{3}\left(\frac{\chi_2'^{3/2}-\chi_1'^{3/2}}{\chi_2'-\chi_1'}\right),\\ b_{11}&=(\alpha L\chi_2'^{1/2}-b_{10})/(\chi_2'-\chi_1'),\\ b_{21}&=-(\alpha L\chi_1'^{1/2}-b_{10})/(\chi_2'-\chi_1'),\end{aligned}\right\} \tag{9}$$

where

$$\chi_n=\chi_n'+\Delta\chi;\ n=1,2. \tag{10}$$

χ_1' and χ_2' are the effective heights of the trapezoidal barrier above the Fermi level on the side adjacent to metal 1 and 2, respectively, which differ from the true metal-insulator work functions χ_1 and χ_2 by an amount $\Delta\chi$. It will be assumed that the barrier is a result of two unequal metal-insulator work functions and the image force. In Simmons'[29] evaluation of b in terms of an average barrier height and an effective tunnel path, the image force barrier essentially is replaced by a rectangular barrier which is lower in height than the image force barrier by [cf. Simmons'[29] Eqs. (33) and (40)]

$$\Delta\chi=[1.15\lambda L/(x_2-x_1)]\ln[x_2(L-x_1)/x_1(L-x_2)] \tag{11}$$

for zero applied voltage, where

$$\lambda=(q^2/8\pi\kappa L)\ln 2,$$

and L is the thickness of the insulating film. The quantity $\Delta\chi=0.11$ eV for the parameters deduced from the experimental data. Using this value of $\Delta\chi$ as an approximate correction term in Eq. (10), solving Eqs. (9) simultaneously and substituting the values for b_{10}, b_{11}, and b_{21} yields

$$\chi_1=0.78\text{ eV};\ \chi_2=0.89\text{ eV}$$

which will represent a slight underestimate, and

$$L=25.7\text{ Å}$$

assuming an effective electron mass in the insulator $m^*/m=1$. Meyerhoffer and Ochs[17] have pointed out that the effective mass theoretically should be near to one.[30,31] Assuming a dielectric constant of 8.0,[18] the thickness of the insulating layer calculated from capacitance is 25.7 Å, and the tunnel path length, calculated from Eq. (4), is 25.6 Å. The aluminum film corresponding to χ_1 is the one on which the oxide was grown. Greater currents are passed when this layer is positive, which is in agreement with other observations.[15,17]

A plot of the experimental data for a thicker aluminum oxide (formed in an oxygen glow discharge) and larger applied voltages is shown in Fig. 9. The data are plotted as log I/V^2 versus $1/V$ for comparison with the Fowler-Nordheim theory.[2] Including the image force correction the slope (for large V) results in a value of $\chi_2=0.85$ eV, which is in good agreement with the value deduced from the low-voltage measurements.

[*Note added in proof.* Recent investigations on the thicker aluminum oxides at larger applied voltages (similar to specimens used to obtain the data shown in Fig. 9) indicate considerably larger effective barrier heights and smaller effective thicknesses than are obtained from the analysis of low-voltage data. The barrier heights given above are based on the assumption of a trapezoidal barrier shape which does not appear to be an adequate representation for all voltages.]

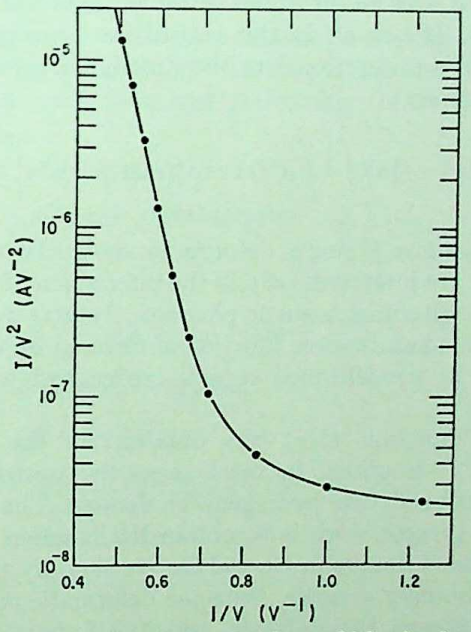

FIG. 9. A Fowler-Nordheim plot for a thick aluminum oxide film. The slope leads to an approximate metal-insulator work function of $\chi_2=0.85$ eV.

V. CONCLUSIONS

The current density through aluminum oxide films less than 30 Å thick, sandwiched between two aluminum films, is presented as a function of temperature and voltage. The analysis of the temperature dependence of the data established that tunneling directly between the two aluminum layers is the predominant mechanism for electron conduction through the aluminum oxide film.

The data are analyzed using the theory of Stratton. The theory is modified to take more accurate account of the back current and compared with the theory of Simmons. Both the modified and Simmons expressions are intractable to experimental analysis. It is indicated that the errors involved in using the simplified version of Stratton's theory are small, therefore, the original form given in Eq. (1), is employed.

The region of validity is established, for quadratic power-series expansions in V, of the integrals arising from the WKB approximation. Fitting the quadratics to the experimental curves for these integrals results in approximate values for the heights of the potential barrier above the Fermi level and the barrier thickness, when a trapezoidal barrier shape (modified by image forces) is assumed.

The actual shape of the potential barrier cannot be extracted with any degree of confidence using only the low-voltage current-density data as a function of temperature. Therefore, even though the preliminary Fowler-Nordheim analysis results in a barrier height in agreement with the value obtained for an image force barrier, a more elaborate investigation is required.

ACKNOWLEDGMENTS

The authors acknowledge with thanks the many helpful and stimulating discussions with R. Stratton and N. G. Einspruch, the technical assistance of P. J. May, Jr., J. W. Taylor for the preparation of samples, and J. C. Blair for the data shown in Fig. 9.

Interaction of Electron on the Donor Center with the Crystal Lattice in Germanium and Silicon

ANDRZEJ MYSZKOWSKI AND STANISŁAW GÓMUŁKA
Institute of Theoretical Physics, Warsaw University, Warsaw, Poland

(Received 8 July 1963)

The diagonal matrix element of interaction of the bound electron with longitudinal acoustic phonon, squared and averaged over all directions of the phonon wave vector, was calculated for n-type Ge and Si assuming a single-deformation-potential constant. The donor wave functions have been taken in the elipsoidal form. Some simple integrals containing the squared and averaged matrix element are given and are used, as an example, to get the one-phonon transition rate in the impurity conduction by "hopping" and the relaxation energy of the lattice deformed by interaction with the donor electron. Appreciable differences are found between the case of elipsoidal and spherical donor wave functions.

INTRODUCTION

THE electron bound to the donor center in the homopolar crystal produces a deformation (a change of the equilibrium positions of the crystal atoms) in the vicinity of the center because of the interaction with acoustic phonons. This deformation influences several physical processes in the crystal. It changes the one-phonon transition probability and gives the possibility of the multiphonon processes in the case of the impurity conduction by "hopping."[1–4] A similar effect occurs in the case of the thermal recombination of donors and electrons.[5] The deformation of the crystal lattice gives also the difference between the energies of thermoionization and photoionization of donors.[6] In the process of absorption of the electromagnetic wave by the bound electron this deformation gives the possibility of the simultaneous absorption of photon and emission of phonons and so has an influence on the shape of the absorption lines.[7] In all papers referred to above[1–7] taking into account lattice-deformation effects requires computation of the diagonal matrix element of deformation potential of the phonon in the ground state of the electron on the isolated donor. This matrix element squared must then be averaged over all directions of the wave vector τ of the phonon. The result in the case of the isotropic sound velocity is proportional to the function $U(\tau)$ which is by definition

$$U(\tau)=(\tfrac{1}{4}\pi)\int\left|\int u^*(\mathbf{r})\exp(i\tau\boldsymbol{\Omega}\mathbf{r})u(\mathbf{r})d^3x\right|^2 d\Omega, \quad (1)$$

if we assume a single deformation-potential constant and we are interested only in the interaction of electron with longitudinal acoustic phonons. By $u(\mathbf{r})$ we denote the ground-state wave function of electron on impurity center in nondeformed crystal lattice and we define $\tau=\tau\boldsymbol{\Omega}$.

The function $U(\tau)$ was obtained in the referred papers[1–7] assuming in most cases the isotropic conduction band (the hydrogen-like donors). The purpose of the present work is to obtain the function $U(\tau)$ in the case of donors in Ge and Si. We simplify the problem assuming a single, isotropic deformation-potential constant and the isotropic velocity of the sound and taking into account only longitudinal acoustic phonons. The results of this paper can be easily used in another materials with similar shape of the conduction-band minima. The paper contains also same simple integrals with the function $U(\tau)$ for Ge and Si. We used them, as an example, to get the corrections to the results of the Ref. 2 which deal with the one-phonon transition rate in the impurityc onduction by "hopping." We obtain also corrections to the lattice relaxation energy.

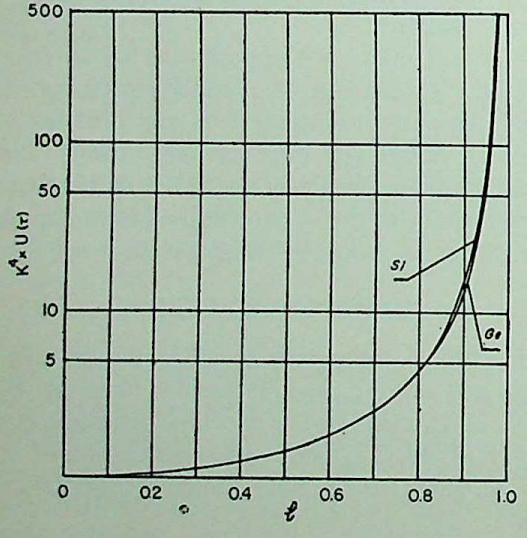

FIG. 1. The dependence of the function $U(\tau)$ on $l=[\alpha/(\alpha+1)]^{1/2}\times[1+(4/a^2\tau^2)]^{-1/2}$. For $l\to 1$ the asymptotic behavior is $(1-l^2)^{-3}/24$ and $(1-l^2)^{-3}/18$ for Ge and Si, respectively.

CALCULATION OF THE FUNCTION $U(\tau)$

In Ge and Si we have in the presence of the chemical shift the donor ground-state wave functions of the

form[8]

$$u(\mathbf{r})=n^{-1/2}\sum_{q=1}^{n}F_q(\mathbf{r})\phi_q(\mathbf{r}). \tag{2}$$

The sum is performed over the n minima of the conduction band (n equals 4 and 6 in Ge and Si, respectively). ϕ_q is the Bloch function for the qth minimum and F_q is of the form

$$F_q(x,y,z)=(\pi a^2 b)^{-1/2}\times\exp\{-[(x^2+y^2)/a^2+z^2/b^2]^{1/2}\}, \tag{3}$$

where the z axis is parallel to the axis containing the qth minimum. The constants a and b are the transverse and longitudinal radii of the orbit, respectively.

With (2) we have

$$\int u^*(\mathbf{r})\exp(i\tau\Omega\mathbf{r})u(\mathbf{r})d^3x=n^{-1}\int\sum_{p,q=1}^{n}F_pF_q\phi_p^*\phi_q\exp(i\tau\Omega\mathbf{r})d^3x. \tag{4}$$

Neglecting terms with $p\neq q$ because of the rapid oscillation of $\exp[i\mathbf{r}(\boldsymbol{\kappa}_q-\boldsymbol{\kappa}_p)]$, where $\boldsymbol{\kappa}_q$ is the wave vector for the qth minimum, and performing the integration we obtain

$$\int u(\mathbf{r})\exp(i\tau\Omega\mathbf{r})u(\mathbf{r})d^3x=n^{-1}\sum_{q=1}^{n}f_q, \tag{5}$$

where

$$f_q=K^{-2}[1-l^2(\Omega\mathbf{p}_q)^2]^{-2}. \tag{6}$$

We denoted here $\boldsymbol{\kappa}_q=\kappa_q\mathbf{p}_q$ and

$$K=1+\tfrac{1}{4}a^2\tau^2, \tag{7}$$

$$l^2=[\alpha/(\alpha+1)][1+(4/a^2\tau^2)]^{-1}, \tag{8}$$

$$\alpha=(a/b)^2-1. \tag{9}$$

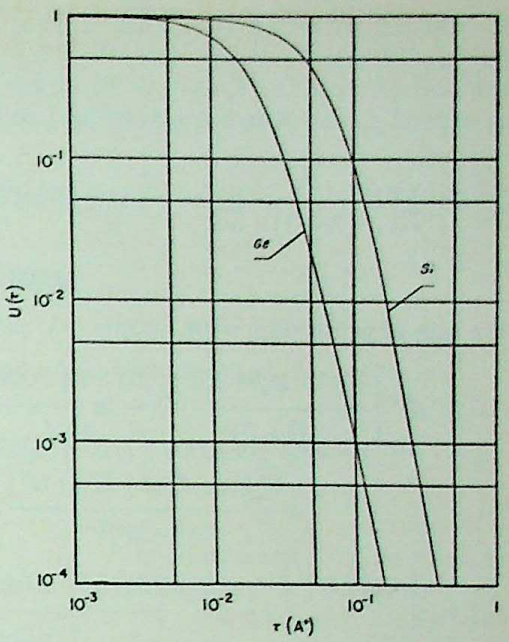

FIG. 2. The function $U(\tau)$ versus wave number τ of the phonon. For $\tau\to\infty$ the asymptotic behavior is $367.4\times K^{-4}$ and $14.81\times K^{-4}$ for Ge and Si, respectively.

For arbitrary τ we have $0\leq l^2<1$.

From (1) and (5) we obtain

$$U(\tau)=n^{-2}\sum_{p,q=1}^{n}u_{pq}(\tau), \tag{10}$$

where

$$u_{pq}(\tau)=(4\pi)^{-1}\int f_pf_qd\Omega. \tag{11}$$

Performing the integral in (11) and denoting $\mathbf{p}_p\mathbf{p}_q=(p,q)$ we obtain

$$u_{pq}=(4\pi K^4)^{-1}\{M[l,(p,q)]+M[l,-(p,q)]\}, \tag{12}$$

where

$$M[l,(p,q)]=(\pi/2)\frac{[(2-l^2)^2-l^4(p,q)^2]\{(7-l^2)[1-(p,q)^2]-2\}+6l^4(p,q)^2[1-(p,q)^2]}{[1-(p,q)^2](1-l^2)[(2-l^2)^2-l^4(p,q)^2]^2}$$
$$+(\pi/16)\frac{\{[18-l^2-l^2(p,q)][1-(p,q)]+4\}[2-l^2-l^2(p,q)]+3l^4[1-(p,q)][1+(p,q)]^2}{[1-(p,q)]^{3/2}[2-l^2-l^2(p,q)]^{5/2}}$$
$$\times\ln\frac{(1+l)\{[1-l(p,q)]\{[2-l^2-l^2(p,q)]^{1/2}+l[1-(p,q)]^{1/2}\}+\{(1-l^2)[1-(p,q)]^{1/2}\}\}}{(1-l)\{[1+l(p,q)]\{[2-l^2-l^2(p,q)]^{1/2}-l[1-(p,q)]^{1/2}\}+\{(1-l^2)[1-(p,q)]^{1/2}\}\}}. \tag{13}$$

In the case of $(p,q)=\pm1$, u_{pq} reduces to

$$\frac{33-40l^2+15l^4}{48(1-l^2)^3}+\frac{5}{32l}\ln\frac{1+l}{1-l}=F(4,\tfrac{1}{2};\tfrac{3}{2};l^2). \tag{14}$$

Digitized by Arya Samaj Foundation Chennai and eGangotri

For $\tau=0(l=0)$, we have from (12) and (13) $u_{pq}=1$ for all p and q and so $U(\tau)=1$. For $\tau\to\infty$, $(l\to[\alpha/(\alpha+1)]^{1/2})$ we have $u_{pq}\to 0$ and $U(\tau)\to 0$.

In the isotropic case ($a=b$, $\alpha=0$, $l=0$) we have simply $u_{pq}=K^{-4}$ and $U(\tau)=K^{-4}$.

If we expand f_p and f_q in powers of l^2 and perform the integral in (11) we get instead of (12)

$$u_{pq}=K^{-4}\sum_{r=0}^{\infty}l^{2r}\frac{1}{(2r+1)!!}\sum_{s=0}^{r}(r-s+1)(s+1)\times\sum_{t=0}^{s}\binom{2s}{2t}(p,q)^{2t}[1-(p,q)^2]^{s-t}(2r-2s+2t-1)!!(2s-2t-1)!!. \quad (15)$$

GERMANIUM AND SILICON

In the case of germanium $n=4$, $(p,q)=+1,\pm\frac{1}{3}$. From (10), (12) and (13) we obtain

$$U_{\mathrm{Ge}}(\tau)=2^{-8}K^{-4}\left\{\frac{4(33-40l^2+15l^4)}{3(1-l^2)^3}+\frac{10}{l}\ln\frac{1+l}{1-l}+\frac{27[(3-2l^2)(3-l^2)(19-4l^2)+6l^4]}{(1-l^2)(3-2l^2)^2(3-l^2)^2}\right.$$
$$+\frac{9[(18-l^2)(3-2l^2)+6l^4]}{l(3-2l^2)^{5/2}}\ln\frac{(1+l)\{(3-l)[(3-2l^2)^{1/2}+l]+3(1-l^2)\}}{(1-l)\{(3+l)[(3-2l^2)^{1/2}-l]+3(1-l^2)\}}$$
$$\left.+\frac{9[(63-2l^2)(3-l^2)+6l^4]}{2^{5/2}l(3-l^2)^{5/2}}\ln\frac{(1+l)\{(3+l)[2^{1/2}(3-l^2)^{1/2}+2l]+6(1-l^2)\}}{(1-l)\{(3-l)[2^{1/2}(3-l^2)^{1/2}-2l]+6(1-l^2)\}}\right\} \quad (16)$$

or from (10) and (15)

$$U_{\mathrm{Ge}}(\tau)=K^{-4}(1.000+1.333l^2+1.644l^4+1.943l^6+2.247l^8+2.567l^{10}+3.191l^{12}+3.285l^{14}+3.608l^{16}+\cdots). \quad (17)$$

In the case of silicon $n=6$, $(p,q)=\pm1$, 0. From (10), (12) and (13) we obtain

$$U_{\mathrm{Si}}(\tau)=2^{-4}3^{-2}K^{-4}\left\{\frac{33-40l^2+15l^4}{(1-l^2)^3}+\frac{15}{2l}\ln\frac{1+l}{1-l}+\frac{24(5-l^2)}{(1-l^2)(2-l^2)^2}\right.$$
$$\left.+\frac{3[(22-l^2)(2-l^2)+3l^4]}{l(2-l^2)^{5/2}}\ln\frac{(1+l)[(2-l^2)^{1/2}+l+1-l^2]}{(1-l)[(2-l^2)^{1/2}-l+1-l^2]}\right\}, \quad (18)$$

or from (10) and (15)

$$U_{\mathrm{Si}}(\tau)=K^{-4}(1.000+1.333l^2+1.644l^4+1.943l^6+2.263l^8+2.628l^{10}+3.048l^{12}+3.528l^{14}+4.069l^{16}+\cdots). \quad (19)$$

Dependence of $K^4U(\tau)$ on l for Ge- and Si-type materials is plotted on the Fig. 1. Taking $\alpha=18.8$, $a=70.8$ Å for Ge and $\alpha=4.2$, $a=22.1$ Å for Si we obtain the dependences of $U(\tau)$ on τ given on the Fig. 2.

PARTICULAR INTEGRALS

We calculate here the integrals of the type $\int_0^\infty U(\tau)\tau^\kappa d\tau$ for $\kappa=0$, 1, 2, 3. We use formula (10) and u_{pq} in the form (14) for $(p,q)=\pm1$ or in the form (15) for $(p,q)\neq\pm1$.

In the case of germanium we obtain

$$\int_0^\infty U_{\mathrm{Ge}}(\tau)d\tau=\frac{15\pi}{64a}\left\{\frac{1}{3}\left[\frac{\alpha}{\alpha+1}\right]^{-1/2}\arcsin\left[\frac{\alpha}{\alpha+1}\right]^{1/2}+1.000+0.1667\frac{\alpha}{\alpha+1}+0.05722\left[\frac{\alpha}{\alpha+1}\right]^2\right.$$
$$+0.02560[\alpha/(\alpha+1)]^3+0.01327[\alpha/(\alpha+1)]^4+0.007581[\alpha/(\alpha+1)]^5$$
$$\left.+0.005640[\alpha/(\alpha+1)]^6+0.002991[\alpha/(\alpha+1)]^7+\cdots\right\}, \quad (20)$$

$$\int_0^\infty U_{\mathrm{Ge}}(\tau)\tau d\tau=\frac{1}{2a^2}\left\{\frac{1}{6}\left[\frac{\alpha}{\alpha+1}\right]^{-1/2}\ln\frac{1+[\alpha/(\alpha+1)]^{1/2}}{1-[\alpha/(\alpha+1)]^{1/2}}+1.000+0.3333\frac{\alpha}{\alpha+1}+0.1526\left[\frac{\alpha}{\alpha+1}\right]^2\right.$$
$$+0.08190[\alpha/(\alpha+1)]^3+0.04855[\alpha/(\alpha+1)]^4+0.03081[\alpha/(\alpha+1)]^5$$
$$\left.+0.02500[\alpha/(\alpha+1)]^6+0.01428[\alpha/(\alpha+1)]^7+\cdots\right\}, \quad (21)$$

$$\int_0^\infty U_{\mathrm{Ge}}(\tau)\tau^2 d\tau=\frac{3\pi}{16a^3}\left\{\frac{1}{3}(\alpha+1)^{1/2}+1.000+0.5000\frac{\alpha}{\alpha+1}+0.2861\left[\frac{\alpha}{\alpha+1}\right]^2+0.1792\left[\frac{\alpha}{\alpha+1}\right]^3\right.$$
$$+0.1195[\alpha/(\alpha+1)]^4+0.08340[\alpha/(\alpha+1)]^5+0.07332[\alpha/(\alpha+1)]^6$$
$$\left.+0.04487[\alpha/(\alpha+1)]^7+0.03187[\alpha/(\alpha+1)]^8+\cdots\right\}, \quad (22)$$

$$\int_0^\infty U_{\mathrm{Ge}}(\tau)\tau^3 d\tau=a^{-4}\left\{\frac{1}{6}(\alpha+1)+\frac{1}{12}\left[\frac{\alpha}{\alpha+1}\right]^{-1/2}\ln\frac{1+[\alpha/(\alpha+1)]^{1/2}}{1-[\alpha/(\alpha+1)]^{1/2}}+1.000+0.6667\frac{\alpha}{\alpha+1}+0.4578\left[\frac{\alpha}{\alpha+1}\right]^2\right.$$
$$+0.3276[\alpha/(\alpha+1)]^3+0.2427[\alpha/(\alpha+1)]^4+0.1848[\alpha/(\alpha+1)]^5+0.1750[\alpha/(\alpha+1)]^6$$
$$\left.+0.1142[\alpha/(\alpha+1)]^7+0.08591[\alpha/(\alpha+1)]^8+\cdots\right\}. \quad (23)$$

In the case of silicon we obtain

$$\int_0^\infty U_{\mathrm{Si}}(\tau)d\tau=\frac{5\pi}{24a}\left\{\frac{1}{2}\left[\frac{\alpha}{\alpha+1}\right]^{-1/2}\arcsin\left[\frac{\alpha}{\alpha+1}\right]^{1/2}+1.000+0.1667\frac{\alpha}{\alpha+1}+0.05500\left[\frac{\alpha}{\alpha+1}\right]^2+0.02321\left[\frac{\alpha}{\alpha+1}\right]^3\right.$$
$$\left.+0.01133[\alpha/(\alpha+1)]^4+0.006138[\alpha/(\alpha+1)]^5+0.003602[\alpha/(\alpha+1)]^6+\cdots\right\}, \quad (24)$$

$$\int_0^\infty U_{\mathrm{Si}}(\tau)\tau d\tau=\frac{4}{9a^2}\left\{\frac{1}{4}\left[\frac{\alpha}{\alpha+1}\right]^{-1/2}\ln\frac{1+[\alpha/(\alpha+1)]^{1/2}}{1-[\alpha/(\alpha+1)]^{1/2}}+1.000+0.3333\frac{\alpha}{\alpha+1}+0.1467\left[\frac{\alpha}{\alpha+1}\right]^2\right.$$
$$\left.+0.07429[\alpha/(\alpha+1)]^3+0.04145[\alpha/(\alpha+1)]^4+0.02494[\alpha/(\alpha+1)]^5+0.01597[\alpha/(\alpha+1)]^6+\cdots\right\}, \quad (25)$$

$$\int_0^\infty U_{\mathrm{Si}}(\tau)\tau^2 d\tau=\frac{\pi}{6a^3}\left\{\tfrac{1}{2}(\alpha+1)^{1/2}+1.000+0.5000\frac{\alpha}{\alpha+1}+0.2750\left[\frac{\alpha}{\alpha+1}\right]^2+0.1625\left[\frac{\alpha}{\alpha+1}\right]^3\right.$$
$$\left.+0.1019[\alpha/(\alpha+1)]^4+0.06752[\alpha/(\alpha+1)]^5+0.04683[\alpha/(\alpha+1)]^6+\cdots\right\}, \quad (26)$$

$$\int_0^\infty U_{\mathrm{Si}}(\tau)\tau^3 d\tau=\frac{8}{9a^4}\left\{\tfrac{1}{4}(\alpha+1)+\frac{1}{8}\left[\frac{\alpha}{\alpha+1}\right]^{-1/2}\ln\frac{1+[\alpha/(\alpha+1)]^{1/2}}{1-[\alpha/(\alpha+1)]^{1/2}}+1.000+0.6667\frac{\alpha}{\alpha+1}+0.4400\left[\frac{\alpha}{\alpha+1}\right]^2\right.$$
$$\left.+0.2971[\alpha/(\alpha+1)]^3+0.2073[\alpha/(\alpha+1)]^4+0.1497[\alpha/(\alpha+1)]^5+0.1118[\alpha/(\alpha+1)]^6+\cdots\right\}. \quad (27)$$

Taking $\alpha=18.8$, $a=70.8$ Å for Ge and $\alpha=4.2$, $a=22.1$ Å for Si we obtain values given in the Table I.

CORRECTIONS TO THE ONE-PHONON "HOPPING" PROBABILITY AND LATTICE RELAXATION ENERGY

According to Ref. 2 the total one-phonon transition rate for the electron transfer from the donor a to the donor b is

$$W_{ba}{}^{1\mathrm{tot}}=W_{ba}{}^{1}(1-A)^2\exp(-\alpha), \quad (28)$$

where $W_{ba}{}^{1}$ is the one-phonon transition rate if we neglect the dependence of the equilibrium positions of the lattice atoms on the state of the carrier. α and A are the quantities described in Ref. 2. In particular for low absolute temperature T

$$\alpha_{T\to 0}=\frac{E_1^2}{\pi\hbar v^3 d}\int_0^\infty U(\tau)\tau d\tau, \quad (29)$$

$$A_{T\to 0}=\frac{\hbar E_1^2}{4\pi^3 v\Delta E_{ba}{}^2 d}\int_0^\infty U(\tau)\tau^2 d\tau. \quad (30)$$

E_1 is the deformation-potential constant, ΔE_{ba} the

Measurement of the Conductivity Effective Mass in Semiconductors Using Infrared Reflection

HENRY A. LYDEN*

Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received 21 November 1963; revised manuscript received 7 February 1964)

There exist various approximate relationships between the conductivity effective mass of free carriers m_c and the angular frequency ω_0 of the reflectivity minimum in the infrared arising from the free-carrier dispersion. A detailed analysis of the reflectivity equation shows that it is possible to obtain a relationship between m_c and ω_0 when in addition one has a knowledge of the free-carrier concentration, the drift mobility, and the dielectric constant of the semiconductor at very high frequencies. This relationship is shown to yield a value of $m_c{}^*=0.145$ for n-type germanium at room temperature using data presented in the literature. This value compares well with the value of $m_c{}^*=0.15$ obtained using a combination of reflection and transmission measurements. The experimental work required to obtain accurate values for m_c using this relationship is considerably less than that required by other techniques, such as cyclotron resonance, magnetoplasma, and combined infrared reflection and transmission measurements, which are presently used. Moreover, this procedure can be applied over very broad ranges of temperature and of free-carrier concentration.

INTRODUCTION

IN this paper[1] we are concerned with the determination of the conductivity effective mass, which is understood to be the effective mass entering in the free-carrier mobility

$$\mu=(e/m_c)\langle\tau\rangle, \tag{1}$$

where e is the electronic charge, m_c is the conductivity effective mass, and $\langle\tau\rangle$ is the relaxation time averaged over all of the free current carriers. The determination of this parameter has received increasing attention in recent years. The earliest and the most extensive investigations to date have utilized cyclotron resonance techniques. For example, the conductivity effective mass has been measured at liquid-helium temperature, where the relaxation time of free carriers is sufficiently long for both germanium and silicon.[2,3] Recently infrared techniques also have been employed for this determination. In one instance, the conductivity effective masses in germanium, silicon, and indium antimonide were obtained from a combination of reflection and transmission measurements conducted at room temperature.[4] In another instance only reflection measurements were required, in conjunction with varying intensities of magnetic field, to determine the conductivity effective masses of mercury selenide and indium antimonide.[5]

We are proposing in this paper that it is possible to determine m_c very accurately simply from a measure-

ment of the frequency of the reflectivity minimum in the far infrared. Through a straightforward differentiation of the reflectivity equation, utilizing the dispersion relations, and the evaluation of this derivative at the minimum, a relationship is obtained which can be solved for m_c using an iterative procedure.

FREE-CARRIER DISPERSION

In the far infrared, at wavelengths longer than that of the intrinsic absorption edge, electromagnetic radiation interacts with the free carriers of the material and undergoes dispersion. The theory of this free-carrier dispersion is developed in detail in a recent book by Moss.[6] He has shown that both classical and quantum mechanical analyses lead to the following relations for the real refractive index n and the absorption index (extinction coefficient) k of free carriers of one type only (i.e., holes or electrons):

$$n^2-k^2-\epsilon_\infty=-\frac{Ne^2}{m\epsilon_0}\frac{\tau^2}{1+\omega^2\tau^2} \tag{2}$$

and

$$2nk\omega=\frac{Ne^2}{m\epsilon_0}\frac{\tau}{1+\omega^2\tau^2}, \tag{3}$$

where ϵ_∞ is the relative dielectric constant of the medium in the absence of any contribution from free carriers at very high frequencies, N is the free-carrier concentration, ϵ_0 is the permittivity of free space, m is the effective mass of the free carriers, and ω is the angular frequency of the infrared radiation.

Several points should be noted with regard to Eqs. (2) and (3). It has been shown for the energy-band model in which ellipsoidal surfaces of constant energy lie along rotation axes of the cubic point group, that the effective mass which enters in these expressions is the conductivity effective mass, m_c.[7] In this case, m_c is defined by the relation $1/m_c=\frac{1}{3}(1/m_l+2/m_t)$, where m_l is the value of the effective-mass tensor associated with the longitudinal axis of the ellipsoidal energy surface and m_t is that associated with each of the two transverse axes of the surface. Secondly, we note that the relaxation time τ is assumed to be independent of frequency and that the total frequency dependence is exhibited explicitly by the quantity ω. This assumption is not restrictive since the relaxation time is determined by the temperature of the crystal, its energy-band structure, and the density of imperfections in the lattice. Finally, it should be noted that the relaxation time τ is necessarily assumed to be energy-independent. This follows from the fact that the terms containing τ have not been averaged, $\langle\ \rangle$, with respect to the distribution function. This last assumption requires additional consideration. For example, we wish to establish the conditions under which τ may be replaced by $\langle\tau\rangle$ in Eqs. (2) and (3). The details of the analysis for establishing these conditions are presented in Appendix A. However, in summary if the relaxation time is assumed to be proportional to a power of the free-carrier kinetic energy $\tau=\tau_0E^s$, it is possible to compare the exact terms $\langle\tau^2/(1+\omega^2\tau^2)\rangle$ and $\langle\tau/(1+\omega^2\tau^2)\rangle$ with the more convenient substitute terms $\langle\tau\rangle^2/(1+\omega^2\langle\tau\rangle^2)$ and $\langle\tau\rangle/(1+\omega^2\langle\tau\rangle^2)$. Such a comparison shows that the latter terms can be substituted for the former under the following conditions with no introduction of error:

(i) when τ is independent of energy, $s=0$, as in the case of neutral impurity scattering,

(ii) when there is total degeneracy and the kinetic energy of all carriers may be considered to be the Fermi energy E_f.

The substitution can be effected under the following conditions with an introduction of error $<13\%$:

(iii) when $s=-\frac{1}{2}$, as in the case of scattering arising from acoustical modes and from dislocations, for all degrees of degeneracy where $\omega\tau\geqq1$ while the degree of degeneracy required increases from $\eta\leqq-4$ to $\eta=0$ as $\omega\tau$ decreases below unity,

(iv) when $s=\frac{1}{2}$, as in the case of optical-mode scattering above the Debye temperature, for all degrees of degeneracy and for all values of $\omega\tau$, and

(v) when $s=\frac{3}{2}$, as in the case of scattering by ionized impurities, only under the condition of total degeneracy. These conditions are not considered to be overly restrictive but, in fact, to be rather generally satisfied. This consideration follows particularly in view of the fact that in order to observe the free-carrier reflectivity minimum at convenient wavelengths ($\approx30\,\mu$), it is often necessary to utilize free-carrier concentrations which result in at least partial, if not total, degeneracy. For these reasons, in our further consideration of Eqs. (2) and (3), we will assume that one of the conditions (i)–(v) is fulfilled and that τ may be replaced by $\langle\tau\rangle$ with an introduction of error $<13\%$.

At this point, it must be recognized that the total dispersion of incident radiation in the far infrared arises from interactions with the free carriers and with the lattice as well. This latter dispersion is important in polar crystals. The complete dispersion relations, which include the contributions of both the free carriers and the lattice of a polar crystal AB, may be expressed as follows[8,9]:

$$n^2-k^2=\epsilon_\infty-\frac{Ne^2}{m_c\epsilon_0\omega^2}\frac{\omega^2\langle\tau\rangle^2}{(1+\omega^2\langle\tau\rangle^2)}+\left[\frac{\epsilon_\infty+2}{3}\right]^2\frac{N_tQ^2}{M\epsilon_0}\left[\frac{(\omega_t^2-\omega^2)\tau_t^2}{\omega^2+(\omega_t^2-\omega^2)^2\tau_t^2}\right] \tag{4}$$

and

$$2nk=\frac{Ne^2}{m_c\epsilon_0\omega^2}\frac{\omega\langle\tau\rangle}{(1+\omega^2\langle\tau\rangle^2)}+\left[\frac{\epsilon_\infty+2}{3}\right]^2\frac{N_lQ^2}{M\epsilon_0}\left[\frac{\omega\tau_l}{\omega^2+(\omega_t^2-\omega^2)^2\tau_l^2}\right]. \quad (5)$$

In both Eqs. (4) and (5) the last term is the contribution made by the ions of the crystal. The parameters in the other terms have been defined following Eqs. (2) and (3). The new parameters are as follows: N_l is the concentration of atom pairs AB; Q is an effective charge defined by $Q=SZe$, where e is the electronic charge, Z is the valence of the compound, and S is a measure of the extent to which the ions of charge Ze are capable of being polarized; M is the reduced atomic mass $1/M=1/M_A+1/M_B$; ω_t is the angular frequency of the transverse lattice vibrations (Restrahlen); and τ_l is a relaxation time related to the damping of the lattice vibrations.

The relative contribution of the lattice to the total dispersion varies from one semiconductor to another. Moreover, it even varies for a single semiconductor depending upon the free-carrier concentration. Consequently, this contribution must be evaluated for each individual case in order to determine if its effect is significant in the over-all dispersion. It is clear, however, that in several instances the lattice polarization may be neglected when analyzing the dispersion in the far infrared. For example, lattice polarization does not enter in connection with the elemental semiconductors, germanium and silicon. Moreover, a combination of several conditions, such as, a small value for ϵ_∞, a large reduced mass M, a slight polarizability ($S\ll1$), and a large free-carrier concentration ($N\gtrsim10^{18}$ carriers/cm^3), can serve to make the effect of the lattice polarization completely negligible.

Because various combinations of these conditions are quite often satisfied, the total dispersion in the far infrared can oftentimes be considered to be described by the simpler Eqs. (2) and (3). In the subsequent analysis we will make this assumption, namely, that the lattice contribution to the total dispersion is negligible in the frequency range of the reflectivity minimum arising from free-carrier absorption.

REFLECTIVITY MINIMUM

The reflectivity of a material for normally incident radiation upon the surface of an infinitely thick sample is given by[10]

$$R=[(n-1)^2+k^2]/[(n+1)^2+k^2], \quad (6)$$

where n and k are described by Eqs. (2) and (3). This equation has been differentiated with respect to the variable Ω after rewriting the dispersion relations in the form:

$$n^2-k^2=\epsilon_\infty-B/(1+\Omega^2) \quad (7)$$

and

$$nk=B/2\Omega(1+\Omega^2), \quad (8)$$

where

$$B=Ne^2\langle\tau\rangle^2/m_c\epsilon_0 \quad \text{and} \quad \Omega=\omega\langle\tau\rangle$$

and assuming that $\langle\tau\rangle$ is not a function of frequency. The condition of zero slope at the reflectivity minimum then yields an equation for the effective mass in terms of the frequency of the reflectivity minimum and other measurable parameters. The equation that results is the following:

$$m_c^{*3}-\frac{3\epsilon_\infty-1}{4\epsilon_\infty(\epsilon_\infty-1)}\frac{(1/\Omega^2)+5+8\Omega^2}{(1+3\Omega^2)}Cm_c^{*2}+\frac{3\epsilon_\infty-2}{2\epsilon_\infty(\epsilon_\infty-1)^2}\times\frac{(1+2\Omega^2)}{(1+3\Omega^2)}C^2m_c^*+\frac{C^3}{4\epsilon_\infty(\epsilon_\infty-1)^2(1+3\Omega^2)}=0, \quad (9)$$

where $m_c^*=m_c/m_0$, m_0 is the free-electron mass, $C=Ne^2/m_0\epsilon_0\omega_0^2$, $\Omega=\omega_0\langle\tau\rangle$, and ω_0 is the angular frequency of the reflectivity minimum. [The derivation of this equation is outlined in Appendix B. It is based entirely on Eqs. (6)–(8), and therefore depends on their applicability to a particular material system for its own validity.]

This equation is quite general in that no approximations are made with respect to the magnitude of Ω nor with respect to the magnitude of ϵ_∞. [However, it is true that Ω must staisfy the conditions under which the substitution of $\langle\tau\rangle$ into Eqs. (2) and (3) was effected.]

We conclude that there are very broad conditions for which Eq. (9) represents an exact relationship, or very nearly so, between the conductivity effective mass and the frequency of minimum reflectivity and other measurable parameters. Equation (9) can therefore be used for the determination of m_c. This can be illustrated by considering the reflection curve for n-type germanium reported by Spitzer and Fan (S-F) and which is reproduced here as Fig. 1. The sample investigated by S-F had a carrier concentration of 3.9×10^{18} electrons/cm^3, $\mu_h=520$ cm^2/V-sec,[11] $\epsilon_\infty=16$ and a reflectivity minimum at $\lambda_0\approx23\ \mu$. By making an initial estimate for the conductivity effective mass, say $m_c^*=0.12$ as determined by cyclotron resonance, one can obtain an initial estimate for Ω. Using this value of Ω and the values for N, ϵ_∞, and ω_0 listed above, Eq. (9) can be solved for m_c^*. This enables one to calculate a revised estimate for Ω and the procedure is repeated until the solution of Eq. (9) yields the same value for m_c^* as

[10] Reference 6, p. 6.

[11] It is recognized that we are here employing a Hall mobility when actually the drift mobility is called for. However, according to the S-F report, the Hall coefficient was measured at 77°K where the Fermi level is $\approx4.5\ kT$ above the conduction band edge for this free-carrier concentration. It is reasonable to conclude that the mobility deduced from $R\sigma$ is very nearly the drift mobility.

before. In actual fact, because Ω^2 is large with respect to unity ($\Omega^2=13$) and therefore Eq. (9) is almost independent of Ω, this procedure converges very quickly. The value obtained for the conductivity effective mass using this procedure for the above example is $m_c^*=0.145$. This compares very well with the value $m_c^*=0.15$ calculated by S-F using their data from both reflection and transmission measurements.

As an additional check on the theory, for example, to show that the free-carrier dispersion can completely account for the observed reflectivity, a theoretical reflection curve can be generated using the effective mass calculated from Eq. (9). When this is done, one finds that the reflectivity curve, reported by S-F for the n-type sample of germanium considered above, is reproduced as exactly as it is possible to determine the values from their report. (The values calculated to achieve this fit are shown in Fig. 1.) Moreover, such a precise fit indicates that we are apparently justified in the substitution of $\langle\tau\rangle$ into Eqs. (2) and (3) and that in this case at least such a substitution produces negligible error. [This result should be compared with Fig. 4a (Appendix A) for $\Omega=3.6$, $\eta=-2$, and $s=-\frac{1}{2}$.]

Before concluding this discussion, it is of interest to consider the effect of various simplifying assumptions upon Eq. (9). For example, the plasma frequency is oftentimes obtained approximately by assuming that $n=1$ [see Eq. (6)], that k is negligibly small compared with unity, and that Ω is very much greater than unity. Under such conditions Eq. (7) can be solved directly to give the result

$$m_c=Ne^2/\omega_0^2\epsilon_0(\epsilon_\infty-1). \quad (10)$$

This expression is sometimes even further simplified by neglecting unity with respect to ϵ_∞ which yields

$$m_c=Ne^2/\omega_0^2\epsilon_0\epsilon_\infty. \quad (11)$$

Now, if the conductivity effective mass is calculated, for the n-type sample of germanium considered here, by means of Eqs. (10) and (11), the resulting values are $m_c^*=0.123$ and 0.115, respectively. These values differ significantly from the value $m_c^*=0.15$ obtained by Spitzer and Fan. This difference serves as justification for the derivation of the more exact Eq. (9).

Finally, it should be noted that Eq. (9) can be very well approximated by a quadratic equation since the constant term is oftentimes negligibly small.

$$m_c^{*2}-\frac{3\epsilon_\infty-1}{4\epsilon_\infty(\epsilon_\infty-1)}\frac{(1/\Omega^2)+5+8\Omega^2}{(1+3\Omega^2)}Cm_c^*+\frac{3\epsilon_\infty-2}{2\epsilon_\infty(\epsilon_\infty-1)^2}\frac{(1+2\Omega^2)}{(1+3\Omega^2)}C^2=0. \quad (12)$$

This equation can be solved directly, with the result that there are apparently two solutions. In actual fact, there is only one allowable solution. The root with the plus sign must be chosen, because it is the root which in the limit of $\Omega^2\gg1$ reduces to the known result expressed in Eq. (10).

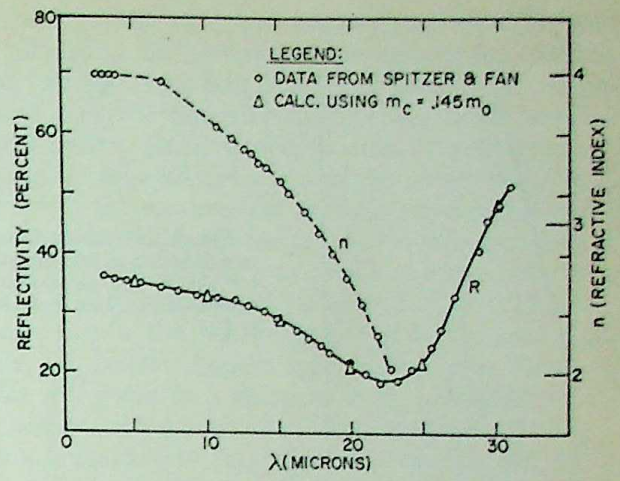

FIG. 1. Reflectivity and refractive index as functions of wavelength for n-type germanium having 3.9×10^{18} cm^{-3} as reported in Ref. 4. In addition, theoretical values for the reflectivity, having been calculated using an effective mass $m_c=0.145\ m_0$, are shown.

COMPARISON WITH OTHER TECHNIQUES

Cyclotron resonance techniques for the determination of the components of the conductivity effective mass have yielded a very great insight into the band structure of germanium and silicon (Ref. 12 gives a good review of this development). However, the condition for the observation of this resonance phenomenon is $\tau\omega_c>1$, where ω_c is the natural cyclotron frequency of rotation of a moving electron in a magnetic field about an axis parallel to the field, and classically this frequency is given by $\omega_c=eB/m_c$. Consequently, experiments in the microwave region, using reasonable magnetic field intensities, require that τ be 10^{-11} sec or longer. This condition is only fulfilled for high-purity semiconductors at low temperatures.

This limitation severely restricts the usefulness of cyclotron resonance for the determination of m_c. For example, some semiconductors have not as yet been prepared in a sufficiently pure form to enable cyclotron resonance measurements to be made. In this group, for example, is the very interesting family of semiconductors PbS, PbSe, and PbTe. Furthermore, there is reason to believe that the value of the conductivity effective mass in some semiconductors may be temperature-dependent. Evidence of this possibility has been reported in connection with investigations of both germanium[13] and lead sulfide.[14] However, because of the stringent condi-

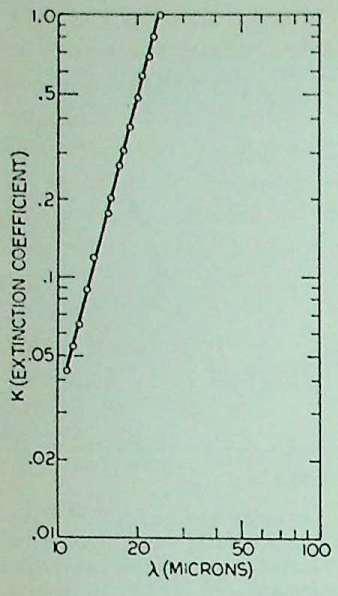

FIG. 2. Absorption index as a function of wavelength for the n-type germanium sample of Fig. 1 as reported in Ref. 4.

tion $\tau\omega_c > 1$, cyclotron resonance measurements are generally restricted to liquid-helium temperatures and so they cannot be utilized for the determination of the temperature dependence of m_c.

More recently, techniques have been developed which have utilized measurements in the far infrared. As mentioned earlier (S-F) obtained values of m_c from a combination of reflection and transmission measurements,[4] and Lax and Wright (L-W) obtained their values from the reflectivity of polarized radiation for several values of magnetic field intensities[5] (magnetoplasma effect). In both of their analyses (S-F and L-W), the simplification of neglecting the contribution of the lattice to the total dispersion has been inferred.

In connection with the S-F procedure, one notes that if the condition $(\omega\tau)^2 \gg 1$ is fulfilled, the dispersion relation of Eq. (2) is independent of τ. Under this constraint, the conditions placed upon the energy dependence of τ, as noted earlier, do not apply. That is, under the constraint that $(\omega\tau)^2 \gg 1$, the relaxation time may have an arbitrary energy dependence without having any effect on the resultant dispersion relationship, which is

$$n^2 - k^2 - \epsilon_\infty \approx Ne^2/m_c\epsilon_0\omega^2. \tag{13}$$

In addition to the simplified dispersion relation of Eq. (13) and the reflectivity relationship expressed in Eq. (6), the S-F procedure utilizes the fact that the transmission through a sample of material of thickness x in the absence of interference fringes and for $k^2 \ll n^2$ is given by[15]

$$T = (1-R)^2 e^{-\alpha x}/(1-R^2 e^{-2\alpha x}), \tag{14}$$

where α is the linear absorption coefficient which is related to the absorption index k by the relation

$$\alpha = 4\pi k/\lambda. \tag{15}$$

[15] Reference 6, pp. 13–14.

The linear absorption coefficient α equals the reciprocal of the distance within which the incident radiation is attenuated by a factor $(\exp)^{-1}$. The procedure outlined by S-F for the determination of m_c is readily deduced from Eqs. (6), (13)–(15).

This method for obtaining the conductivity effective mass of free carriers is relatively simple compared with cyclotron resonance techniques. It does require that $(\omega\tau)^2 \gg 1$. However, since the frequencies are of the order of 10^{13}–10^{14} rad/sec, τ may be of the order of 10^{-13} sec compared with 10^{-11} sec for cyclotron resonance. Consequently, measurements can be made on less pure materials and at higher temperatures. Furthermore, it may or may not require transmission measurements. Under certain conditions where k increases very rapidly with wavelength (see Fig. 2), it is possible to consider the reflection region where $k^2 \ll (n-1)^2$ and thus obtain m_c directly from Eqs. (6) and (13). However, one must beware that going to wavelengths much smaller than λ_0 means that $n^2 \to \epsilon_\infty$ and small errors in the absolute reflectivity can cause very large errors in m^* calculated from Eqs. (6) and (13). Consequently, in general, the S-F procedure requires transmission measurements which in turn require the preparation of very thin samples. For their transmission measurements, S-F used samples whose thickness was of the order of 10 μ. Such thicknesses represent a few thousand atomic layers and are very often difficult to achieve without producing extensive damage to the remaining material. For example, it has been possible to achieve such thicknesses in lead telluride only with very careful grinding and polishing techniques and then only very small surface areas ($\approx 600 \times 50\ \mu$) were obtained so that special optical techniques must be utilized.[16]

The other procedure mentioned above, the measurement of the magnetoplasma reflection as proposed by L-W,[5] eliminates the necessity of making transmission

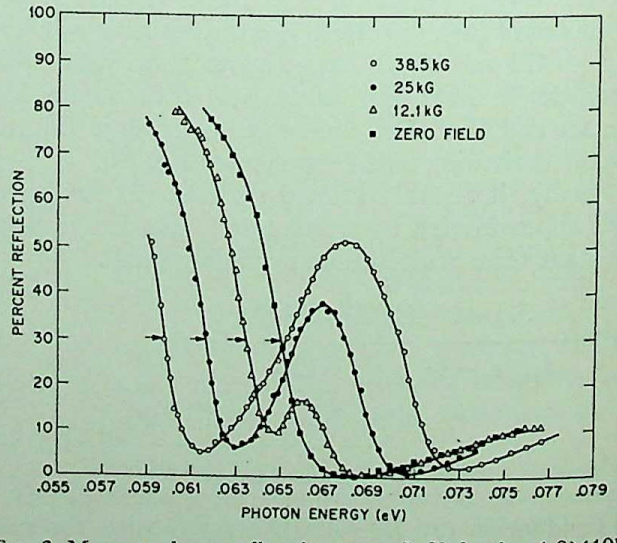

FIG. 3. Magnetoplasma effect in n-type InSb having 1.8×10^{18} cm^{-3} as reported in Ref. 5.

Digitized by Arya Samaj Foundation Chennai and eGangotri

measurements. This method utilizes the fact that, in the presence of properly polarized radiation, a magnetic field shifts the minimum in the reflectivity to both sides of the zero-field minimum. This results in the appearance of two minima. The displacement of these minima to either side of the zero-field minimum is directly proportional to the cyclotron resonance frequency $\omega_c = eB/m_c$. In their investigation, L-W have determined the shift as a function of magnetic field strength and have determined m_c from the slope of this dependence. Their data for the magnetoplasma effect in n-type indium antimonide are shown in Fig. 3.

This procedure, even though it offers the advantage of eliminating transmission measurements, does contain several inherent drawbacks. For example, magnetic field strengths of 25-kG or less would produce a shift in the minimum of approximately $\pm\frac{1}{2}\,\mu$ for the germanium sample of Fig. 1. Consequently, for zero-field reflection minima which are shallow and which have a width of a couple of microns, as for example the reflectivity minimum observed by S-F for germanium at room temperature in Fig. 1, the actual shift of the minimum is very difficult to measure. In fact, in their original article Lax and Wright found that the positions of the shifted minima were sufficiently indistinct so that it was expedient to determine the shift from that of the reflection edge on the long-wavelength side of the reflection minimum at an isoreflection point. This shift is that indicated by the arrows in Fig. 3. However, this latter method for obtaining the shift of the reflection minimum is also subject to certain disadvantages. First of all, it is not clear that the edge should shift the same amount as the minimum since the latter shift was determined assuming that losses are negligible. This is certainly not the case in the region of the reflection edge on the long-wavelength side of the reflection minimum because in this region we have the condition $k>n$. Furthermore, because k increases very rapidly in this region of the reflectivity, the depth of penetration of the incident radiation becomes increasingly shallow. For example, from Eq. (15) we see that the penetration depth $(1/\alpha)$ for $\lambda=30\,\mu$ and $k\approx 2$ is only of the order of $1\,\mu$. Consequently, the surface preparation becomes increasingly important in this region of the reflectivity curve. Surface damage can therefore distort the reflectivity in this wavelength range. Such surface effects make it even more difficult to determine the relationship of the observed shift in the reflection edge to the cyclotron resonance frequency.

CONCLUSIONS

The relationship between m_c and ω_0 presented in Eq. (9) offers some unique advantages in the determination of m_c. It has rather widespread applicability since it is valid for totally degenerate statistics and for almost all degrees of degeneracy when $|s|\leq\frac{1}{2}$, where s is the power of the energy dependence of τ. Equation (9) is not limited by any assumption that $\omega\tau>1$. It is much more applicable than the simplified relation of Eq. (11). It eliminates the necessity of determining the transmission through very thin samples of material on the one hand and the necessity of applying large magnetic fields perpendicular to the direction of propagation of polarized infrared radiation on the other. What is required is the measurement of the infrared reflectivity in order to determine the frequency of minimum reflection. It is not even necessary to obtain absolute reflectivity data. Relative values can serve equally well. That is, a percentage of the incident and/or of the reflected radiation can be lost through experimental error. Although this will result in a decrease in the resolution of the minimum, if the minimum is nevertheless discernible, it is still possible to determine m_c from Eq. (9). Moreover, this procedure is not overly sensitive to the effects of surface damage on the long-wavelength side of the reflectivity minimum. It has been noted above that the surface preparation becomes increasingly important in this region because of the decreasing depth of penetration into the sample. A damaged sample surface has the tendency of dispersing the radiation thereby reducing the reflectivity in this long wavelength region and of presenting a $\langle\tau\rangle$ which is different from that of the bulk material. The reflectivity in the region of the minimum is also subject to distortion from this mechanism only less so than in the region of the absorption edge because of the increased depth of penetration of the incident radiation.

Consequently, m_c can be obtained using Eq. (9) over the large temperature range in which the reflectivity minimum is measurable. The free-carrier concentration of the semiconductor material of interest is limited only by the requirement of single-carrier conduction, by the requirement that the lattice contribution to the dispersion be relatively unimportant, and by the requirement that the reflectivity apparatus be capable of analyzing the reflection near the free-carrier dispersion minimum. However, these limitations on the applicability of this procedure are also common to the other procedures which utilize infrared radiation.

ACKNOWLEDGMENT

I am very greatly indebted to Professor Arthur C. Smith of the Electrical Engineering Department at the Massachusetts Institute of Technology for his advice on the matters presented here.

APPENDIX A

It is convenient to substitute terms expressed as functions of $\langle\tau\rangle$ into Eqs. (2) and (3). Such a substitution is only approximately equivalent to the exact terms. The nature of the approximation involved can be appreciated by examining the following ratios:

$$\frac{\langle\tau^2/(1+\omega^2\tau^2)\rangle}{\langle\tau\rangle^2/(1+\omega^2\langle\tau\rangle^2)} \quad \text{and} \quad \frac{\langle\tau/(1+\omega^2\tau^2)\rangle}{\langle\tau\rangle/(1+\omega^2\langle\tau\rangle^2)} \qquad (16, 17)$$

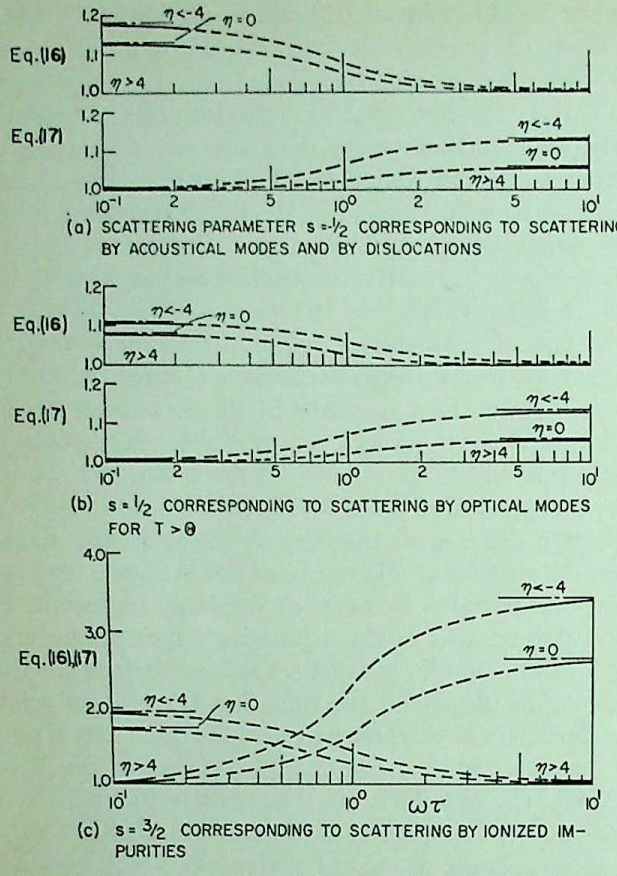

FIG. 4. Asymptotic limits of the ratios (16,17) plotted as functions of $\omega\tau$ for various values of the scattering parameter s and for three degrees of degeneracy $\eta<-4$, $=0$, >4.

under the conditions of $\omega\tau\gg1$ and $\omega\tau\ll1$. Under these conditions the above ratios approach the following limiting values:

$$\text{for } \omega\tau\gg1\text{: } 1 \text{ and } \langle\tau^{-1}\rangle\langle\tau\rangle$$
$$\text{for } \omega\tau\ll1\text{: } \langle\tau^{2}\rangle\langle\tau\rangle^{-2} \text{ and } 1.$$

Under these limiting conditions, it is apparent that for complete degeneracy these ratios are unity. In the limit of nondegeneracy these limiting values become

$$\text{for } \omega\tau\gg1\text{: } 1 \text{ and } \Gamma(5/2-s)\Gamma(5/2+s)[\Gamma(5/2)]^{-2}$$
$$\text{for } \omega\tau\ll1\text{: } \Gamma(5/2+2s)\Gamma(5/2)[\Gamma(5/2+s)]^{-2} \text{ and } 1$$

The asymptotic limits for various scattering mechanisms are shown in Fig. 4 for reduced Fermi potentials of $\eta<-4$, $=0$, and >4.

Appendix B

The condition $\partial R/\partial\Omega=0$ yields the equation

$$(n^2-1-k^2)n'+2nkk'=0, \tag{18}$$

where the prime signifies $\partial/\partial\Omega$. Solving for k and k' from Eq. (8) and substituting into (18) yields

$$(n^4-n^2-3\beta^2)n'+2\beta n\beta'=0, \tag{19}$$

where $\beta=B/[2\Omega(1+\Omega^2)]$. Combining Eqs. (7) and (8) yields

$$n^4=\epsilon n^2+\beta^2, \tag{20}$$

where $\epsilon=\epsilon_\infty-[B/(1+\Omega^2)]$, and upon substituting (20) into (19), we obtain

$$[(\epsilon-1)n^2-2\beta^2]n'+2\beta n\beta'=0. \tag{21}$$

By solving (20) for n^2 (choosing the positive root to keep n real), by differentiating this result with respect to Ω, and by substituting $(n^2)'/(2n)$ for n' in Eq. (21), we obtain

$$[(\epsilon-1)n^2-2\beta^2][-2n^2\Omega^3+\beta(1+3\Omega^2)]$$
$$+2n^2\beta(1+3\Omega^2)(2n^2-\epsilon)=0. \tag{22}$$

Equation (22) can be rewritten in the form

$$n^4=G(\Omega)n^2+H(\Omega)\beta^2, \tag{23}$$

where $G(\Omega)$ and $H(\Omega)$ are complicated functions of Ω. Equating (23) and (20) yields

$$n^2=\beta^2(H-1)/(\epsilon-G). \tag{24}$$

Dividing Eq. (20) by n^2 and substituting for n^2 from Eq. (24) yields the relationship

$$\beta^2=(\epsilon-G)(H\epsilon-G)/(H-1)^2. \tag{25}$$

After much simplification (25) reduces to Eq. (9) of the text.

Pressure Effect on Resistivity of $Ga(As_{1-x}P_x)$

G. E. Fenner
General Electric Research Laboratory, Schenectady, New York

(Received 2 January 1964)

The change of resistance of n-type $Ga(As_{1-x}P_x)$ samples under hydrostatic pressure up to 15 000 atm was measured between 190 and 363°K. Large pressure-dependent resistance changes were observed for samples with $x \approx 0.35$. These observations are consistent with the presence of another conduction band edge of much lower mobility presumably along $k = (100)$ into which electrons are transferred when the relative energy separation between the two edges is lowered by pressure. The measured results are compared with calculations based on the model proposed by Ehrenreich. The agreement between theory and experiment is found to be good if certain parameters are varied in a systematic way. For lightly doped material the mobility ratio of electrons in the light mass band to those in the heavy mass band is found to be large and to decrease rapidly with increasing temperature. At higher carrier concentrations both the magnitude of the mobility ratio as well as its variation with temperature are substantially reduced. At 300°K the (000) and (100) minima are found to cross at $x \approx 0.44$ if we assume Vegard's law to be valid. The experimental data are best explained if it is assumed that the separation between the two sets of minima changes at a rate of $>1\times10^{-4}$ eV/°K.

INTRODUCTION

In the last few years considerable progress has been made in the understanding of compound semiconductors, in particular those consisting of elements from the III–V columns in the periodic table. A comprehensive review of the transport properties of a number of these has been given by Ehrenreich,[1] who also deduced the band structure of $Ga(As_{1-x}P_x)$ as a function of the composition variable x. The details have been exhaustively covered by that author in an earlier publication[2] and therefore we shall only review those points of his model that are of direct concern to us here. Unlike the majority of semiconductors investigated to date, $Ga(As_{1-x}P_x)$ displays two sets of conduction band edges which are close enough in energy over an appreciable portion of the composition range so that their combined influence on the electrical behavior of the semiconductor has to be considered. The separation in energy between the two sets of minima depends upon x and it vanishes for $x \approx 0.5$. For $x < 0.5$ the (000) minimum is lowest in energy, while for $x > 0.5$ the (100) valleys are believed to be lowest. Because of the large differences in the mobilities and density of states between them, the bulk properties of the material can be expected to change appreciably as the region $x = 0.5$ is approached. It is the purpose of this paper to report measurements made in that transition region under the application of hydrostatic pressure and to derive values for parameters that so far have been speculative or not known at all. The influence of hydrostatic pressure on the band structure of semiconductors has been discussed by Paul.[3] He also touches upon some of the discrepancies in the experimental results in GaAs, which have a direct bearing on the model of both that compound and that of $Ga(As_{1-x}P_x)$ itself.

Our approach in this paper is to assume the correctness of the model proposed in Ref. 2. We hope to determine several band-structure parameters by fitting our results to this model. As will become apparent shortly, the biggest difficulties in accomplishing our task arise from the lack of homogeneity in the crystals themselves.

EXPERIMENTAL DETAILS

The $Ga(As_{1-x}P_x)$ samples used for the measurements were obtained from various sources. The most homogeneous samples were cut from crystals grown by halogen-assisted vapor transport in a sealed capsule somewhat similar to the method reported by Pizzarello.[4] Others were grown from excess gallium solution and one was an epitaxially grown sample purchased from the Merck Company. All crystals were doped with Te. X-ray determination of the lattice constant in conjunction with Vegard's law was used to establish the composition most accurately. All the crystals grown by vapor transport were prepared to yield $x \approx 0.35$. Whenever possible the specimens were cut into rectangular bars about 10 mm long and 1 mm square. Ohmic contacts were made by alloying tin dots to the semiconductor. The pressure was generated in a cylindrical multiple wall pressure cell of conventional design.[5] The pressure generating piston was driven directly by the platen of a 50-ton press. At room temperature the measurements were carried out inside this cylinder, while at the other temperatures the samples were enclosed in a small pressure cell similar to the one reported by Fitchen.[6] The large pressure cylinder then was used as the pump and connected to the small cell by $\frac{1}{8}$-in. o.d., 0.024-in. i.d. hard-drawn stainless-steel tubing manufactured by the Harwood Engineering Company. The electrical connections were made by the use of

0.062-in. swaged metallic sheathed thermocouple wire.[7] At temperatures below 300°K a mixture of n pentane and isopentane served as the pressure fluid while at temperatures above that n pentane alone was used. The pressure was measured by a seasoned manganin wire gauge[5] mounted inside the pressure cylinder. The gauge calibration was established using a recent determination of the freezing pressure of Hg at 0°C.[8] The accuracy of the pressure measurements is estimated to be better than 1%.

RESULTS

The application of hydrostatic pressure on Ga($As_{1-x}P_x$) increases the energy gap between the conduction band minimum at $k=(000)$ and the top of the valence band at the rate of about 1.1×10^{-5} eV/atm. The energy separation between the (100) minima and the valence band has a small negative pressure coefficient and therefore the net result is a decrease of the relative energy separation ΔE between the (000) and (100) conduction band valleys under pressure. As long as $\Delta E \gg kT$ the number of electrons transferred to the energetically higher lying minima per unit dilatation of the crystal is small. Once ΔE has been reduced to a few kT either by very high pressures in the case of [2]GaAs or by the proper choice of composition in Ga(AsP), the rate of transfer of electrons to the higher valleys increases rapidly. Because of the much lower electron mobility in the (100) valleys, the bulk resistance of the material increases many fold until all the current is carried by electrons in the (100) valleys. After that a further increase in pressure does not change the resistance appreciably. This general characteristic is demonstrated by the measurements shown in Figs. 1, 3, and 4.

As mentioned already our plan is to compare experiment and theory by choosing certain parameters of Ehrenreich's model until a best fit with the measured values is obtained. With the assumptions set down in the Appendix we find for the relative resistance at pressure P

$$\frac{\rho(P)}{\rho(0)}=\frac{b+\nu}{1+\nu}\frac{1+\nu e^{\alpha P/kT}}{b+\nu e^{\alpha P/kT}}, \qquad \text{(A1)}$$

where $b=\mu_1/\mu_2$ is the mobility ratio between valleys 1 and 2, $\nu=b_\rho e^{-\Delta E(0)/kT}=n_2(0)/n_1(0)$ the ratio of the number of electrons in valley 2 to the number in valley 1 at atmospheric pressure, and α the pressure coefficient of the energy separation between valleys 1 and 2. Valley 1 refers to the minimum at $k=(000)$ while 2 refers to the set of equivalent minima along $k=(100)$. In trying to fit Eq. (A1) to the experimental data, the value for the pressure coefficient α was accepted from earlier work. It was deduced directly from pressure measurements on [2]GaAs and probably can be accepted with some confidence.[9] Should a small correction for this value become necessary it would merely lead to a minor correction in b as seen by Eq. (A4) of the Appendix. The density of states ratio b_ρ is numerically quite uncertain[2] and may be subject to correction. Fortunately for most of our considerations b_ρ is absorbed into the factor ν and will only become important when the band structure at a particular value of x is discussed.

Figure 1 shows the results of measurements made on sample 21a-11, the crystal with the smallest carrier concentration of all our samples. This single-crystal specimen obtained from a crystal grown by vapor transport also had a small variance in composition and therefore we will base our conclusions largely on that particular sample. Other bars cut from adjacent parts of the same crystal gave results very close to 21a-11, so that our confidence seems justified. Except for the high-pressure region, i.e., the region after the bands have crossed, the fit is considered to be very good. The outstanding feature of the curves plotted in Fig. 1 is the behavior of $b=\mu_1/\mu_2$ as a function of temperature. It has a very large value at 200°K but decreases markedly as the temperature is increased. For the deviations between the expected and the actual measured values at

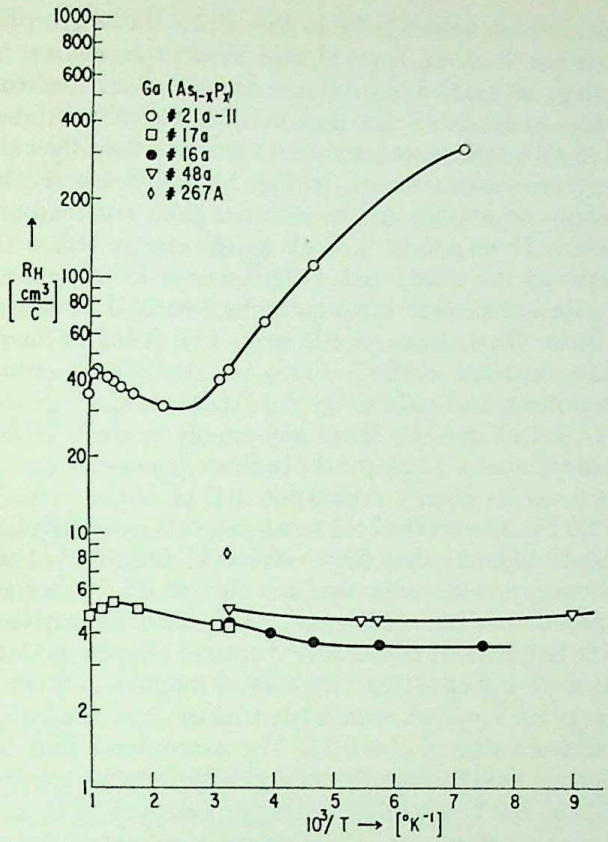

FIG. 2. Hall constant versus $1/T$ at atmospheric pressure.

high pressures, we offer the following explanation: The inspection of the Hall coefficient (Fig. 2) for this sample reveals that freeze out of carriers occurs below 400°K. This implies that an appreciable number of carriers is occupying one or more deep levels at the temperatures at which our experiments are performed. If we suppose that these levels have a pressure shift equal to that of the (000) minimum, then the number of electrons in that band will not change under pressure as long as the other minima are sufficiently far removed in energy. As the (000) minimum approaches the (100) minima, some of the carriers in the impurity levels can now be thermally excited into the (100) minima. Now our assumption that the total number of electrons in the conduction band remains constant is no longer valid. Because of the large mobility of electrons in the (000) minimum, this effect will not be noticeable until the latter valley is almost empty; i.e., until the bands have crossed. Then, as carriers are transferred from the bound impurity states to the low but finite mobility (100) band, the resistance decreases in agreement with the observations. The effect should become more pronounced as the temperature is decreased, because the ratio of electrons in the (000) minimum to the number in bound states is decreased even before the pressure is applied. For the samples that do not show the freeze out, this decrease in resistance does not occur, giving further support to the correctness of our reasoning.

Figure 3 shows the results of measurements made on sample 17a. This specimen is also a single crystal and are similar in composition to 21a-11. The major difference between the two crystals is the much larger carrier concentration of 17a. This difference shows up in the reduction of the mobility ratio b which can be traced to the increased influence of ionized impurity scattering in the heavier doped crystal. Because this scattering process is most important at low temperatures, it reduces the temperature dependence of b.

The results of measurements on additional samples are shown in Fig. 4. Specimen 48a is a polycrystalline sample which shows a pressure dependence similar to 17a. However, the factor ν which results in the best fit with the experimental data has a different temperature dependence for the two samples. It is probable that the polycrystalline sample 48a has a larger variation in composition which would explain the different behavior. A very pronounced effect of this variation can be seen in sample 267 A with $x=0.24\pm0.05$. This epitaxially grown single crystal shows such large variations in composition that no agreement between our model and experiment can be accomplished.

Finally, we have measured a sample with a composition of $x\approx0.61$ and find the change in resistance linear up to 10 000 atm at room temperature with $\Delta\rho/(\rho P) = -14.5\pm1\times10^{-6}$ atm^{-1}. This agrees in sign with the

measurements made on[10] silicon and[11] GaP, but is larger in magnitude than either one of these.

We shall now attempt to gain additional information from the measurements made on sample 21a-11. From the pressure data we find $\nu=5.6\pm1$. (See Table I.) If we accept the value of $b_\rho=70(+40, -20)$ determined by Ehrenreich,[2] we find the energy separation between valleys 1 and 2 at zero pressure given by $\Delta E(0)=0.065$ eV $(+0.017, -0.013)$. X-ray lattice-parameter evaluation resulted in a value of $a_0=5.5806\pm0.0002$ or, assuming the validity of Vegard's law, $x=0.359$. Linear extrapolation of our energy separation ΔE to the terminal compounds GaAs and GaP shows that we cannot match both values given in Ref. 2 simultaneously. The pressure data of Howard and Paul[12] rule against an energy separation between the direct and indirect band edges in GaAs of less than 0.3 eV. Ehrenreich found 0.36 eV as the most consistent value based on Hall and pressure measurements. In Fig. 5 we have plotted the energy separation ΔE as deduced from our measurements. If we accept 0.36 eV as the energy separation between the (000) and (100) minima for GaAs, the separation for GaP turns out to be 0.46 eV if we assume a linear dependence of ΔE on x. This is 0.1 eV larger than reported earlier.[1] From an analysis of optical absorption and reflectivity data Zallen and Paul[13] find 2.75–2.8 eV for the direct gap energy in GaP. With a value of about 2.2 eV for the indirect gap energy E_G this leads to an energy separation ΔE of about -0.5 to -0.6 eV. Photothreshold measurements by Spitzer and Mead[14] indicate that $\Delta E\approx-0.45$ eV. Engeler,[15] of this laboratory, concludes that a value of 0.5 eV for the separation of the (100) and (000) band is consistent with Spitzer and co-workers'[16] optical absorption data. Figure 5 indicates the two sets of minima to cross in energy at $x_c\approx0.44$, somewhat smaller than the earlier deduced value of $x_c\approx0.53$. The assumption that ΔE depends linearly on x is undoubtedly only an approximation, but the deviations are not expected to be large enough to affect our determination of x_c materially.

The main difficulties in the interpretation of our results show up when we try to determine the effect temperature has on the energy separation ΔE. Again accepting the value $b_\rho=70$ independent of temperature, we can find ΔE from ν. This is done in Table I for three samples discussed earlier. In order to arrive at the probable error of these determinations, curves calculated by varying both b and ν were compared with the actual measurements. The limit of agreement was defined as that point at which the deviations of the calculated curves from the measured have passed outside the experimental tolerances. The discrepancies in the temperature coefficient of ΔE for the three samples are larger than the experimental error. In view of the difficulties arising from crystal inhomogeneities, as exemplied by results from sample 267 A, this is not too surprising. It must be concluded, though, that $\partial\Delta E/\partial T=(\partial/\partial T)(E_{100}-E_{000})$ is larger than 1×10^{-4} eV/°K.

While the changes of resistance under pressure can readily be understood in terms of the adopted model, the interpretation of the Hall data derived from the same samples is not at all certain. The Hall coefficient for the two-band model is given by

$$R_H=[(1+\nu)/en][(b^2+\nu)/(b+\nu)^2],$$

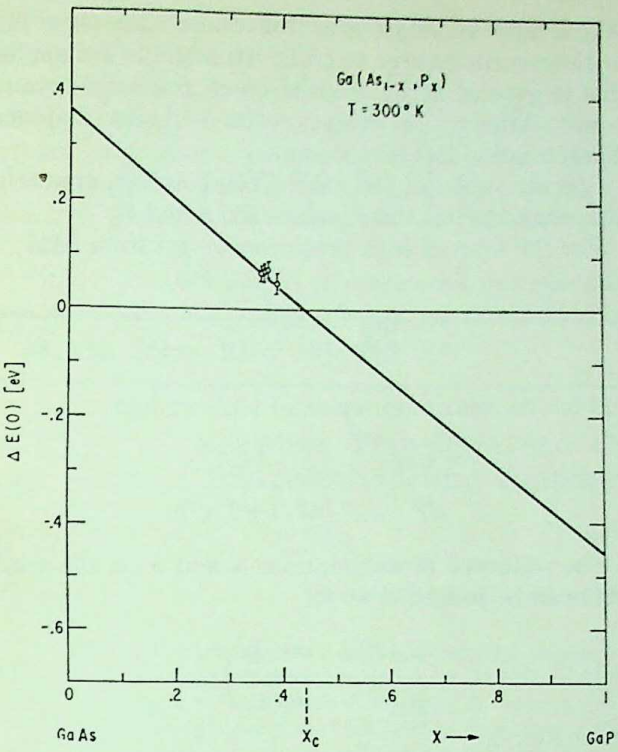

FIG. 5. Energy separation $\Delta E(0)$ versus composition at atmospheric pressure and 300°K. The uncertainty in the experimental points is due to the experimental errors as well as the large uncertainty in the knowledge of $b\rho$.

where scattering factors of the order of 1 have been set equal to 1. Under the condition $n_1+n_2=n=$constant, R_H has a maximum value of $(1+b)^2/4b$ when $n_2/n_1=b$. The temperature at which this maximum occurs increases with b and ΔE. To be consistent with the parameters deduced from the pressure experiments, the Hall coefficient should have increased appreciably at room temperature over its value at lower temperatures assuming ΔE to be temperature-independent. This, however, is contrary to the experimental evidence. Furthermore, the maximum of R_H occurs at much higher temperatures than expected from the energy separation of the (000) and (100) valleys at room temperature.

For the lightly doped sample 21a-11, the rapid freeze out below 400°K invalidates our assumption that the total number of electrons in the conduction band remains constant. This fact and the rapid decrease of b with increasing temperature could be advanced as a reason for the poor agreement with the measured Hall coefficient. Both arguments are not supported by the measurements made on the rest of the samples and, therefore, we are forced to look for other possible explanations. As mentioned earlier, the pressure measurements at various temperatures are best explained if we assume ΔE to have a positive temperature coefficient in excess of 1×10^{-4} eV/°K. An increase of the energy separation ΔE at a rate of about 2×10^{-4} eV/°K and a decreasing b would suffice to keep R_H approximately constant to higher temperatures, except that this is contrary to the experience with the other group IV and III–V semiconductors as well as the terminal compounds themselves. It should be noted, however, that very little is known about transport properties of ternary compounds and some of the extrapolations might well be in error.

CONCLUSIONS

The close agreement between the measured values and the calculations based on Ehrenreich's model of the $Ga(As_{1-x}P)$ conduction band must be considered strong evidence for the correctness of the essential points of that model. While we have not directly proved that the energetically higher lying minima are indeed along the ⟨100⟩ directions, the self-consistency of our results gives strong support to this identification.

The large mobility ratio ($b>50$) deduced from our room temperature measurements on the lightly doped sample is significant, since this is necessary for the interpretation of the large pressure-dependent resistance changes in GaAs observed by Howard and Paul.[12] The rapid decrease of the mobility ratio b with increasing temperature could explain the smallness of b derived from high-temperature Hall data. Extended to GaAs, it suggests that this is the reason for the apparent difference in $b=10$ reported by Aukerman and Willardson[17] and the b based on room-temperature pressure measurements. But in view of the discrepancies between our pressure and Hall data, this interpretation must be considered with caution. The composition x_c at which the (000) and (100) minima are equal in energy is smaller than earlier estimates, excepting the recent determination of Spitzer and Mead.[14] The extrapolation of their results to GaAs leads to an energy separation which is too small. Their results can be brought into agreement with ours if we assume some variation in composition in their samples. This variation would have the effect of lowering the apparent energy of the (100) band edge for a given value of x explaining the difference in their results.

ACKNOWLEDGMENTS

I would like to thank H. Ehrenreich, W. Paul, R. O. Carlson, W. Engeler and R. N. Hall for many informative and helpful discussions; S. J. Silverman and T. J. Soltys for the Hall measurements and G. J. Charney for his assistance with the pressure measurements. The crystals were kindly supplied by R. F. Reihl, S. J. Silverman, and R. N. Hall.

APPENDIX

We are assuming that the conduction band of Ga(As,P) exhibits two sets of minima, one minimum at

$k=[000]$ (valley 1) and a set of minima along $k=[100]$ in the Brillouin zone (valley 2). The separation in energy between the minima at the different points in the Brillouin zone is supposed to be a linear function of the composition of the alloy as shown in Fig. 5. For the purpose of the analysis we make these further simplifying assumptions:

1. Boltzman statistics apply.
2. Intervalley scattering is neglected.
3. The total number of carriers in the conduction band is constant.
4. The mobility ratio $b=\mu_1/\mu_2$ is independent of pressure. (Subscript 1 refers to the low-mass band at $k=[000]$ throughout this analysis. Furthermore, symbols used are those of Ehrenreich.[2])
5. $b_\rho=(m_\rho/m_1)^{3/2}=70$ is also pressure- and temperature-independent; $m_\rho=$density of state mass in the valleys at $k=[100]$.
6. The energy separation between different minima is $\Delta E=\Delta E(0)-\alpha P$ where $\alpha=1.1\times10^{-5}$ eV/atm.

With these assumptions we find for the relative resistance at pressure P,

$$\frac{\rho(p)}{\rho(0)}=\frac{b+\nu}{1+\nu}\frac{1+\nu e^{\alpha P/kT}}{b+\nu e^{\alpha P/kT}}, \tag{A1}$$

where

$$\nu=\frac{n_2(0)}{n_1(0)}=\left(\frac{m_\rho^{3/2}}{m_1}\right)e^{-\Delta E(0)/kT}.$$

The logarithmic derivative of the expression (A1) is given by

$$\frac{d\ln\rho}{dP}=\left(1-\frac{1}{b}\right)\frac{\alpha}{kT}\frac{\nu e^{\alpha P/kT}}{[1+(\nu/b)e^{\alpha P/kT}](1+\nu e^{\alpha P/kT})}. \tag{A2}$$

Since ν can directly be converted into composition by the use of Fig. 5, this last equation gives essentially a universal curve in which composition and pressure can be interchanged. In principle, it should therefore be possible to plot the experimental values of the logarithm of resistance versus pressure, differentiate this curve and fit the resulting curve to (A2). Attempts to accomplish that in general were not satisfactory, primarily because b was different in every crystal and the graphical differentiation lacked accuracy.

Specific values of (A1) and (A2), however, are useful in finding the unknown parameters ν and b.

For the limit of high pressures, we get from (A1)

$$\lim_{P\to\infty}\frac{\rho(P)}{\rho(0)}=\frac{b+\nu}{\nu+1}, \tag{A3}$$

and for the maximum value of (A2) we find

$$\left.\frac{d\ln\rho}{dP}\right|_{\max}=\frac{\alpha}{kT}\frac{1-1/b}{1+2/\sqrt{b}}. \tag{A4}$$

The influence of assumptions 4 and 5 on the result (A1) can be judged if we let

$$\frac{\mu_1(P)}{\mu_1(0)}=\left(\frac{m_1(0)}{m_1(P)}\right)^n. \tag{A5}$$

From Ref. 2,

$$\frac{m_1(P)}{m_1(0)}=\frac{E_G(P)}{E_G(0)}\frac{1+(1/2)E_G(0)[E_G(0)+\Delta]^{-1}}{1+(1/2)E_0(P)[E_G(P)+\Delta]^{-1}}, \tag{A6}$$

where $E_G(0)$ and $E_G(P)$ are the band-gap energy at atmospheric pressure and at pressure P respectively and Δ the spin-orbit splitting energy. If polar scattering is the dominant scattering mechanism, n in equation (A5) equals $\frac{3}{2}$ and (A1) can be corrected by replacing the one in the numerator by the right hand side of (A6) raised to the $\frac{3}{2}$ power. Since $\Delta\ll E_G$ (A6) is approximately

$$1+\frac{1}{E_G(0)}\left(\frac{\partial E_G}{\partial P}\right)P.$$

This factor has to be considered only for values of ν and P where the electron transfer to the higher band edge is insignificant.

Resistive Transition and Current Density Characteristics in Superconducting Niobium Containing Dissolved Gases*

WARREN DESORBO
General Electric Research Laboratory, Schenectady, New York
(Received 5 March 1963; revised manuscript received 4 February 1964)

Oxygen and nitrogen as interstitial solutes in niobium cause the metal in transverse field to exhibit anomalous resistance minima or critical current maxima (peak effect). The anomaly appears at H_{c2}, the upper critical field of these Type II superconductors. The resistance in the mixed state is decreased by exceeding the solubility limit, by cold working and by strain aging at 170°C, masking out the anomaly. Rapidly quenching from the solution temperature decreases the anomaly. The results suggest that the anomaly is strongest at some intermediate stage of the process of segregation and precipitation at dislocations. Resistance in the mixed state is increased by introducing more solute, by quenching, and by etching. Structural changes brought about by cold working, strain aging, and rapid quenching responsible for large changes in $J_c(H)$ or $R(H)$ in the mixed state also cause changes in the region $H_{c2}<H<H_{c3}$. In this latter region, field orientation effects and observed H_{c3}/H_{c2} ratios are roughly consistent with the concept of a superconducting surface sheath as recently proposed by Saint-James and de Gennes. Pure niobium, however, tends to exhibit consistently higher ratios.

I. INTRODUCTION

SUPERCONDUCTING transition metals in Group V of the periodic table have been noted for their anomalous behavior which is usually attributed to the presence of chemical and/or structural impurities. An important metal of this group is niobium, which serves as a base metal in the fabrication of many high-field, high-current-carrying superconductors. The influence of substitutional[1] and interstitial[2] solutes on some superconducting properties of noibium has been recently summarized. Other investigations have also appeared, revealing the importance of small amounts of interstitial impurities on the substructures of the metal (e.g., see Ref. 3).

Unusual superconducting behavior occurring in niobium has been reported in both the resistance-field[4] and critical current-field characteristics.[5] Recently, some striking resistance decreases following an initial rise were observed[6] during the superconducting transition of the metal: (a) when the current I through the wire, and temperature T were kept constant and a transverse magnetic field was increased continuously; or (b) when the current and field were held constant and T varied. The field at which the resistance minimum takes place was found to be independent of J, occurring at a field comparable to the upper critical field, H_{c2} of a Type II superconductor.[7,8] It is pointed out in this report that this anomalous behavior is readily observed in niobium containing small amounts of interstitial solutes such as oxygen or nitrogen but is not observed in outgassed niobium. The results are compared with the magnetic behavior of the solutions which have already been described[2] as Type II superconductors. The influence of solute concentration, field orientation, cold working, strain aging, quenching, and etching on the resistance-field transition and on the current

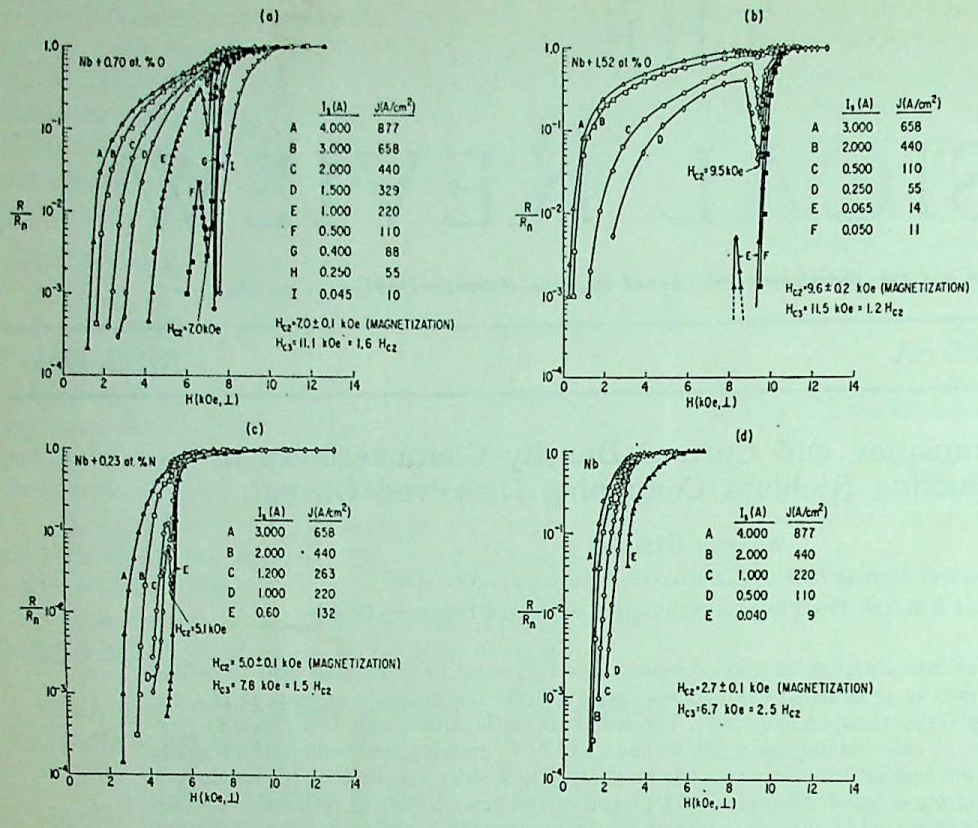

FIG. 1. The resistive characteristics R/R_n as a function of current density and applied transverse field at 4.2°K for wire (0.030-in. diam) specimens of (a) Nb+0.70 at.%O (T_c=8.7$_8$°K); (b) Nb+1.52 at.%O (T_c=8.0$_4$°K); (c) Nb +0.23 at.% N (T_c=9.20°K); and Nb (T_c=9.4$_6$°K). H_{c3} values are evaluated at $J\approx10$ A/cm².

density-field characteristics both in the mixed state below H_{c2} and in the region $H_{c2}\lesssim H\lesssim H_{c3}$ are summarized. The dependence of H_{c3}—the field at which the specimen is completely normal—on these factors is cited.

II. EXPERIMENTAL

The niobium wire specimens (0.030-in. diam) were made from an electron-beam melted stock obtained from the Stauffer-Temescal Company, Richmond, California, hereafter referred to as Nb(S-T) (see Ref. 2). Rods, about 0.250-in. diam were machined from the ingot then swaged and drawn to wire form. The resistance ratio, $R_{298°K}/R_{10°K}$, of the wire "as received" was about 110. The quantitative addition of the interstitial solute was carried out by a procedure developed earlier by Powers and Doyle[9]. The interstitial solute was introduced at temperatures between 1000–1100°C. The specimen was then homogenized by heating at about 1200–1300°C for approximately 1 h. Prior to the introduction of the gas, the specimen had been annealed and outgassed at about 1800–2000°C for several hours at a residual pressure less than 1×10^{-7} mm Hg. After this treatment and prior to the introduction of the interstitial, the resistance ratio of the wire was about 500. An analysis of a similarly prepared specimen reported by Seybolt[10] gave oxygen content 6±3 ppm and nitrogen content 5±3 ppm.

The resistance transition as a function of field at constant current density was measured at 4.2°K potentiometrically with a noise level less than 0.1 μV. Referred to in terms of R/R_n, where R is the resistance in the transition and R_n, the normal resistance, the noise level is less than 1×10^{-3} except for data obtained with low current densities ($J<125$ A/cm²) for outgassed niobium. The critical current of the wire specimen in a given field was also measured potentiometrically and the value taken was that which produced approximately 0.1 μV across the potential leads. The fields were produced by a small niobium wire (0.004-in. diam) wound iron-core magnet (0.040-in. slot) designed and built by H. R. Hart, Jr., following an original design due to Autler.[11] Field direction was in all cases transverse to the wire and to current flow. Field orientation for ribbon samples, either perpendicular ($H\perp$w.s.) or parallel ($H\|$w.s.) to the wide surface were obtained by mounting the ribbon in a form permanently fixed between the pole pieces.

The magnetic induction measurements were carried out by a technique used earlier by Bean.[12] A typical

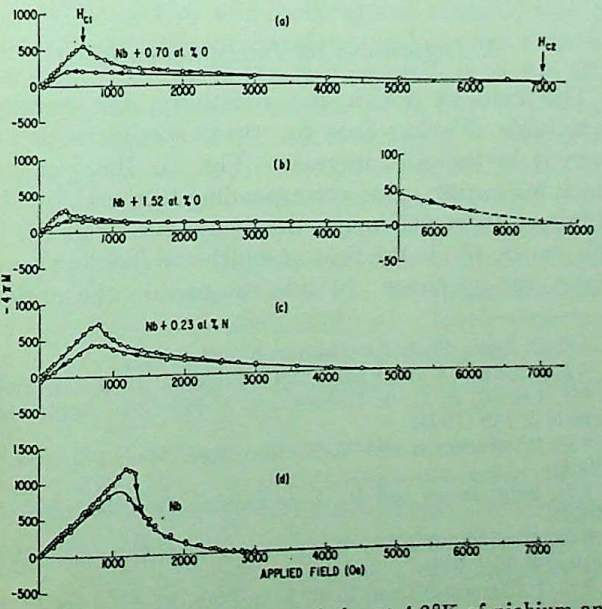
sample prepared for these measurements consisted of 7–10 wire segments, approximately 1.2 cm long, bundled together into a cylindrical form in a paper "straw." The ends of each wire were etched (50% HF, 50% HNO_3) to remove any strains. The sample cylinder was immersed in liquid helium at zero field. Magnetization measurements were made at 4.2°K by flipping it in and out of a copper coil (about 2000 turns) coaxial with an external steady field. The coil was connected to a flux meter whose deflection was proportional to the magnetization of the specimen. The magnetic field measurements were accurate to ±10 Oe; while $-4\pi M$ values were accurate to ±5 Oe.

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. Influence of Oxygen and Nitrogen in Niobium

1. Resistive Transition at Constant Current Density

The resistive transition R/R_n as a function of transverse field H and current density J at 4.2°K for four wire specimens of niobium containing (a) 0.70 at.% oxygen, (b) 1.52 at.% oxygen, (c) 0.23 at.% nitrogen, and (d) niobium outgassed and annealed is shown in Fig. 1. The resistance decrease in the transition, after an initial rise, is apparent for each of the interstitial solid solutions of niobium containing oxygen or nitrogen at current densities below a maximum value J_{max} and above a minimum value J_{min}. The drop in resistance is most pronounced at current densities near J_{min}. Increasing the interstitial concentration in the homogeneous solid solution tends to decrease both J_{min} and J_{max}. For example, for specimen Nb+0.70 at.% oxygen, $J_{max}\sim 1000$ A/cm² and $J_{min}\sim 90$ A/cm²; while for specimen Nb+1.52 at.% oxygen, $J_{max}\sim 800$ A/cm² and $J_{min}\sim 12$ A/cm². For a given specimen, the field corresponding to the maximum decrease in R/R_n, after an initial rise, appears to be almost independent of J and coincides with H_{c2}, the upper field required for $-4\pi M=0$ (compare Fig. 1 and Fig. 2).



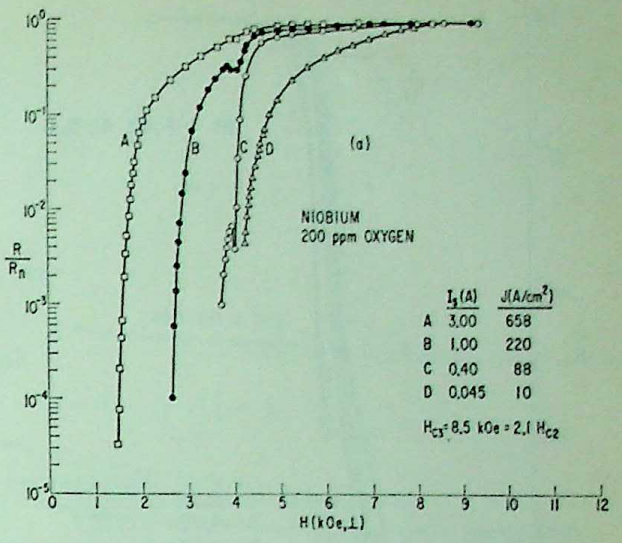


FIG. 2. Magnetization characteristics at 4.2°K of niobium and niobium containing interstitial solutes of oxygen and nitrogen (0.030-in. diam wires).

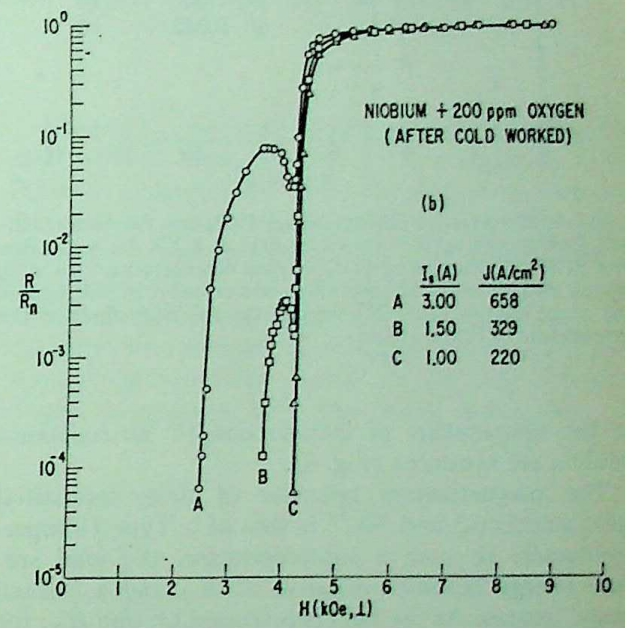

FIG. 3. The resistive transition R/R_n as a function of applied field at 4.2°K for a niobium wire containing 200 ppm oxygen (a) before cold worked diam=0.030 in.), H_{c2} evaluated at $J=10$ A/cm² and (b) after cold worked by hammering (diam ≈0.027 in.). $H_{c2}=8.0$ kOe$=1.9\ H_{c2}$ at $J=200$ A/cm².

For niobium outgassed and annealed, no apparent discontinuities in the transition are seen even at low current densities [Fig. 1(d)]. At these small J values the noise level in R/R_n is greater than 1×10^{-3}. However, the anomaly can still be observed in niobium containing as little as 200 ppm oxygen [Fig. 3(a) and (b)]. When the oxygen is beyond the solubility limit

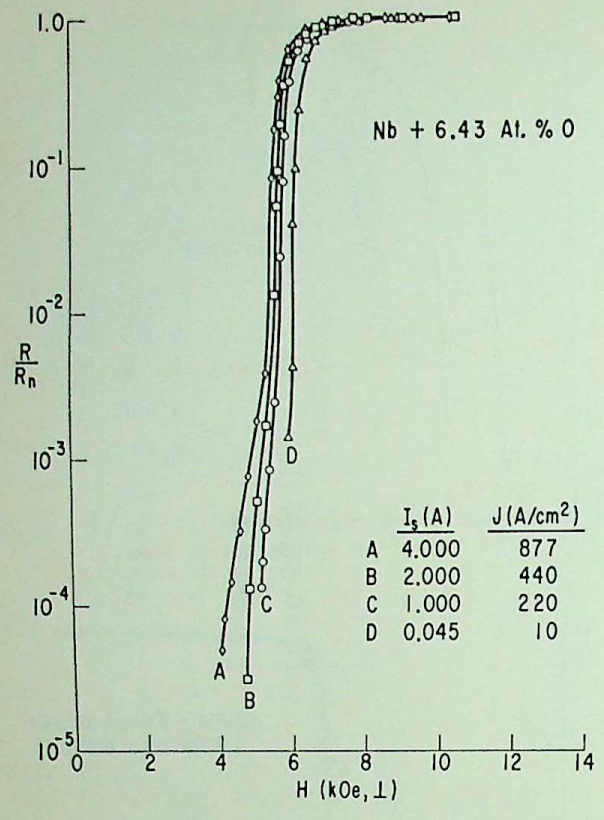

FIG. 4. The resistive characteristics R/R_n as a function of current density and applied tranverse field at 4.2°K for a niobium wire (0.030-in. diam) containing oxygen concentration [6.4 at.% oxygen plus some nitride contamination revealed by micrograph and x-ray studies (Ref. 2)] beyond the solubility limit at the temperature of introduction.

at the temperature of introduction,[13,14] no resistance minima are apparent (Fig. 4).

The magnetization behavior of these interstitial solid solutions,[2] and Nb,[15] is that of a Type II superconductor. In such a superconductor, the total surface energy becomes negative at H_{c1} and a "mixed state" ensues. As the field is increased beyond H_{c1}, the flux penetration increases until at H_{c2} the transformation to the normal state is achieved. The model is based on the material being homogeneous and defect-free, exhibiting reversible magnetization characteristics. It is believed that the resistance $R(H)$ in the "mixed state" is associated with flux motion or creep of the kind discussed by Kim, Hempstead, and Strnad,[16] i.e., resistance is determined from the rate at which flux filaments are moving. Based on this model, increasing the interstitial concentration seems to increase the flux motion for a given J since R increases [compare Fig. 1(a) and 1(b)]. When the solubility limit of the interstitial is exceeded, no resistance appears below H_{c2} within the limits of the measurements (compare Fig. 4 and Fig. 9, Ref. 2). In the "mixed state" the interaction of defects, inhomogeneities, or precipitates with flux filaments controls the hysteresis of the type described by Bean[17,18] and the equivalent critical current.[16,19]

Anderson and Kim[20] have suggested a possible explanation of the anomalous resistance drop after an initial rise based on the flux-creep model. As H_{c2} is approached, the lattice flux lines are expected to become more rigid, slowing down the rate of flux motion. Oxygen and nitrogen present in small concentrations would tend then to favor this process.

Above H_{c2} the variations in resistivity appear at smaller current densities dependent on the measuring currents. R approaches R_n at H_{c3}, the field at which the material is completely normal. There are two possible explanations for the variation of the $R(H)$ curve in this region. One is that recently proposed by Saint-James and de Gennes[21] envisioning a superconducting sheath along parts of the sample which disappears at H_{c3}. Recently, experimental evidence[22–24] has appeared showing that this remanent superconductivity is basically a surface effect in agreement with this point of view. Some supporting evidence for this is also presented in this work (see below). An alternative explanation may be that above H_{c2} a real resistance occurs; and that the shape of this portion of the $R(H)$ curve manifests the destruction of the final traces of superconductivity due to lattice irregularities such as dislocations, grain boundaries, and inhomogeneities having a higher critical field than the matrix. The connected regions would play an important role near and just above H_{c2}, while the discontinuous superconducting regions would be responsible for the shape of the curve at the top of the transition.

2. *Influence of the Interstitial on H′*

The field at which the resistivity first becomes detectable H' decreases for these specimens as the current in the wire increases (Fig. 5). It appears to reach a limiting value corresponding to the value H_{c1}, obtained from the magnetization curve (Fig. 2). In this curve, H_{c1} is the field at which the flux first penetrates the specimen. In this comparison the applied

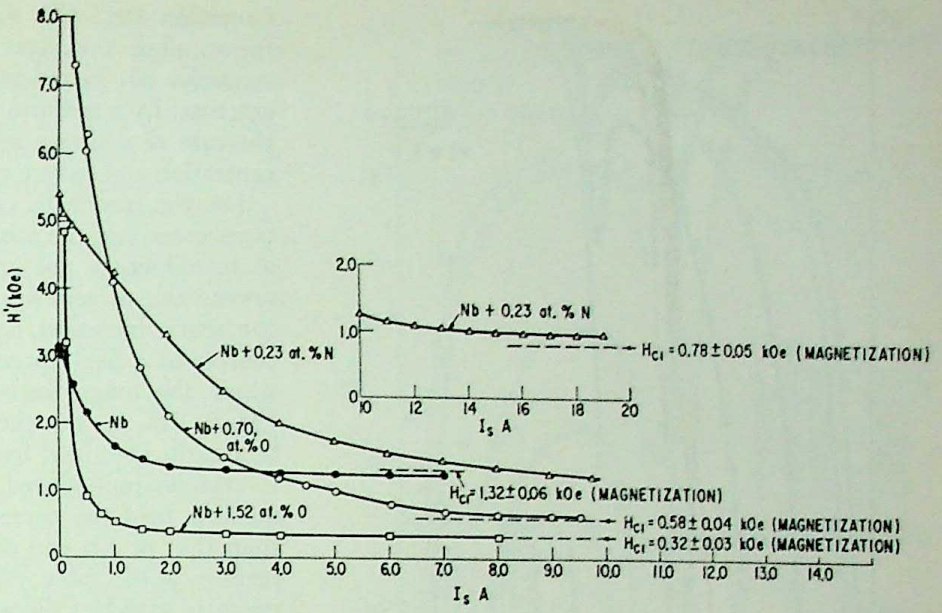

FIG. 5. The transverse field H' required for the initial appearance of resistance ($R/R_n \lesssim 1\times10^{-3}$) at 4.2°K as a function of specimen current I_s (amperes). The values of H_{c1} are evaluated from the magnetization curve.

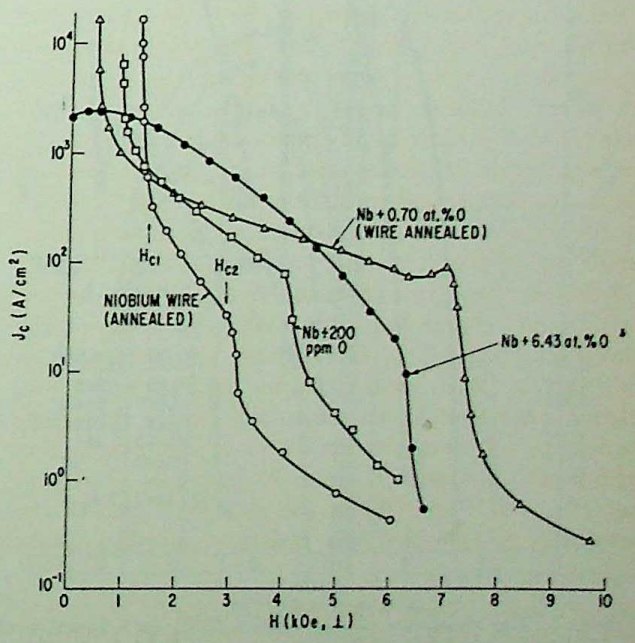
field value does not contain the small correction due to the magnetic field generated by the current in the wire. H' decreases as the interstitial solute concentration increases. The resistive transition occurring between H' and the field at which the resistance minimum occurs, H_{c2}, for a given J becomes broader as the solute concentration increases [compare Figs. 1(a) and 1(b)]. More quantitative comparisons should be done at the same reduced temperature since oxygen present interstitially lowers the transition temperature.[2]

3. Critical Current Density

The critical current density J_c as a function of transverse field, of wire specimens of annealed niobium and annealed niobium containing various concentrations of oxygen is shown in Fig. 6. J_c extends to higher fields as the oxygen concentration increases. This is no longer true when the solubility limit is exceeded. A comparison of the curves with their respective magnetization data (Fig. 2) clearly defines three portions: (1) below H_{c1}, a sharp decrease in $J_c(H)$ takes place analogous to the behavior in a "soft" superconductor; (2) the "mixed state" region between H_{c1} and H_{c2}, where the anomalous behavior in the threshold-field curve (peak effect) related to the resistance minimum discussed above is evident in the niobium containing 0.70 at.% oxygen and (3) a region above H_{c2}.

Below H_{c1}, one assumes that the transport current J is carried in a thin shell (London penetration depth). Between H_{c1} and H_{c2}, it is believed that the transport current is controlled by the interaction of defects and flux filaments and that the net flow of current is dependent on the concentration gradient of flux filaments resulting from this interaction. J_c is determined as soon as the motion of the flux filaments is detected.[16,19]

Above H_{c2}, evidence cited below seems to indicate that current could be carried by a superconducting layer as suggested by Saint-James and de Gennes.[21] An alternative explanation could be that starting at H_{c2}, the continuous supercurrent flux filaments in the main body of the matrix no longer exist and the current carrying mechanism changes to that associated with extended defects consisting of higher critical field superconducting structural defects or physical filaments. Similar suggestions have been made earlier (e.g., see



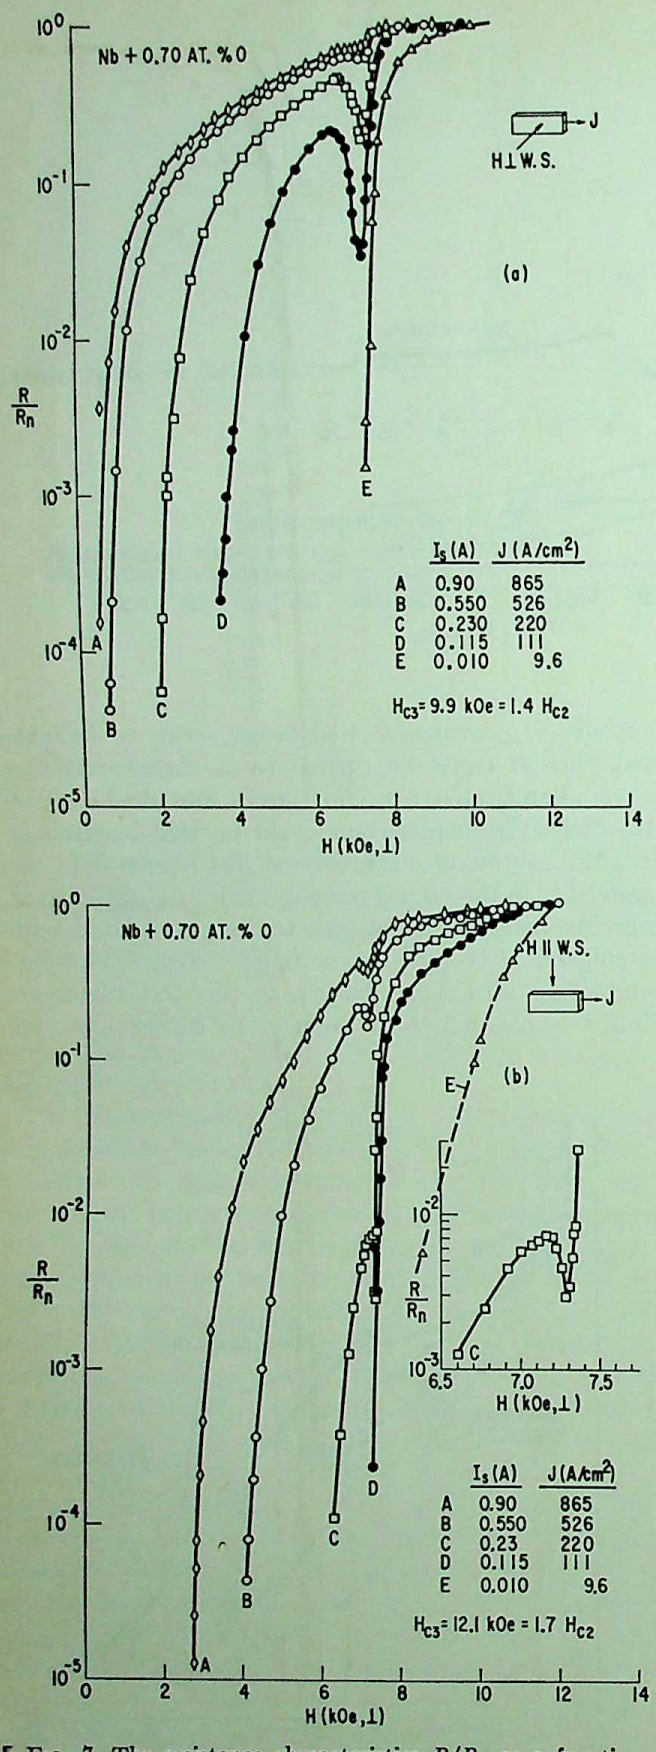


FIG. 6. Threshold current density-field behavior of some annealed niobium wires (0.030-in. diam) containing various amounts of oxygen. Annealed and outgassed niobium is also shown for comparison ($T=4.2$°K).

F FIG. 7. The resistance characteristics R/R_n as a function of applied transverse field at 4.2°K for an annealed ribbon of niobium (0.032×0.007 in.) containing 0.70 at.% oxygen (a) with field perpendicular to the wide side ($H\perp$w.s.); (b) with field parallel to the wide side ($H\|$w.s.). H_{c3} values are evaluated at $J\simeq 10$ A/cm².

discussion Ref. 25). $J_c(H)$ drops off rapidly in this region since the superconducting paths would, presumably, not be continuous nor necessarily be characterized by a uniform critical field. One would expect the rate of decrease of $J_c(H)$ to depend on the concentration and nature of the defects.

For the specimens containing oxygen in concentrations exceeding the solubility limit at the temperature of introduction, the critical current has a relatively lower value at zero field, remaining almost constant as the field is increased, decreases monotonically and then sharply at a field approximately corresponding to that where the magnetization becomes zero ($B=H$) (see Fig. 9, Ref. 2). For this specimen H_{c1} and H_{c2} cannot be clearly identified from the magnetic behavior since it exhibits pronounced magnetic hysteresis. At intermediate field the current density is somewhat higher than that of Nb and dilute Nb-O solutions indicating perhaps some more effective interaction of the precipitates with flux filaments in the Nb matrix.

B. Influence of Field Orientation

1. Resistive Transition at Constant Current Density

a. Nb+0.70 at.% Oxygen-Annealed Ribbon. Figures 7(a) and 7(b) show the resistance transition of an annealed niobium ribbon containing 0.70 at.% oxygen for $H\perp$w.s. and $H\|$w.s., respectively. $R(H)$ in the mixed state for a given J is lower than for the wire specimen [see Fig. 1(a)]. Of the two field orientations, it is smaller when $H\|$w.s. The anomalous resistance minimum is also smaller for this field direction. While H_{c2} is independent of field direction, H_{c3} has a higher value when $H\|$w.s. In either case, H_{c3} tends to decrease as J increases. If H_{c3} is evaluated at the smallest J, namely $J=10$ A/cm², the ratio $H_{c3}/H_{c2}=1.68$, when H is parallel to the wide side. This value is in good agreement with the Saint-James and de Gennes analysis[21] which predicts $H_{c3}/H_{c2}=1.695$, when H is parallel to the surface. For H perpendicular to the surface, the Saint-James and de Gennes analysis reduces to that of Abrikosov with no remanent superconductivity expected beyond H_{c2}. In this study when the field is perpendicular to the wide side of the annealed ribbon [Fig. 7(a)] some remanent superconductivity does exist and $H_{c3}/H_{c2}=1.37$ ($J=10$ A/cm²). The ratio is smaller than the theoretical value, although the edges of the ribbon specimen provide some surface parallel to the field.

b. Nb+0.70 at.% Oxygen-Cold-Worked Ribbon. When a ribbon, the same geometry as that above, is made by cold-working niobium wire containing 0.70 at.% oxygen (i.e., wire uniformly compressed to a flat ribbon) there occurs a decrease in the resistance in the mixed state and an enhancement of the resistance

[21] W. DeSorbo, Rev. Mod. Phys. 36, 90 (1964).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

minimum for either of the two field directions when compared with the results obtained on the annealed specimen [compare Fig. 7(a) with 8(a) and 7(b) with 8(b)]. The resistance decrease is more pronounced when $H\|$w.s. of the ribbon. This decrease in $R(H)$ in the mixed state upon cold working is consistent with the point of view[16] that R is determined from the rate at which flux filaments are moving. Increasing dislocation (or defects) and/or segregation and precipitate concentration impedes the motion decreasing R. The Nb–O solutions, as prepared, are all supersaturated at room temperature (equilibrium solubility at room temperature is vanishingly small.)[13,14] Upon cold working, the dislocations can help take oxygen out of solution since they can serve as sites for segregation and precipitation and provide paths for enhanced diffusion.

The resistive anomaly and its enhancement by cold work may be related to the relative orientation between the flux filaments in the mixed state and defects with that of the field.[26] On the basis of the Anderson and Kim[20] suggestion, flux line rigidity would not only increase near H_{c2} with cold work, but it would also be anisotropic. With the type of deformation used in this work, this relative orientation would be expected to be a complex one. The demagnetization coefficient itself seems to be important in the low-field region. The small change, if any, of H_{c2} upon cold work (see Fig. 9) implies, from the Abrikosov model, that the mean free path of the bulk specimen has not been altered appreciably and that possibly only a small fraction of the total solute atom segregating to defects are responsible for the large changes in the resistive characteristics observed in the mixed state. The small changes in H_{c2} with cold work accompanied by large changes in magnetization peak and hysteresis loop are consistent with earlier observations made on some lead-base alloys.[27]

For cold-worked ribbon, H_{c3} is larger than that observed on the annealed ribbon, and the ratio H_{c3}/H_{c2} equals 1.91 ($J=111$ A/cm^2) for either field direction [see Figs. 8(a) and (b)] and is expected to be even larger for smaller J. The increase in H_{c3} is anticipated if defects participate in the nucleation to the superconducting sheath as suggested by Saint-James and de Gennes. The distinction in $R(H)$ between parallel and perpendicular field orientations for the cold worked ribbon is less apparent in the region H_{c2} to H_{c3} [compare Figs. 8(a) and (b)]. These observations are in agreement with similar results recently reported by Hempstead and Kim[23] on some substitutional solid solutions of Type II superconductors.

c. Dependence of H'—Nb+0.70 at.% Oxygen (An-

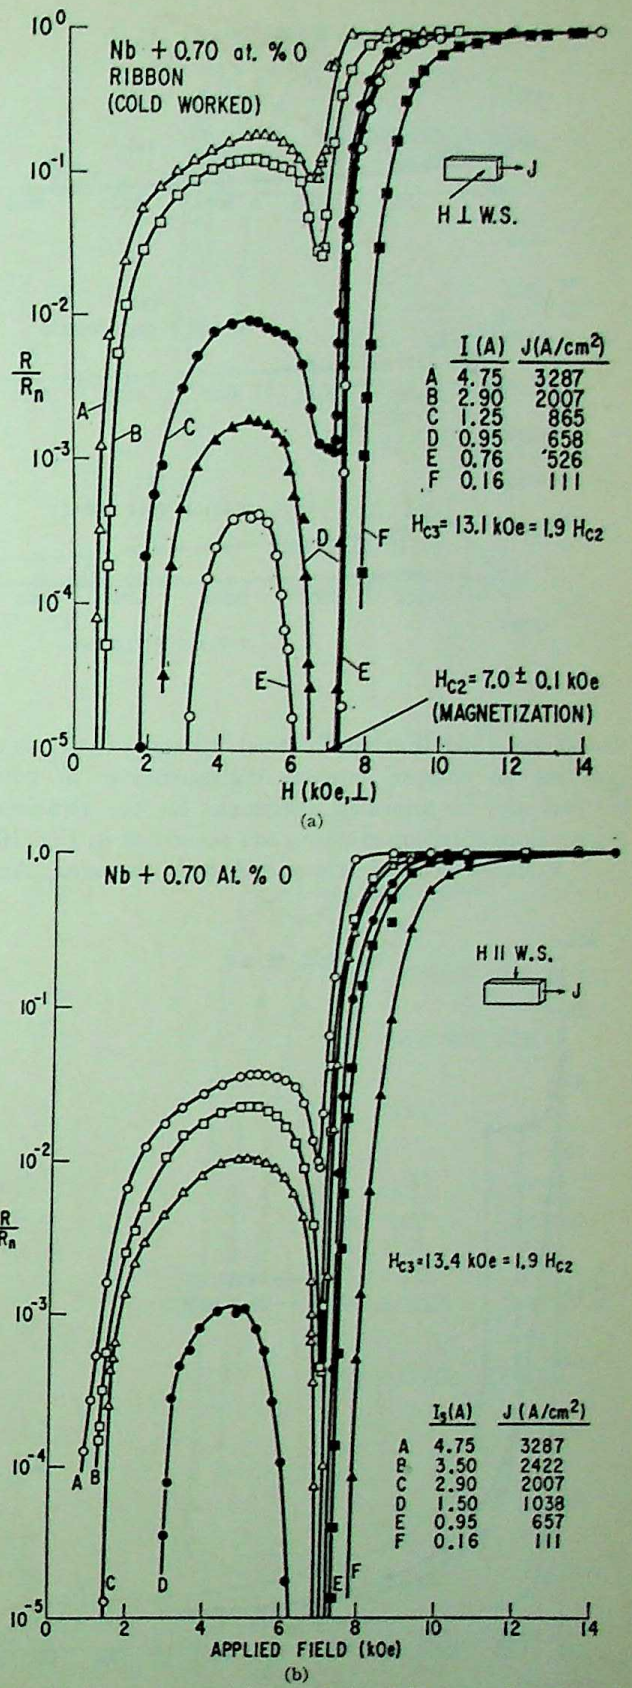

FIG. 8. The resistance characteristics R/R_n as a function of applied transverse field at 4.2°K for a cold-worked ribbon (0.032×0.007 in.) containing 0.70 at.% oxygen (a) with field perpendicular to wide side; (b) with field parallel to the wide side. H_{c3} values were evaluated at $J=111$ A/cm^2.

[26] Anisotropic effects observed in current density-field studies of some substitutional alloys [J. J. Hauser and R. G. Treuting, Phys. Chem. Solids 24, 371 (1963)] have been related to the presence of an "anisotropic filamentary structure" produced by cold rolling and not specifically to changes in the demagnetization coefficient.

nealed and Cold-Worked Ribbons). Changes in H' as a function of sample current corresponding to cold worked and to annealed specimens for the two-field orientations mentioned above are presented in Fig. 10.

d. Niobium Ribbon—Outgassed and Annealed. Annealed niobium ribbon, whose interstitial concentration is less than 5 ppm, does not exhibit the resistance anomaly when the field orientation is either perpendicular or parallel to the wide side [Figs. 11(a) and (b)]. The resistance in the mixed state below H_{c2} (see also Fig. 12 for H_{c2} evaluated from the magnetization data) is larger when the field is perpendicular to the wide side.

Above H_{c2}, the resistance is smaller when $H\|$w.s. of the ribbon. This could be due to the existence of a superconducting sheath predicted for this field orienta-

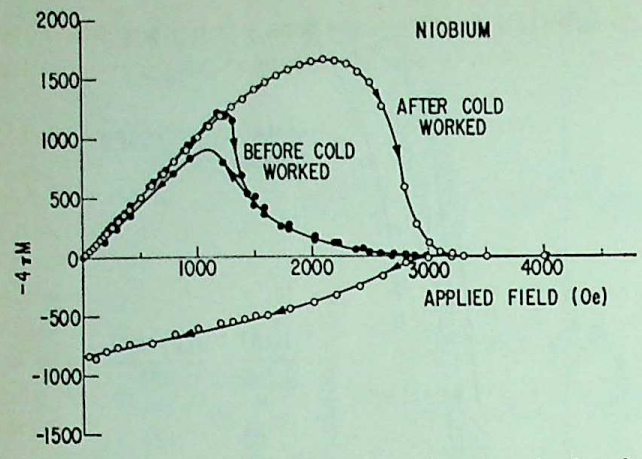

FIG. 12. The influence of cold work on the magnetization characteristics of niobium containing less than 5 ppm oxygen content for an annealed specimen (0.030-in. diam wire) and the same specimen cold worked by compression (ribbon 0.032×0.007 in.) $T=4.2°K$.

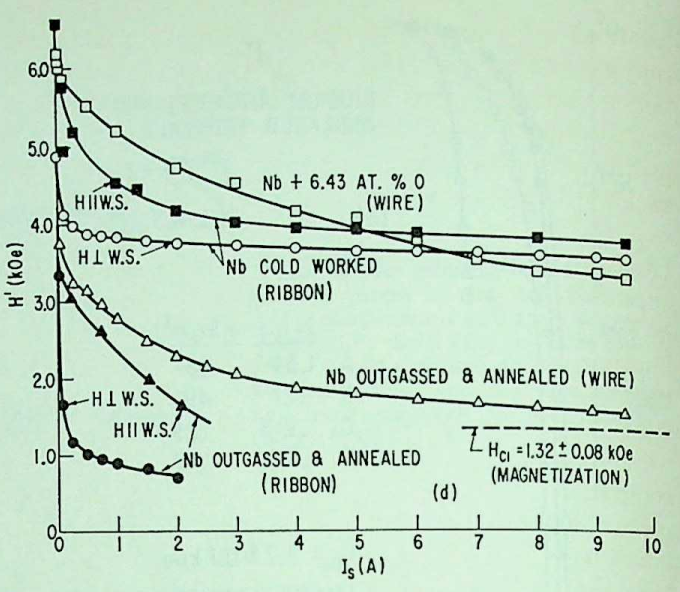

FIG. 13. The field H' at which the resistivity first appears as a function of current is summarized for Nb ribbons shown in Fig. 11. The results for Nb+6.4 at.% O (wire 0.032-in. diam) are also shown ($T=4.2°K$).

tion.[21] However, the ratio H_{c3}/H_{c2} is equal to 2.44 ($J=10$ A/cm²) which is larger than the theoretical value (see note added in proof). It is interesting to note that for pure niobium $K(=H_{c2}/\sqrt{2}H_c)$ is small compared to the values observed in the Nb–O solutions (see Table I). For $H\perp$w.s., $H_{c3}/H_{c2}=1.85$ ($J=10$ A/cm²) smaller than that observed for the parallel field orientation but still larger than the theoretical value (see note added in proof).

e. Niobium Ribbon—Outgassed and Cold Worked. For the cold-worked ribbon, whose interstitial concentration is less than 5 ppm, $R(H)$ [see Fig. 11(c) and (d)] could not be detected below H_{c2} (Fig. 11) within the limits of the measurements. Again, such results are in agreement with the notion that in the mixed state, $R(H)$ is dependent on the rate of motion of flux filaments.[16] In niobium with low interstitial concentration the dis-

locations are effective in reducing this rate. In these cold-worked ribbons H_{c3} and the ratio H_{c3}/H_{c2} are larger than the corresponding values observed in annealed ribbons. Again, the distinction between the field orientation of the resistance transition is less significant, similar to the behavior in cold-worked Nb–O ribbons.

f. H' Dependence on Field Orientation in Niobium (Ribbon). The field H' at which the resistivity first appears as a function of sample current is summarized in Fig. 13 for annealed and cold-worked niobium. The limiting value of H' at high current approaches H_{c1} for the annealed wire. For the annealed ribbon, the limiting value may be smaller than H_{c1} for either field direction, while for cold-worked ribbon it is larger than H_{c1}. For comparison, the results are also shown for niobium containing oxygen beyond the solubility limit at the temperature of introduction. H' for this material is large as in cold-worked Nb.

2. Critical Current Density—Annealed and Cold-Worked Nb and Nb+0.70 at.% Oxygen

The threshold current-field data $J_c(H)$ for cold-worked ribbons of both Nb+0.70 at.% oxygen and Nb are summarized in Figs. 14 and 15, respectively, where they are compared with the data obtained on similar but annealed ribbon specimens. The data on annealed wire specimens are also shown for comparison. The values of H_{c1} and H_{c2} were obtained from the magnetization data. Cold working increases the critical current carrying capacity in the mixed state in both materials by introducing dislocations. These play a role in stabilizing the flux filaments in the mixed state reducing $R(H)$. In Nb-O solutions, some segregation and precipitation at these dislocations may be participating in this process.

The anomolous increase in $J_c(H)$ curve (peak effect) related to the resistance minimum, discussed above, is evident in the interstitial solid solution even before cold work (Fig. 14). This is in contrast to the behavior in substitutional solid solutions where it is usually necessary to cold work the material to bring out the anomaly where it also occurs at H_{c2}.[25] However, upon cold working these interstitial solutions (ribbons), the peak is enhanced when the field is perpendicular to the wide side, always coincident with smaller J_c values in the mixed state below H_{c2}. For this same material the peak virtually disappears when the field is parallel to the flat surface, but $J_c(H)$ is now larger in the mixed state. Mendelssohn (see discussion of Ref. 25) attributes the peak effect, occurring only in the transverse field, to a more favorable relative orientation assumed by the direction of the superconducting paths and the field as H_{c2} is approached (see also Hauser and Treuting, Ref. 26). An alternative explanation is that proposed by Anderson and Kim[20] (see above). In either outgassed or cold-worked niobium no anomalous variation is evident in the $J_c(H)$ curve for either of the two field orientations used to examine the ribbons (Fig. 15).

Above H_{c2} field orientation effects on $J_c(H)$ are quite evident for both Nb+0.70 at.% oxygen and Nb after each has been annealed (see Fig. 14 and 15, respectively). The ribbon specimens show a greater ability to carry superconducting current when the field is parallel to the surface which would be expected from the Saint-James and de Gennes model.[21] In cold-

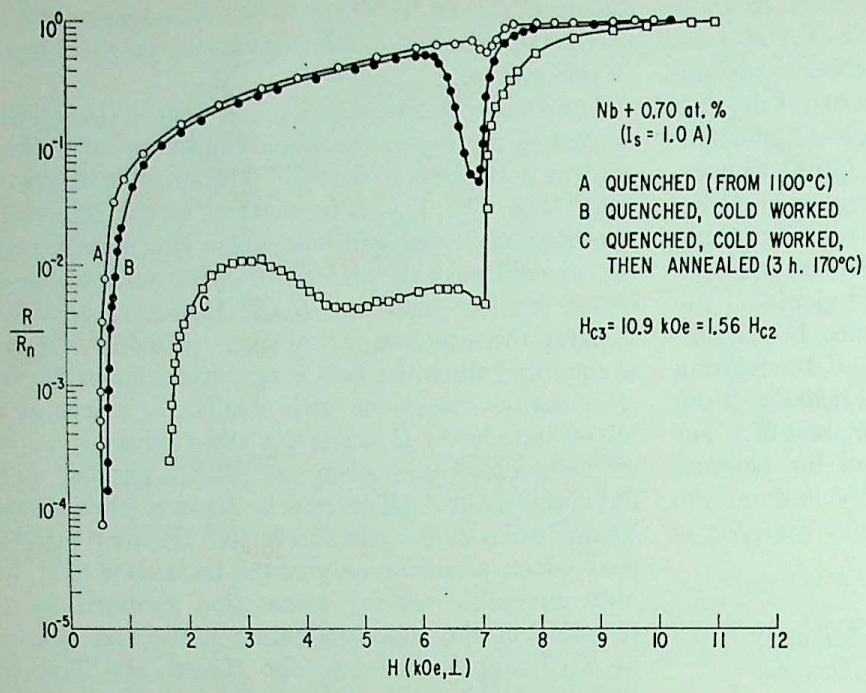

FIG. 16. Resistance characteristics R/R_n of a wire specimen (0.030-in. diam) of Nb+0.70 at.% oxygen; (a) quenched in helium exchange gas from an homogenization temperature 1100°C to room temperature; (b) quenched and cold worked by uniform compression roughly to a rectangular form approximately 0.028×0.032 in.; (c) after (b) the same wire was given a low temperature anneal, 3 h at 170°C ($J=220$ A/cm^2) ($T=4.2$°K). At this current density $H_{c3}=10.9=1.56$ H_{c2}.

worked ribbons the field orientation effect on $J_c(H)$ is smaller and for Nb ribbon it is nonexistent just below H_{c2} with the deviations going over into the opposite direction for small $J_c(H)$ values. Similar results have been observed in cold-worked Nb+3 at.% Ti.[25] These results corroborate the dependence of resistance on field orientation above H_{c2} described above. As the defect concentration increases, the distinction between $R(H)$ for $\parallel$ and $\perp$ field orientation becomes less significant.

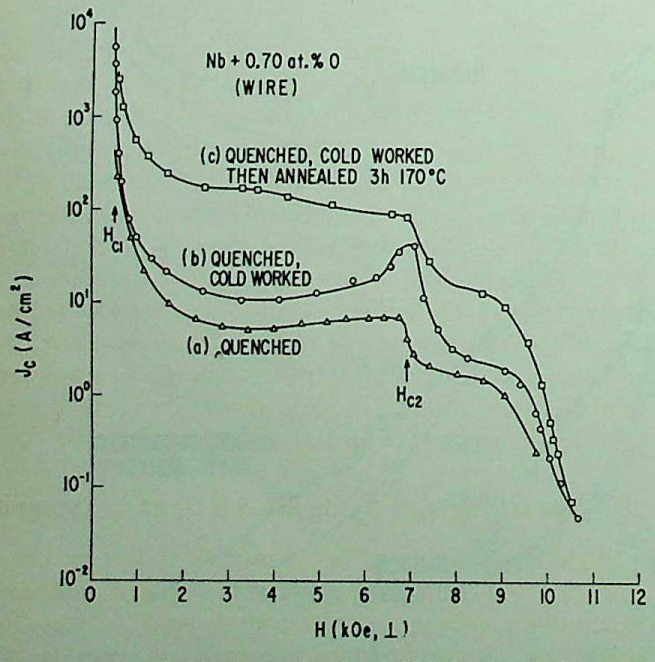

FIG. 17. Threshold current-density field behavior of the same specimens shown in Fig. 16 ($T=4.2$°K).

C. Ratio H_{c3}/H_{c2} and Oxygen Concentration in Niobium

The ratio H_{c3}/H_{c2} observed on annealed niobium wires containing various concentrations of oxygen are summarized in Table I. The values are approximately equal to those observed on ribbon samples when $H\parallel$w.s. (e.g., Nb and Nb+0.70 at.% oxygen). The ratio is largest for pure niobium which also has the lowest K. It decreases with increasing K and increasing solute concentration (see note added in proof).

D. Strain Aging Nb+0.70 at.% Oxygen

Some preliminary experiments have been carried out to vary the degree of interstitial segregation to dislocations. This was done by studying both $R(H)$ and $J_c(H)$ on a wire specimen, Nb+0.70 at.% oxygen, (a) quenched, (b) then cold worked, and (c) annealed at 170°C for 3 h in a pressure less than 1×10^{-7} mm Hg. $R(H)$ data are summarized in Fig. 16 for $J=220$ A/cm^2. The resistance in the mixed state is approximately the same before and after cold working. However, the resistance anomaly in the latter is much more pronounced. Strain aging at 170°C decreases the resistance in the mixed state by a significant amount, masking out the resistance minimum.

Above H_{c2}, the data show little, if any, change in resistance upon quenching and cold work for the current density shown. The strain aging process does, however, tend to decrease R. H_{c3}/H_{c2} for the J shown is approximately 1.4_2 for these wire specimens, both before and after quenching; increasing to approximately 1.6 after strain aging.

The process of homogenizing, cold working and low

temperature anneal on $J_c(H)$ and on the magnetization loop are summarized in Figs. 17 and 18, respectively. It is interesting to note that strain aging brings $J_c(H)$ in the mixed state up to where it was for slow-cooled specimens (compare Fig. 17 with Fig. 14). This result cannot be deduced from the corresponding magnetization loops (compare Fig. 16 with Fig. 8). It seems that structural changes brought about by cold working and by strain aging responsible for changes in $J_c(H)$ in the mixed state also cause changes above H_{c2} (see Fig. 17). The results indicate that in these specimens, if a superconducting sheath is carrying the current above H_{c2}, this sheath appears to be dependent on structural changes. Below H_{c1}, the current, carried in the penetration depth, appears to be independent of these changes.

The results, both $R(H)$ and $J_c(H)$, suggest that the anomalous peak effect, or resistance minimum, is strongest at some intermediate stage of the process of segregation and precipitation at dislocations. This conclusion is in agreement with the suggestion made earlier[25] that a solute or impurity atom is probably necessary for the appearance of the anomaly in both interstitial as well as substitutional solid solutions. The more wide-spread appearance of the anomaly in the former solutions has been attributed[25] to the far greater mobility (e.g., see Ref. 28) of the interstitial atom. This makes the interstitial solute atom segregate more easily to structural irregularities, such as dislocations.

As mentioned above, the anomaly is readily evident in niobium containing as little as 200 ppm oxygen, but not in Nb containing less then 5 ppm oxygen. Recent transmission electron microscopy studies[3] have shown that the presence of relatively small amounts of interstitial impurity (probably as little as 150 ppm) has a strong influence on the annealing structures of the metal. Dislocations were reported to act as sinks for interstitials present as interstitial atmospheres or precipitates. These would also tend to retard the rate of the recrystallization process and probably account for a wide variety of structures seen after high-temperature anneals. The appearance of the anomaly in niobium reported earlier[4-6] was probably due to the presence of small but significant amounts of interstitial impurities in the metal.

At present, the experimental results outline the dependence of the peak effect on various structural features, but a satisfactory theory has not been developed. Some proposed alternative explanations have been cited above. Hauser and Treuting[26] have suggested that anisotropy in defect structure is probably responsible for the minimum ("valley effect") in the $J_c(H)$ curve but reported no evidence for the presence of a second phase. Preliminary optical microscopy studies on some of the specimens reported here revealed precipitate particles only in cold-worked specimens (ribbons) occurring at a high density in certain areas presumably regions of greater dislocation density.

E. Quenching and Aging Nb+0.70 at.% Oxygen

Since strain aging at temperatures as low as 170°C has a marked effect on the mixed state, some additional experiments were carried out to study aging of quenched specimens. Some preliminary work on varying the homogenization or solution temperature, T_h was also

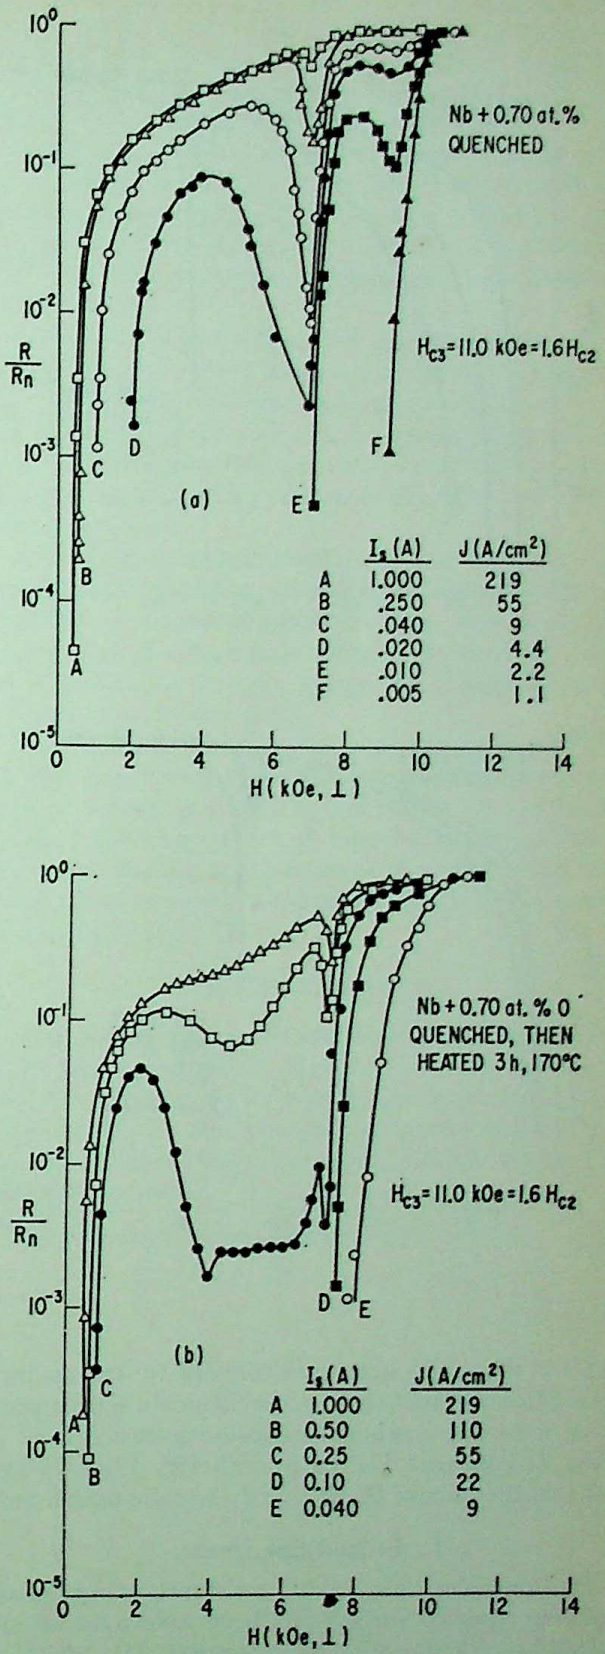
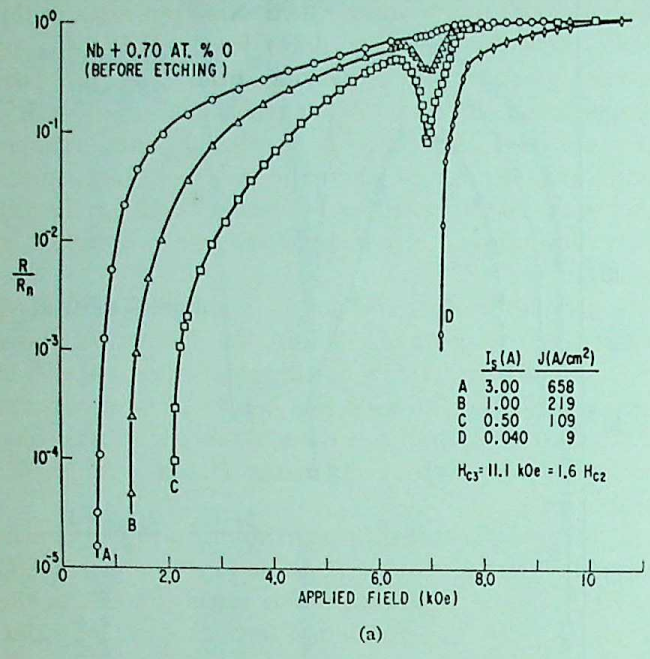
attempted. In these experiments T_h was decreased to liquid nitrogen temperature in less than 20 sec.

The resistive transition of a sample Nb+0.70 at.% oxygen quenched from $T_h=1000°C$ is shown in Fig. 19(a). When compared to a similar specimen cooled from the same temperature to room temperature at a slower rate (approximately 1 h) [Fig. 1(a)], it is evident that increasing the supersaturation, as well as the degree of disperseness of the solute, increases $R(H)$ in the mixed state. In the rapidly cooled specimen, a secondary dip is evident below the primary one occurring at H_{c2}. Upon aging at room temperature for 23 days, $R(H)$ remains essentially unaffected, although the secondary dip has disappeared [Fig. 19(b)]. A low temperature anneal, 3 h at 170°C, reveals a small decrease in $R(H)$, a reappearance of the secondary peak, and definite changes above H_{c2} at low current density [Fig. 19(c)]. Upon cold working the specimen and then annealing (3 h at 170°C), pronounced decreases are evident in the mixed state [Fig. 19(d)] similar to the strain aging results shown in Fig. 16.

In the region $H_{c2}\lesssim H\lesssim H_{c3}$ the process of quenching, aging, annealing, and strain aging decreases $R(H)$. Structural changes responsible for resistance changes in the mixed state are also responsible for changes observed above H_{c2}. The results again emphasize the importance of segregation and precipitation at dislocations on reducing resistance both in the mixed-state region as well as in the region above H_{c2}. If the superconducting sheath proposed for Type II superconductors[21] is responsible for the variations of $R(H)$ above H_{c2}, then the sheath is influenced by the segregation and precipitation at dislocations. However, for these wire specimens, H_{c3} ($J=4.4$ A/cm^2) appears to be unaffected by the various structural changes introduced. The ratio H_{c3}/H_{c2} remains constant with a value approximately equal to 1.6.

Upon increasing the homogenization temperature from 1000 to 1200°C and quenching rapidly, $R(H)$ in the mixed state tends to remain unchanged but the resistance minimum is now larger [compare Fig. 20(a) with Fig. 19(a)]. Increasing the homogenization temperature does not appear to change the ratio, $H_{c3}/H_{c2}=1.6$. However, in this case the resistive transitions at low current density reveal some distinct secondary minima between H_{c2} and H_{c3}. These secondary anomalies may be a consequence of some strains introduced in the wire upon cooling from higher T_h which provide new diffusion paths resulting in some regions having a slightly higher solute concentration with a corresponding higher H_{c2}. Another possibility is that these new variations are due to differences in structure that may exist at the surface and the interior of the niobium matrix when the metal is deformed a relatively small amount.[3] This different surface structure may also have a higher H_{c2}. Upon heating this specimen at 170°C for 3 h, the minima above H_{c2} disappear [Fig. 20(b)]. A relatively larger decrease in





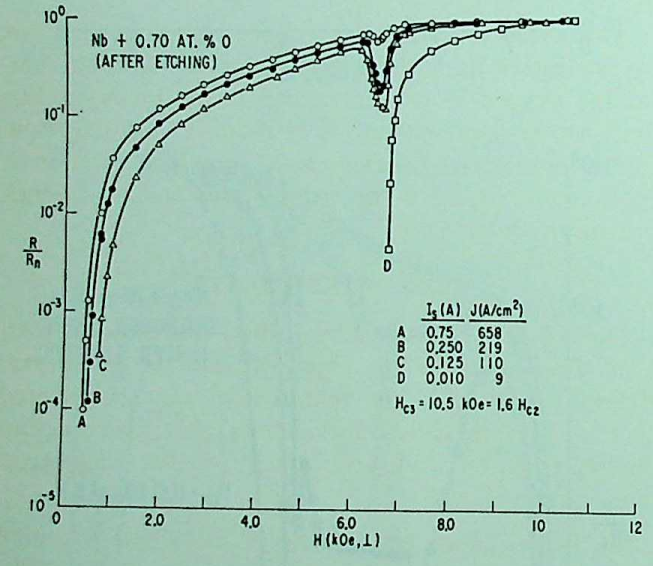


FIG. 20. The resistance characteristics R/R_n of niobium wire (0.030-in. diam) containing 0.70 at.% oxygen ($T=4.2°$K); (a) quenched in helium exchange gas from an homogenization temperature of approximately 1200°C; (b) then heated 3 h at 170°C. H_{c3} evaluated at $J=10$ A/cm^2.

(a)

(b)

(c)

FIG. 21. The resistive characteristics R/R_n as a function of applied transverse field at 4.2°K; (a) before etching specimen of niobium +0.70 at.% O, wire (0.030-in. diam); (b) after etching diameter reduced from 0.030 to 0.015 in. diam; (c) the field H' required for the initial appearance of resistance ($R/R_n \lesssim 1\times10^{-3}$) at 4.2°K as a function of specimen current I_s (amperes) before and after etching.

$R(H)$ in the mixed state, probably due to strain aging, takes place over that observed for an identical treatment given a similar specimen originally quenched from a lower T_h [compare Fig. 20(b) with Fig. 19(c)]. Note also that the value of H_{c3} or H_{c3}/H_{c2} remains unchanged.

F. Etched Specimens

The anomalous dip in the resistance transition of niobium reported earlier[6] has been known to be influenced by etching (see discussion Ref. 25). Nb–O or Nb–N specimens prepared in this work when etched with a solution consisting of 8 HNO_3, 2 H_2O, 1 HF showed only little changes in the dip characteristics even when the diameter was reduced by one half [compare Figs. 21(a) and (b)]. For example for $J=110$ A/cm², the field at which the minimum occurs, changes from 6.95 kOe before etching to 6.75 kOe after etching. This small decrease indicates only a small change in the average solute concentration. Assuming that changes in H_{c2} reflect average changes in solute concentration, the experiment could be useful in investigating diffusion of nonmetallic solutes in superconducting transition metals. After etching a significant increase in $R(H)$ in the mixed state, however, does occur, indicating less effective pinning of flux filaments. Above H_{c2}, the influence of etching on $R(H)$ is small or negligible. H_{c3}/H_{c2} remains unchanged and equal to approximately 1.6.

H' as a function of specimen current exhibits a decreasing trend upon reducing the wire diameter by etching [Fig. 21(b)]. Its limiting value may be smaller than H_{c1}.

SUMMARY

1. Oxygen and nitrogen as interstitial solutes in niobium cause the metal in transverse field to exhibit anomalous resistance minima or critical current maxima (peak effect). The anomaly is evident in niobium containing as little as 200 ppm oxygen but not in niobium whose interstitial concentration is approximately 5 ppm.

2. The anomaly appears at H_{c2}, the upper critical field of these Type II superconductors determined magnetically.

3. The anomaly is increased by cold working but decreased by strain aging (3 h, 170°C) and by rapid quenching. These results suggest that the anomaly is strongest at some intermediate state of the process of segregation and precipitation at dislocations.

4. The resistance (R) in the mixed state is decreased by exceeding the solute solubility limit, by cold working and by strain aging at 170°C; it is increased in the mixed state by introducing more interstitial solute, by quenching and by etching.

5. Small changes, if any, of H_{c2} upon cold work seem to indicate that only a small fraction of the total solute atom segregating to defects are responsible for large changes in both the resistive and critical current characteristics.

6. For an annealed ribbon of niobium containing 0.70 at.% oxygen ($K=3.6$) and for field orientation parallel to the wide side, H_{c3}/H_{c2} gradually increases for decreasing current density reaching a value 1.68 for $J=10$ A/cm^2, in good agreement with the predicted value of Saint-James and de Gennes. For transverse field, H_{c3}/H_{c2} is equal to 1.37.

7. For an annealed niobium ribbon containing less than 5 ppm oxygen ($K=1.2_4$) for field orientation parallel to the wide side, $H_{c3}/H_{c2}=2.44$ ($J=10$ A/cm^2), larger than the predicted value. The value is approximately equal to the ratio observed for an *annealed* niobium *wire* in a *transverse* field. Niobium wires in this field orientation show a dependence of H_{c3}/H_{c2} on oxygen concentration, varying from 2.44 for pure niobium ($K=1.2_4$) to 1.21 for niobium containing 1.52 at.% oxygen ($K=6.0_3$). It is possible that inhomogeneities in the sample where the surface is characterized by one K and the interior by another could artifically force this ratio in either direction (see note added in proof).

8. In cold-worked ribbons of niobium +0.70 at.% oxygen, or cold-worked niobium, the distinction, above H_{c2}, in $R(H)$ or $J_c(H)$ for field orientations parallel or perpendicular to the wide side becomes less significant than the corresponding values observed for annealed ribbons. Cold working increases H_{c3}/H_{c2} for either field orientation.

9. Structural changes brought about by rapid quenching, aging, strain aging responsible for changes in $J_c(H)$ or $R(H)$ in the mixed state also cause changes in the region $H_{c2}<H<H_{c3}$ but do not seem to affect the value of $H_{c3}=1.6\ H_{c2}$ for wire specimens (Nb+0.70 at.% oxygen) in transverse fields.

Note added in proof. Subsequent results carried out by the author on both pure niobium and niobium containing oxygen in concentrations below the solubility limit at the temperature of introducing oxygen show the value H_{c3}/H_{c2} is independent of κ. The value is in good agreement with the Saint-James and de Gennes theoretical value 1.695.[29]

(Received 7 January 1964)

The wave-packet nature of an experimental beam is discussed. The theory of wave-packet scattering is applied to wave packets with exponential time dependence scattered from resonances in both the isolated-resonance and overlapping-resonance regions. It is shown how a sequential description of scattering depends on some of the resonance parameters in the scattering amplitude. The meaning and usefulness of some experimentally possible wave-packet experiments is discussed.

1. INTRODUCTION

SCATTERING of a particle from a many-body system can be divided into two types with respect to a time interval τ and a corresponding energy interval $\delta(\sim\hbar/\tau)$.[1] If the scattering amplitude as a function of energy varies rapidly over the energy interval δ, the scattering is said to be compound scattering; if the amplitude varies slowly over this interval, we have direct scattering. τ is several orders of magnitude greater than the time it takes the incident particle to traverse a distance the size of the scatterer in free space.

In most actual scattering experiments time is not resolved. The incident beam has an energy spread. The cross section can be regarded as the weighted sum of cross sections for independent experiments, each with definite incident energy. This will be discussed in Sec. 2. It is still possible to define a time delay Δt according to the definition of Wigner,[2]

$$\Delta t = -i\hbar(d/dE)\ln S(E), \tag{1}$$

where $S(E)$ is the S-matrix element for the scattering problem. This time delay may be thought of as the time it takes for the phase of one incident wave to catch up with that of another whose energy differs from it by an infinitesimal amount, and whose phase shift in the scatterer is therefore infinitesimally different.

If the S-matrix element is divided according to some physical prescription into a rapidly and a slowly varying component, this definition is difficult to apply and it certainly does not tell us anything about each component separately. The rapidly varying component corresponds to a large Δt, that is, to particles that spend a long time on the average in the scatterer, and the slowly varying component corresponds to a small Δt, that is to particles that pass rapidly over the scatterer without significant time delay.

An experiment which measures the relative amount of direct and compound scattering has been suggested by Eisberg, Yennie, and Wilkinson.[3] The experiment also defines an energy interval which is the reciprocal of the time delay. The information is obtained from the energy spectrum of bremsstrahlung from elastic scattering of charged particles.

One would like to make a classical picture in which particles are described as being in the scatterer for varying times. To do this one must make a wave-packet argument. It will be shown in Sec. 2 that the physical situation corresponding to a meaningful wave-packet argument is necessarily a time-dependent scattering experiment.

Wave-packet arguments are made for example by Friedman and Weisskopf[4] for the case of shape-elastic and compound-elastic scattering. They show that for nonoverlapping levels (resonances) of the compound system the time delay is the average over the beam energy spread of the time delays for the individual levels. If time delay is defined according to Wigner's definition, this result is obtained at once. It has been done explicitly for example by Goldberger and Watson.[5]

If, however, time delay is defined as the average time delay in the emerging of a wave packet in a hypothetical time-dependent experiment complementary to the usual energy-dependent experiment, then the result is not so clear. The delayed wave packet would be expected to interfere with the immediately scattered wave packet from the shape elastic scattering. It is commonly stated that if the two wave packets are sufficiently short in time they will not interfere.[6] This

situation is now extreme hypothetical. It requires very good time definition in the experiment. In an actual experimental situation, time is undefined and the wave packets interfere completely. It may also be asked whether the scattering amplitude, and hence, for example, the angular distribution will not be dependent on the width of the incident wave packet, since, for short wave packets (in time), we might not expect such complete interference as for long wave packets.[7]

The question of what actually happens to a scattered wave packet has been investigated by Sasakawa.[8] He shows that for the scattering of a wave packet from an isolated resonance, the variation of the cross section with energy is characterized not by the width of the resonance but, in addition, by the width of the wave packet. In Sec. 3 we will re-derive this result using a different mathematical technique and Lorentzian wave packets. The Lorentzian shape is one shape for the energy spectrum that can be realized experimentally.

In Sec. 4 we will consider the scattering of wave packets from a system in which the compound levels overlap. This gives new insight into the optical model, which is defined for this purpose as the model for which the time delay in the complementary time-dependent experiment would be small. Our treatment is more general than Sasakawa's treatment of the same situation in a special case.

The usual definition of the optical-model scattering amplitude[9] is that it is the average of the actual scattering amplitude over an energy interval δ. In the actual situation, amplitudes for different energies are independent and it is the cross sections that are experimentally averaged. The meaning of the energy averaging process will be discussed.

In Sec. 5 we will discuss the possibility of performing scattering experiments with time definition which are complementary to the usual ones in which energy but not time is resolved. One such experiment has been suggested by the present authors.[10]

2. DEPENDENCE OF THE SCATTERING CROSS SECTION ON THE INITIAL BEAM CHARACTERISTICS

A beam consists of particles whose energy is defined within certain limits. The time of arrival of particles at a specific point may also be defined within limits by modulating the amplitude of the beam. In general the limits on the time and energy resolution of the beam are wider than those imposed by the uncertainty principle. For example some particles may be moving faster than others because they were accelerated a little more in the accelerator. The fast and slow beams could in principle be separated by a magnetic spectrometer. This type of energy uncertainty will be called classical uncertainty. On the other hand, if the time of arrival of a particle at a point is defined within a time interval τ, we cannot in principle measure its energy with a definition better than $\delta=\hbar/\tau$. This type of uncertainty will be called quantal uncertainty.

A beam with both classical and quantal uncertainty is described by a collection of wave packets with different mean wave numbers $\mathbf{k}_j$ whose position at time t is measured with respect to different initial position vectors $\mathbf{r}_i$. The value of $\mathbf{r}_i$ specifies the starting time of the wave packet at the source. One such wave packet may be written

$$\xi_{ij}(\mathbf{r},t)=(2\pi)^{-\frac{1}{2}}\int\Delta(\mathbf{k}_j,\delta;\mathbf{k})\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}_i)]d^3k. \quad (2)$$

Suppose that the number of packets of type j is given by n where

$$n=\Phi_j N. \quad (3)$$

N is the total number of wave packets.

We wish to know the cross section for a scattering experiment with an incident beam which can be described in this way. For simplicity we will consider only one spin state. We must be careful to distinguish two cases.

Case A. If the $\mathbf{r}_i$ are such that the wave packets do not overlap both before and after scattering, the scattering of each wave packet may be considered as an individual event. The total cross section is the sum of the cross sections for the scattering of each wave packet.

Case B. The $\mathbf{r}_i$ are such that the wave packets overlap. In this case different wave packets will interfere and the cross sections for individual wave packets do not add incoherently.

The mathematical description of these cases is as follows. For case A we will consider wave packets with the same value $\mathbf{r}_0$ of $\mathbf{r}_i$ and describe the beam by means of a density matrix. The density matrix at time t is

$$\rho(\mathbf{r},\mathbf{r}',t)=\sum_j\Phi_j\xi_{0j}(\mathbf{r},t)\xi_{0j}^*(\mathbf{r}',t). \quad (4)$$

According to the standard theory of wave-packet scattering,[11] ξ_{0j} is given in the case where the space occupied by the wave packet is large compared to the size of the scatterer but small compared to the distance of the detector by

$$\xi_{0j}(\mathbf{r},t)=(2\pi)^{-\frac{1}{2}}\int\Delta(\mathbf{k}_j,\delta;\mathbf{k})\exp(-i\mathbf{k}\cdot\mathbf{r}_0-iEt/\hbar)\times[\exp(ikr)/r]f(k,\Omega)d^3k. \quad (5)$$

$f(k,\Omega)$ is the scattering amplitude for scattering of particles into a detector whose angular position is Ω. $\Delta(\mathbf{k}_j,\delta;\mathbf{k})$ is a weight function which confines the wave packet to a volume in momentum space centered at $\mathbf{k}_j$ and of width δ. δ is the *quantal uncertainty*.

We will not be interested in the angular uncertainty in the wave packet, so we will write

$$\Delta(\mathbf{k}_j,\delta;\mathbf{k})=\frac{\delta(\theta_k-\theta_0)\delta(\phi_k-\phi_0)}{2\pi k^2\sin\theta_k}\Delta(k_j,\delta;k), \quad (6)$$

where (θ_k,ϕ_k), (θ_0,ϕ_0) are, respectively, the angular coordinates of $\mathbf{k}$ and $\mathbf{k}_j$, the beam direction.

The probability $P_j(t)$ of detecting a particle at time t at the detector whose position is $\mathbf{r}_d$ is, for the wave packet j,

$$P_j(t)=N_j|\xi_{0j}(\mathbf{r}_d,t)|^2r_d^2d\Omega. \quad (7)$$

This defines the normalization N_j of ξ_{0j}. The differential cross section is

$$(d\sigma/d\Omega)(\mathbf{k}_j,\delta)=v_0N_jr_d^2\int_{-\infty}^{\infty}|\xi_{0j}(\mathbf{r}_d,t)|^2dt, \quad (8)$$

where v_0 is the group velocity of the wave packet.

We may write the differential cross section for the beam described by the density matrix (4) as

$$d\sigma/d\Omega=v_0N_jr_d^2\int_{-\infty}^{\infty}\rho(\mathbf{r}_d,\mathbf{r}_d,t)dt. \quad (9)$$

Substituting from (4) and interchanging the order of summation and integration we have

$$d\sigma/d\Omega=\sum_j\Phi_jv_0N_jr_d^2\int_{-\infty}^{\infty}|\xi_{0j}(\mathbf{r}_d,t)|^2dt$$

$$=\sum_j\Phi_jd\sigma(\mathbf{k}_j,\delta)/d\Omega. \quad (10)$$

This is the result stated above for case A. Since we are only interested in the differences of the peak energies E_j for different wave packets j, we may replace the sum in (10) by an energy integral.

$$\frac{d\sigma}{d\Omega}=\int\Phi(E')\frac{d\sigma}{d\Omega}(E',\delta)dE'. \quad (11)$$

The cross section is the energy average of the cross sections for individual wave packets with different peak energies. In particular, for beams with negligible quantal uncertainty the cross section is the energy average of the cross sections for scattering events with plane wave and outgoing spherical wave boundary conditions. For this reason we will call ϕ, the width of the weight function $\Phi(E)$, the *classical uncertainty*.

We will now consider the more general case B and see under what circumstances the distinction between classical and quantal uncertainty can be maintained.

In terms of plane-wave states $\eta(\mathbf{k})$, the most general density matrix is

$$\rho(\mathbf{r},\mathbf{r}',t)=\int\int a(\mathbf{k},\mathbf{k}')\eta(\mathbf{k}')^*\eta(\mathbf{k})d^3kd^3k'. \quad (12)$$

We wish to write (12) in diagonal form in terms of wave-packet states ξ_{ij}.

$$\rho(\mathbf{r},\mathbf{r}',t)=\sum_{ij}\Phi_j\xi_{ij}\xi_{ij}^*. \quad (13)$$

We must know if this diagonalization is unique. If so, we can assign a definite classical weight factor Φ with uncertainty ϕ and a definite quantal weight factor Δ with uncertainty δ. If not, the distinction is meaningless.

In mathematical terms the question is as follows. Can the Hermitian matrix $\rho(\mathbf{r},\mathbf{r}',t)$ in (12) be diagonalized by more than one transformation of the type (2) of the basis vectors? A necessary condition for the diagonalization to be unique[12] is that the states ξ_{ij} must be orthogonal like the states η.

In fact we have

$$\int\xi_{ij}\xi_{i'j'}d^3r=(2\pi)^{-3}\int\Delta(\mathbf{k}_j,\delta;\mathbf{k})\Delta(\mathbf{k}_{j'},\delta;\mathbf{k})^*$$

$$\times\exp[-i\mathbf{k}\cdot(\mathbf{r}_i-\mathbf{r}_{i'})]d^3k. \quad (14)$$

The overlap integral in (14) is approximately zero if the wave packets have sufficiently different starting times given by $\mathbf{r}_i$ and $\mathbf{r}_{i'}$ because of the rapid oscillations of the integrand.

In case A the wave packets have a definite physical significance. The quantal uncertainty leads to alterations in the usual cross sections, as will be shown in the succeeding sections. In case B the wave packets may be regarded as mathematical aids to the visualization of the scattering process. For example we can decompose a plane wave into an infinite number of overlapping wave packets and then follow the propagation of one of these packets. Nevertheless, this would be without physical significance because the scattering amplitudes for all the packets must be recombined to obtain the cross section.

The vital point is that the wave packets both before and after the scattering must be quite distinct in space and time for the quantal uncertainty to have any physical significance.

3. SCATTERING OF A WAVE PACKET FROM A RESONANCE

In the usual theory of scattering it is assumed that $f(k,\Omega)$ in Eq. (5) varies much more slowly with energy than the wave packet amplitude factor $\Delta(\mathbf{k}_j,\delta;\mathbf{k})$; that is, that the quantal uncertainty δ is negligible in com-

[12] U. Fano, Rev. Mod. Phys. 29, 74 (1957).

parison with the width of the energy fluctuations of the scattering amplitude.

We will consider the case where δ is comparable with Γ_s, the width of the compound state $|s\rangle$ of the system comprising the incident particle and the scatterer whose energy ϵ_s is near the central energy E_0 of the wave packet. In the present section we will suppose that only one state $|s\rangle$ contributes to the scattering amplitude at the energies covered by the wave packet.[12a] We will be interested in only one wave packet $j=0$.

Since we are interested in the energy rather than the momentum of the wave packet, it will be convenient to transform the integral in (5) to an energy integral. The transformation is trivial when k is proportional to E as it is for photons ($E=\hbar ck$).

For our discussion of hypothetical time-dependent experiments with finite-mass particles complementary to the usual energy-dependent experiments, we can make the assumption, following Friedman and Weisskopf,[4] that the source and detector are sufficiently close to the scatterer for wave packet spreading to be negligible. We will neglect the final term in the following expansion of E:

$$E=\frac{\hbar^2}{2m}[2\mathbf{k}\cdot\mathbf{k}_0-k_0^2+|\mathbf{k}-\mathbf{k}_0|^2]. \tag{15}$$

Photon wave packets do not spread for practical purposes.

We must now consider a particular form for the energy amplitude factor $\Delta(E_0,\delta;E)$ corresponding to $\Delta(\mathbf{k}_0,\delta;\mathbf{k})$. Wave packets made by electronic means (see Sec. 5) would have a rise and decay function in time that is something like an exponential. We will therefore consider a wave packet that has an exponential rise and decay, with time constant $\hbar/\delta$. We will assume that the beam is switched off as soon as it has attained full strength, so that there is no time for which the beam intensity is constant. The experimental difficulty is in fast switching on and off. Since we want as short a packet in time as possible, this is then the most realistic form. The energy amplitude factor for this form is

$$\Delta(E_0,\delta;E)=\frac{\delta/2\pi}{(E-E_0)^2+\delta^2/4}. \tag{16}$$

One shape of wave packet is already available in nature. This is the photon wave packet from the decay of a level $|s\rangle$ of a many-body system. It has a half-exponential time spectrum. If the moment of excitation of the level is taken as zero time, then the probability of emission of a photon decays exponentially with a time constant $\hbar/\Gamma_s$. In this case we have

$$\Delta(E_0,\Gamma_s;E)=\frac{i/2\pi}{E-E_0+i\Gamma_s/2}. \tag{17}$$

We will use the form (16) for most of our discussion.

For the scattering amplitude we will use the expansion of Siegert, Humblet, and Rosenfeld,[13]

$$f[k(E),\theta]=\frac{1}{2i}\sum_l(2l+1)P_l(\cos\theta)\times\left[C_l(E)+\sum_n\frac{R_{ln}}{E-\epsilon_{ln}+\frac{1}{2}i\Gamma_{ln}}\right]. \tag{18}$$

The nonresonant term $C_l(E)$ varies slowly with energy. The splitting off of this term is not unique and can be made according to some physical prescription. Equation (5) now becomes

$$\xi(\mathbf{r},t)=\frac{K}{2\pi}\sum_l(2l+1)P_l(\cos\theta)\int_0^\infty\frac{\delta}{(E-E_\delta)(E-\bar{E}_\delta)}\times\exp(iEX)\left[C_l(E)+\sum_n\frac{R_{ln}}{E-\epsilon_{ln}+i\Gamma_{ln}/2}\right]dE, \tag{19}$$

where

$$X=[(r_0+r)/v_0-t]/\hbar,\quad E_\delta=E_0-i\delta/2,\quad K\bar{K}=1/8\pi r^2. \tag{20}$$

We have dropped the subscripts on $\xi(\mathbf{r},t)$ because we are now interested only in one particular wave packet.

The integral in (19) is now in a convenient form for contour integration if we make the approximation of extending the lower limit to $-\infty$, thus neglecting the contributions of bound states.

We will first consider the scattering of the wave packet according to the nonresonant scattering amplitude $C_l(E)$ whose variation with energy can be neglected over the energies of the wave packet. Performing the integration in Eq. (19) we find

$$\begin{aligned}\xi(\mathbf{r},t)&=K\sum_l(2l+1)P_l(\cos\theta)C_l(E)\exp(i\bar{E}_\delta X),\quad X>0\\&=K\sum_l(2l+1)P_l(\cos\theta)C_l(E)\times\exp(iE_\delta X),\quad X<0.\end{aligned} \tag{21}$$

The wave packet is centered at $X=0$, i.e., at

$$t=(r_0+r)/v_0. \tag{22}$$

Hence, the nonresonant packet is propagated without time delay. The time spectrum of $|\xi(\mathbf{r},t)|^2$ is an exponential rise and fall, $\exp(-\delta t/\hbar)$.

The differential cross section is, according to Eq. (8),

$$d\sigma/d\Omega=\tfrac{1}{4}|\textstyle\sum_l(2l+1)P_l(\cos\theta)C_l(E)|^2. \tag{23}$$

Thus, the differential cross section for nonresonant (potential) scattering is independent of the quantal uncertainty δ and identical with that for a normal beam in which δ is negligible.

[12a] *Note added in proof*. The decay of a single resonance has been investigated by R. G. Newton, Ann. Phys. (N. Y.) 14, 333 (1961).

We will now consider the scattering from an isolated resonance state $|s\rangle$. Taking one term of the sum in (18) we have for the integral in (18)

$$I=\int_{-\infty}^{\infty}\frac{\delta/2\pi}{(E-E_\delta)(E-\bar{E}_\delta)}\frac{R_s}{E-E_s}\exp(iEX)dE, \quad (24)$$

where

$$E_s=\epsilon_s-i\Gamma_s/2. \quad (25)$$

Integration round an infinite semicircle in the upper half plane gives

$$I=\frac{R_s}{\bar{E}_\delta-E_s}\exp(i\bar{E}_\delta X), \quad X>0. \quad (26)$$

This means that the leading edge of the wave packet, that is, the part for times greater than $(r_0+r)/v_0$, is propagated with the same shape as it originally had, but, of course, with a different magnitude. The propagation of the trailing edge (the tail) of the wave packet is given by integration round a contour in the lower half plane

$$I=\frac{R_s}{E_\delta-E_s}\exp(iE_\delta X)$$
$$-i\delta\frac{R_s}{(E_s-E_\delta)(E_s-\bar{E}_\delta)}\exp(iE_sX), \quad X<0. \quad (27)$$

The time spectrum given by $|I|^2$ is a decaying oscillatory function. In particular, if the time width of the wave packet is much less than the decay constant of the state $|s\rangle$, the time spectrum of the tail has the shape $\exp(-\Gamma_s t/\hbar)$. This corresponds to exciting the resonance suddenly and watching it decay with its natural time constant.

The differential cross section is

$$\frac{d\sigma}{d\Omega}=\frac{R_s\bar{R}_s[(E-\epsilon_s)^2\Gamma_s/2+(\Gamma_s+\delta)^2(\Gamma_s/2+\delta)/4]}{2\Gamma_s[(E-\epsilon_s)^2+(\Gamma_s+\delta)^2/4]^2}. \quad (28)$$

This reduces to the Breit-Wigner form for very small quantal uncertainty δ. The most significant thing is that the width of the energy spectrum is $\Gamma_s+\delta$. Note also that the differential cross section for scattering from a single resonance is reduced in magnitude for large quantal uncertainty. For large δ, $d\sigma/d\Omega$ is of order $1/\delta$.

In view of the arguments often made about the noninterference of potential and resonance scattering for large δ, it is interesting to consider the interference term. Denote the additional cross section due to the interference of potential and resonant scattering by $d\sigma_I/d\Omega$. It arises from the last term in the splitting of the scattering into potential and resonant parts

$$|\xi(\mathbf{r},t)|^2=|\xi_P(\mathbf{r},t)|^2+|\xi_R(\mathbf{r},t)|^2$$
$$+2\,\mathrm{Re}\bar{\xi}_P(\mathbf{r},t)\xi_R(\mathbf{r},t). \quad (29)$$

Taking only the s state for simplicity of notation,

$$\frac{d\sigma_I}{d\Omega}=\tfrac{1}{2}\left\{R_s\bar{C}_0(E)\frac{(E-\epsilon_s)+i(\Gamma_s/2+\delta)}{[(E-\epsilon_s)+i(\Gamma_s+\delta)^2/4]^2}\right\}, \quad (30)$$

$$=\tfrac{1}{2}\,\mathrm{Re}[R_s\bar{C}_0(E)]\frac{(E-\epsilon_s)(E-\epsilon_s)^2+(\Gamma_s+\delta)(\Gamma_s+3\delta)/4}{[(E-\epsilon_s)^2+(\Gamma_s+\delta)^2/4]^2}$$
$$+\tfrac{1}{2}\,\mathrm{Im}[R_s\bar{C}_0(E)]\frac{(E-\epsilon_s)^2\Gamma_s/2+(\Gamma_s+\delta)^2(\Gamma_s+2\delta)/8}{(E-\epsilon_s)^2+(\Gamma_s+\delta)^2/4}. \quad (31)$$

The coefficient of $\mathrm{Im}[R_s\bar{C}_0(E)]$ is of order $1/\delta$ for large δ. Hence the interference term in the cross section does become smaller for larger δ, that is for better defined wave packets in time, but so also does the resonant scattering term, both being of order $1/\delta$. The potential scattering term is not affected by δ.

4. SCATTERING FROM MANY LEVELS AND THE OPTICAL MODEL

We will now consider the energy region where, for a given channel, the resonances in the scattering amplitude are such that the average width is greater than the average spacing, so that many levels contribute at each energy over the energy spread of the wave packet.

The levels in this region are defined by some plausible model such as has been discussed by Brown[9] for nuclei. Their widths are of the order of 1 eV, so that the corresponding lifetime, 10^{-15} sec, is too short for a practical wave-packet experiment. However, it is interesting to consider a hypothetical wave-packet experiment in order to give a proper quantum mechanical sequential description of the passage of a particle through the scatterer, when we know the S-matrix element for the scattering.

This gives us another way of looking at the optical and direct interaction models. We will restrict ourselves to elastic scattering for simplicity. The optical model has been considered in two ways, each with a different

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

starting point. The first way starts with a Schrödinger equation. The optical-model Hamiltonian is shown to be an approximation to the many-body Hamiltonian. The second way is independent of any Hamiltonian assumption and starts with the scattering amplitude. The average over some energy interval I of the scattering amplitude S is shown to be capable of being calculated from an optical-model Hamiltonian. The average cross section is split into two terms.

$$\langle\sigma\rangle=|\langle S\rangle|^2+\langle|S-\langle S\rangle|^2\rangle. \tag{32}$$

The first term is the optical-model or shape elastic cross section. The second term is the fluctuation or compound elastic cross section.

A third, classical, definition of the optical model is sometimes given. The optical-model cross section is the cross section for propagation without time delay while the compound elastic cross section is the remainder.

It is not clear that the last two definitions are equivalent. The splitting in Eq. (32) requires a definition of the averaging procedure. Some authors, for example Brown,[9] have gone to much trouble to discuss the averaging procedure. Brown's argument is essentially a wave-packet argument since it uses an average of the scattering amplitude over an energy interval I. We have seen in Sec. 2 that for a beam without significant time resolution it is the cross sections, not the amplitudes, that are averaged.

Another condition for the validity of this definition of the optical model is required. The average over amplitudes must be nearly equivalent to the average over cross sections. This means that the compound elastic cross section must be very small compared with the optical model cross section.

A quantal statement of the third definition of the optical model must be given by a detailed wave-packet description. It is quite conceivable that the scattering amplitudes for certain problems are such that a large proportion of the cross section is due to time-delayed wave packets. This question will be discussed in detail by one of us (LRD) in a subsequent publication.

At present we will just consider the propagation of the wave packet in general and show how it leads to a large proportion of immediate propagation in the case $\Gamma\gg D$ where Γ is the average level width and D is the average spacing.

Considering only the S wave for simplicity and omitting the potential scattering term, Eq. (19) gives for the time dependence of the trailing edge of the wave packet

$$\xi(\mathbf{r},t)=K\exp(iEX)\sum_n\frac{R_n}{E-\epsilon_n+i(\Gamma_n-\delta)/2}\Bigg\{\exp(\delta X/2)-\frac{i\delta\exp(\Gamma_n X/2)\exp i(\epsilon_n-E)X}{E-\epsilon_n+i(\Gamma_n+\delta)/2}\Bigg\}. \tag{33}$$

The second term in the bracket is the one containing the properties of the scattering amplitude rather than the wave packet. Each level n contributes an exponential tail to the amplitude with a time-delay constant $\hbar/\Gamma_n$. However, this contribution is multiplied by a phase factor $\exp[i(\epsilon_n-E)X]$ which gives a partial cancellation of the tails when the packets from different levels are superposed.

If the level widths Γ_n are much greater than the average spacing D, the factor ϵ_n-E can be large so that the phase factor oscillates rapidly. In this case the phases of the contributions from different levels tend to be random so the tails cancel out giving a large proportion of propagation without time delay.

Thus the sequential description of scattering gives the same result as the usual energy description. The optical model is valid when $\Gamma\gg D$.

The dependence of (33) on the magnitude of the quantal uncertainty δ is also interesting. As δ is increased the magnitude of the contribution from each level to the scattered packet decreases. However more levels contribute significantly to the sum. If the phases of the residues R_n are random the magnitude of the scattered packet will decrease rapidly with increasing δ. If they are correlated, the magnitude will decrease less rapidly. The range of the correlations between levels can be determined in principle by varying δ. This will be discussed in detail in a subsequent publication.

5. POSSIBLE WAVE-PACKET EXPERIMENTS

The condition for a time-dependent scattering experiment is that the experimental definition of time must be accurate in comparison with the characteristic time of the scattering amplitude. That is, we must have δ not much less than Γ.

Experimental definition of time is at present possible for times as short as about 10^{-10} sec. Typical nuclear values for $\hbar/\Gamma$ are 10^{-15} sec, so wave-packet experiments cannot be performed with nuclei except in special cases. These cases are metastable states which can have lifetimes as long as 10^{-7} sec.

One experiment has actually been done using the Mössbauer effect with the 14-keV γ ray from Fe^{57}, which has a decay constant of 10^{-7} sec, by Holland, Lynch, Perlow, and Hanna.[14] The time spectrum of the incident wave packet was defined by using as zero time the time of formation of the 14-keV state, which was defined by the time of emission of the 128-keV γ ray (a fast decay) from the next highest state in the γ-ray cascade from the decay of Co^{57}. The wave packet has an exponential time spectrum with $\delta=\hbar/10^{-7}$ sec. This wave packet was scattered resonantly from an Fe^{57} target. The time spectrum of the final state and the increased width of the absorption line were both

[14] R. E. Holland, F. J. Lynch, G. J. Perlow, and S. S. Hanna, Phys. Rev. Letters 4, 181 (1960); F. J. Lynch, R. E. Holland, and M. Hamermesh, Phys. Rev. 120, 513 (1960).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

observed. In this case $\delta=\Gamma_s$. The width of the wave packet in this experiment is of course fixed. By looking at the scattering at times less than 10^{-7} sec, Holland *et al.* were able to observe greater widths, but for these cases the shape of the incident packet was not defined. The spectrum of total elapsed time gives only an upper limit to the time width of the incident wave packet because it is not known if the delay occurred in the source or the scatterer.

The Mössbauer effect is, of course, a wave-packet scattering experiment in which the absorption cross section is measured. If we do not define time but merely observe the cross section we lose the wave-packet property, that is the quantal uncertainty. The cross section is obtained using Eq. (17) to define the energy amplitude factor of the wave packet.

$$\frac{d\sigma}{d\Omega}=\frac{R_s^2}{2\Gamma_s}\frac{1}{(E_0-E_s)^2+\Gamma_s^2}. \tag{34}$$

Thus, we have the well-known result that the linewidth in the Mössbauer effect is twice the width of the level, assuming all the nuclei in the target are capable of absorbing resonantly.

Defining the starting time of the excitation of the metastable state puts a quantal uncertainty into the beam equal to Γ_s. The method of Holland *et al.* defines the starting time with a minimum tolerance equal to the lifetime of the next highest state in the γ-ray cascade. This is shorter than the experimental time resolution, which is itself much shorter than $\hbar/\Gamma_s$.

One way of varying the time width of the wave packet would be to vary the resolution with which the starting time is measured. It is possible by this method to decrease δ, but not to increase it.

A better experimental way of varying the wave-packet width in the Mössbauer effect has been suggested by the present authors. A third resonant absorber is introduced between the source and the target. This absorber is accelerated in a very short time (10^{-9} sec) to a speed sufficient to shift the resonance so that the incident beam is no longer absorbed and can hit the target. It is then slowed down again quickly so that the time duration of the pulse is of the order of 10^{-9} sec. This method would produce approximately the exponential wave packet [Eq. (16)] that we have used in the calculations of Secs. 3 and 4. It is experimentally just possible to achieve the requisite acceleration by using a very thin foil of Fe^{57} as one plate of a parallel plate condenser in a vacuum which is charged first with one sign and then with the opposite sign by an rf pulse. However, the acceleration may be achieved more easily using a piezo-electric crystal. Another possibility is to use the Stark effect to shift the resonance. This requires a tightly bound dielectric crystal containing nuclei with a metastable state.

Wave-packet experiments in the atomic energy region may be interesting. An absorber of laser material placed in a laser beam and moved for a short time as suggested above would produce wave packets of laser intensity. The quantal uncertainty would be much greater than that of a beam from a pulsed laser, whose quantal uncertainty can be no greater than the width of the laser state.

All such experiments observe only the scattering of a wave packet from a single resonance with a trivial angular distribution. Overlapping resonances, even in atoms, would probably have widths of the order of a few tenths of an electron volt. Wave-packet experiments in this region with $\delta\sim\Gamma$ would require time lengths of 10^{-15} sec which seems impossible at present. The possibility of doing time-dependent electron-scattering experiments from atoms is not experimentally remote and would be interesting.

Using laser wave packets, it may be possible to observe the changes in angular distribution due to the interference of potential and resonant scattering as the quantal uncertainty is changed. The potential scattering could be obtained by diffraction of laser light round a small crystal of laser material.

Coherence Properties of Blackbody Radiation.* I. Correlation Tensors of the Classical Field

C. L. MEHTA AND E. WOLF
Department of Physics and Astronomy, University of Rochester, Rochester, New York
(Received 9 December 1963)

This paper is concerned with the extension of some recently reported results, especially those of Bourret (1960), relating to coherence properties of blackbody radiation. An explicit expression for the complex electric correlation tensor $\mathcal{E}_{ij}(\mathbf{r},\tau)$ of blackbody radiation is derived, and on the basis of it spatial coherence ($\tau=0$) is discussed in detail. The behavior of diagonal as well as nondiagonal components is illustrated by contour diagrams. In particular, it is found that the nondiagonal components of the correlation tensor, even though being zero for zero-space separation ($\mathbf{r}=0$), acquire, in general, nonvanishing values when $\mathbf{r}\neq 0$. The magnetic and mixed correlation tensors are also discussed.

1. INTRODUCTION

IT is a common notion that the most incoherent radiation is blackbody radiation in an equilibrium enclosure. Recent researches[1–4] have shown that even in this type of radiation there is coherence in a sufficiently small space-time region. Bourret[1] has derived expressions for the second-order electric correlation tensor of blackbody radiation, using techniques analogous to those employed in the theory of isotropic turbulence of an incompressible fluid. Such a correlation tensor describes the correlation between the Cartesian components (denoted by subscripts i, j) of the electric field $\mathbf{E}^{(r)}(\mathbf{r},t)$ at two space-time points $\mathbf{r}_1$ and $\mathbf{r}_2$, at time instants t_1 and t_2,

$$\mathcal{E}_{ij}^{(r)}(\mathbf{r}_1,\mathbf{r}_2,t_1,t_2)=\langle E_i^{(r)}(\mathbf{r}_1,t_1)E_j^{(r)}(\mathbf{r}_2,t_2)\rangle, \quad (1.1)$$

where sharp brackets denote the time average:

$$\langle E_i^{(r)}(\mathbf{r}_1,t_1)E_j^{(r)}(\mathbf{r}_2,t_2)\rangle = \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} E_i^{(r)}(\mathbf{r}_1,t_1+t)E_j^{(r)}(\mathbf{r}_2,t_2+t)dt. \quad (1.2)$$

Sarfatt[3] rederived some of Bourret's results using quantum mechanical density matrix techniques.

The components of the correlation tensors discussed by Bourret and Sarfatt are real functions of space and time. However, numerous recent researches on coherence properties of light have shown that an appropriate measure of coherence is provided by certain complex rather than real correlation functions (cf. Ref. 5), and this is also supported by recent investigations of Glauber[6] based on quantum field theoretical calculations. (See also Sudarshan,[7a,b] Wolf,[8] Mandel, Sudarshan and Wolf,[9] Mandel.[10]) The appropriate complex electric correlation tensor $\mathcal{E}_{ij}(\mathbf{r}_1,\mathbf{r}_2,t_1,t_2)$ may be derived from the real correlation tensor defined by (1.1), by using the concept of an analytic signal.[11,5] Assuming the field to be stationary in time, so that $\mathcal{E}_{ij}^{(r)}$ depends on t_1 and t_2 only through the time difference $\tau=t_1-t_2$, the complex correlation tensor is given by[12]

$$\mathcal{E}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=2[\mathcal{E}_{ij}^{(r)}(\mathbf{r}_1,\mathbf{r}_2,\tau)+i\mathcal{E}_{ij}^{(i)}(\mathbf{r}_1,\mathbf{r}_2,\tau)], \quad (1.3)$$

where

$$\mathcal{E}_{ij}^{(i)}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\frac{1}{\pi}P\int_{-\infty}^{\infty}\frac{\mathcal{E}_{ij}^{(r)}(\mathbf{r}_1,\mathbf{r}_2,\tau')}{\tau'-\tau}d\tau' \quad (1.4)$$

is the Hilbert transform of $\mathcal{E}_{ij}^{(r)}(\mathbf{r}_1,\mathbf{r}_2,\tau)$ and P denotes the Cauchy principal value at $\tau'=\tau$.

Bourret and Sarfatt have restricted their discussion of the tensor to certain special cases only, namely, to those characterizing temporal correlation ($\mathbf{r}_1=\mathbf{r}_2$) and lateral and longitudinal spatial correlation ($\tau=0$). Their results do not provide information about the nondiagonal components of the correlation tensor, though, in principle such information could be obtained with the help of their formulas.

[12] An alternative, but equivalent, definition of the complex correlation tensor, which will be needed later is as follows: With the real field $\mathbf{E}^{(r)}(\mathbf{r},t)$ we associate the complex analytic signal $\mathbf{E}(\mathbf{r},t)$, i.e.,

$$\mathbf{E}(\mathbf{r},t)=\mathbf{E}^{(r)}(\mathbf{r},t)+i\mathbf{E}^{(i)}(\mathbf{r},t),$$

where $\mathbf{E}^{(i)}$ is the Hilbert transform of $\mathbf{E}^{(r)}$. Then the complex correlation tensor $\mathcal{E}_{ij}$ may be expressed in the form

$$\mathcal{E}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\langle E_i(\mathbf{r}_1,t+\tau)E_j^*(\mathbf{r}_2,t)\rangle. \quad (1.3a)$$

The equivalence of the definitions (1.3) and (1.3a) is shown in Ref. 17, pp. 464–466, where also a certain mathematical refinement connected with questions of convergence is discussed.

In this paper an explicit expression for the complete second-order complex electric correlation tensor of blackbody radiation is derived and a number of diagrams are obtained, which show the behavior of the elements of this tensor. The magnetic and the mixed second-order complex correlation tensors are also discussed.

In paper II (Ref. 13) the electromagnetic correlation tensors defined on the basis of quantum field theory will be evaluated for blackbody radiation and will be compared with the corresponding tensors defined in the present paper on the basis of semiclassical theory. Higher order correlation tensors will also be considered in paper II.

2. EXPLICIT EXPRESSION FOR THE SECOND-ORDER COMPLEX ELECTRIC CORRELATION TENSOR OF BLACKBODY RADIATION

In this section a new expression for the normalized complex electric correlation tensor $\gamma_{ij}(\mathbf{r},\tau)$ of blackbody radiation will be derived. For any stationary field, the normalized correlation tensor is defined by the formula

$$\gamma_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\frac{\mathcal{E}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)}{[\mathcal{E}_{ii}(\mathbf{r}_1,\mathbf{r}_1,0)]^{1/2}[\mathcal{E}_{jj}(\mathbf{r}_2,\mathbf{r}_2,0)]^{1/2}}, \quad (2.1)$$

where $\mathcal{E}_{ij}$ is the correlation function (1.3). The normalization ensures[5] that $0\leq|\gamma_{ij}|\leq 1$. In the case of blackbody radiation in a cavity whose linear dimensions are large compared with the mean wavelength of the radiation, the field is isotropic and $\mathcal{E}_{ij}$ and γ_{ij} depend effectively on $\mathbf{r}_1$ and $\mathbf{r}_2$ through the difference $\mathbf{r}=\mathbf{r}_1-\mathbf{r}_2$ only.

An integral expression for $\gamma_{ij}(\mathbf{r},\tau)$ for blackbody radiation has been obtained by Kano and Wolf.[2] They showed that

$$\gamma_{ij}(\mathbf{r},\tau)=\frac{45\alpha^4}{8\pi^5}\int\frac{k^2\delta_{ij}-k_ik_j}{k\{\exp(\alpha k)-1\}}\times\exp\{i(\mathbf{k}\cdot\mathbf{r}-kc\tau)\}d^3k, \quad (2.2)$$

where

$$\alpha=\hbar c/KT, \quad (2.3)$$

c being the vacuum velocity of light, $\hbar$ the Planck's constant divided by 2π, K the Boltzmann constant and T the absolute temperature. The integration in (2.2) is taken over the whole $\mathbf{k}$ space. The normalization constant in (2.1) has the value

$$[\mathcal{E}_{ii}(\mathbf{r}_1,\mathbf{r}_1,0)]^{1/2}[\mathcal{E}_{jj}(\mathbf{r}_1,\mathbf{r}_2,0)]^{1/2}\equiv\mathcal{E}_{ii}(0,0,0) \quad \text{(no summation)}$$

$$=\frac{64}{45}\frac{\pi^6K^4T^4}{(hc)^3}. \quad (2.4)$$

Equation (2.2) may be written as

$$\gamma_{ij}(\mathbf{r},\tau)=\frac{45\alpha^4}{8\pi^5}(\partial_i\partial_j-\delta_{ij}\nabla^2)\int\frac{\exp\{i(\mathbf{k}\cdot\mathbf{r}-kc\tau)\}}{k(e^{\alpha k}-1)}d^3k, \quad (2.5)$$

where $\partial_i\equiv\partial/\partial r_i$. Using spherical polar coordinates for $\mathbf{k}$, with the polar axis along the direction of $\mathbf{r}$, we obtain

$$\gamma_{ij}(\mathbf{r},\tau)=\frac{45\alpha^4}{8\pi^5}(\partial_i\partial_j-\delta_{ij}\nabla^2)\int_0^\infty kdk\frac{e^{-ikc\tau}}{e^{\alpha k}-1}\int_0^\pi e^{ikr\cos\theta}\sin\theta d\theta\int_0^{2\pi}d\phi$$

$$=\frac{45\alpha^4}{2\pi^4}(\partial_i\partial_j-\delta_{ij}\nabla^2)\frac{1}{r}\int_0^\infty\frac{\sin kr\,e^{-ikc\tau}}{e^{\alpha k}-1}dk. \quad (2.6)$$

The last integral can be written as

$$\sum_{n=1}^\infty\frac{1}{2i}\int_0^\infty\{e^{ik(r-c\tau)}-e^{-ik(r+c\tau)}\}e^{-n\alpha k}dk=\frac{1}{2i}\sum_{n=1}^\infty\left\{\frac{1}{n\alpha-i(r-c\tau)}-\frac{1}{n\alpha+i(r+c\tau)}\right\},$$

so that γ_{ij} may be expressed in the form

$$\gamma_{ij}(\mathbf{r},\tau)=\frac{45\alpha^4}{2\pi^4}(\partial_i\partial_j-\delta_{ij}\nabla^2)\sum_{n=1}^\infty\frac{1}{(n\alpha+ic\tau)^2+r^2}.$$

Carrying out the differentiation on the right-hand side, we finally obtain the following expression for the normalized complex electric correlation tensor of blackbody radiation:

$$\gamma_{ij}(\mathbf{r},\tau)=\frac{90\alpha^4}{\pi^4}\sum_{n=1}^\infty\left\{\frac{\delta_{ij}}{\{(n\alpha+ic\tau)^2+r^2\}^2}+2\frac{r_ir_j-r^2\delta_{ij}}{\{(n\alpha+ic\tau)^2+r^2\}^3}\right\}, \quad (2.7)$$

where r_i, r_j are the components of the vector $\mathbf{r}$ with respect to i and j axes, respectively.

3. TEMPORAL COHERENCE

Restricting ourselves first to the case $\mathbf{r}=0$, Eq. (2.7) gives the following expression for the normalized tensor that characterizes *temporal coherence*:

$$\gamma_{ij}(0,\tau)=(90/\pi^4)\zeta(4,1+ic\tau/\alpha)\delta_{ij}, \quad (3.1)$$

where $\zeta(s,a)$ is the generalized Riemann zeta function[14]

[13] C. L. Mehta and E. Wolf, following paper, Phys. Rev. 134, A1149 (1964).

[14] E. T. Whittaker and G. N. Watson, *A Course of Modern Analysis* (Cambridge University Press, New York, 1958), p. 265; (also Dover Publications, Inc., New York, 1962), p. 265.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

defined by

$$\zeta(s,a)=\sum_{n=0}^{\infty}\frac{1}{(n+a)^s}. \tag{3.2}$$

It should be noted that the tensor $\gamma_{ij}(0,\tau)$ is *diagonal.*

The expression (3.1) for the temporal degree of coherence of blackbody radiation is identical with the expression derived by Kano and Wolf[2] and discussed in detail by them [cf. Eq. (11) of their paper]. In particular they gave diagrams showing the behavior of the modulus and the argument of $\gamma_{ii}(0,\tau)$ as function of τ.

4. SPATIAL COHERENCE

Setting $\tau=0$ in Eq. (2.7) we obtain the following expression for the normalized tensor that characterizes *spatial coherence*:

$$\gamma_{ij}(\mathbf{r},0)=\frac{90}{\pi^4}\sum_{n=1}^{\infty}\left\{\frac{\delta_{ij}}{(n^2+r^2/\alpha^2)^2}+\frac{2}{\alpha^2}\frac{r_ir_j-\delta_{ij}r^2}{(n^2+r^2/\alpha^2)^3}\right\}. \tag{4.1}$$

It is seen from this expression that $\gamma_{ij}(\mathbf{r},0)$ is real. The series on the right-hand side of (4.1) may easily be summed with the help of the result[15]

$$\sum_{n=1}^{\infty}\frac{1}{n^2+a^2}=\frac{\pi}{2a}L(\pi a), \tag{4.2}$$

where $L(x)$ is the Langevin function

$$L(x)=\coth x-1/x. \tag{4.3}$$

Successive term by term differentiation of (4.2) gives

$$\sum_{n=1}^{\infty}\frac{1}{(n^2+a^2)^2}=-\frac{1}{2a}\frac{d}{da}\left\{\frac{\pi}{2a}L(\pi a)\right\}, \tag{4.4}$$

$$\sum_{n=1}^{\infty}\frac{1}{(n^2+a^2)^3}=\frac{\pi}{16a}\frac{d}{da}\left\{\frac{1}{a}\frac{d}{da}\left[\frac{1}{a}L(\pi a)\right]\right\}. \tag{4.5}$$

If we set

$$\mathbf{r}=(\alpha/\pi)\mathbf{r}', \tag{4.6}$$

so that r' represents the separation of points in the cavity in units of α/π, (4.1) gives, with the help of (4.4), (4.5), and (4.3),

$$\gamma_{ij}(\mathbf{r}')\equiv\gamma_{ij}(\mathbf{r},0)=\frac{45}{4r'^4}\left[A(r')\delta_{ij}+B(r')\frac{r_i'r_j'}{r'^2}\right], \tag{4.7}$$

where

$$\left.\begin{aligned}A(r')&=-r'\coth r'-r'^2\operatorname{csch}^2r'\\&\quad-2r'^3\operatorname{csch}^2r'\coth r'+4,\\B(r')&=3r'\coth r'+3r'^2\operatorname{csch}^2r'\\&\quad+2r'^3\operatorname{csch}^2r'\coth r'-8.\end{aligned}\right\} \tag{4.8}$$

[15] L. B. W. Jolley, *Summation of Series* (Dover Publications, New York, 1961), p. 22, Series number 124.

Equation (4.7) is valid for all $\mathbf{r}'$ but is not suitable for computing $\gamma_{ij}(\mathbf{r}')$ when r' is small. For small r', however, we directly obtain from (4.1), on expanding in powers of r',

$$\gamma_{ij}(\mathbf{r}')\equiv\gamma_{ij}(\mathbf{r},0)=\delta_{ij}\left[1-\frac{8}{21}r'^2+\frac{3}{35}r'^4+\cdots\right]+\frac{r_i'r_j'}{r'^2}\left[\frac{4}{21}r'^2-\frac{2}{35}r'^4+\cdots\right]\quad(r'<\pi). \tag{4.9}$$

If we set $i=j=x$ in (4.7) and (4.9) and take $\mathbf{r}'$ in the direction of the x axis, we obtain the following expressions for the *longitudinal coherence function* $\gamma_{xx}^{\text{long}}$:

$$\gamma_{xx}^{\text{long}}(\mathbf{r}')=\frac{45}{2r'^4}(r'\coth r'+r'^2\operatorname{csch}^2r'-2)\qquad(r'<\infty), \tag{4.10a}$$

$$=1-\frac{4}{21}r'^2+\frac{1}{35}r'^4+\cdots\qquad(r'<\pi), \tag{4.10b}$$

where $r'=x'=\pi x/\alpha$.

On the other hand, if $\mathbf{r}'$ is chosen perpendicular to the x axis, then we obtain from (4.7) the following expression for *lateral coherence function* γ_{xx}^{lat}:

$$\gamma_{xx}^{\text{lat}}(\mathbf{r}')=\frac{45}{4r'^4}[4-r'\coth r'-r'^2\operatorname{csch}^2r'-2r'^3\coth r'\operatorname{csch}^2r'],\qquad(r'<\infty), \tag{4.11a}$$

$$=1-\frac{8}{21}r'^2+\frac{3}{35}r'^4+\cdots\qquad(r'<\pi), \tag{4.11b}$$

where $r'=(y'^2+z'^2)^{1/2}=\pi(y^2+z^2)^{1/2}/\alpha$.

Expressions for $\gamma_{yy}^{\text{long}}$, γ_{yy}^{lat}, $\gamma_{zz}^{\text{long}}$, and γ_{zz}^{lat} are, of course, strictly similar. The expressions (4.10a)–(4.11b) are in agreement with those derived by Bourret.[1]

Next we will examine the three-dimensional distribution of $\gamma_{ij}(\mathbf{r}')$. First, let us consider a particular nondiagonal component, say the xy component. From (4.7) and (4.9), we obtain

$$\gamma_{xy}(\mathbf{r}')=\frac{45x'y'}{4r'^6}[3r'\coth r'+3r'^2\operatorname{csch}^2r'+2r'^3\operatorname{csch}^2r'\coth r'-8]\qquad(r'<\infty), \tag{4.12a}$$

$$\sim\frac{4}{21}x'y'+\cdots\qquad(r'<\pi). \tag{4.12b}$$

In Fig. 1, the xy section of the surface of constant $\gamma_{xy}(\mathbf{r}')$ is shown. $\gamma_{xy}(\mathbf{r}')$ is positive in the I and III quadrants and negative in II and IV quadrants, attaining peak values at four points, denoted by letters A_1, A_2, B_1, B_2 in the figure, at distances $r=\alpha r'/\pi\sim2.3\alpha/\pi$ from

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

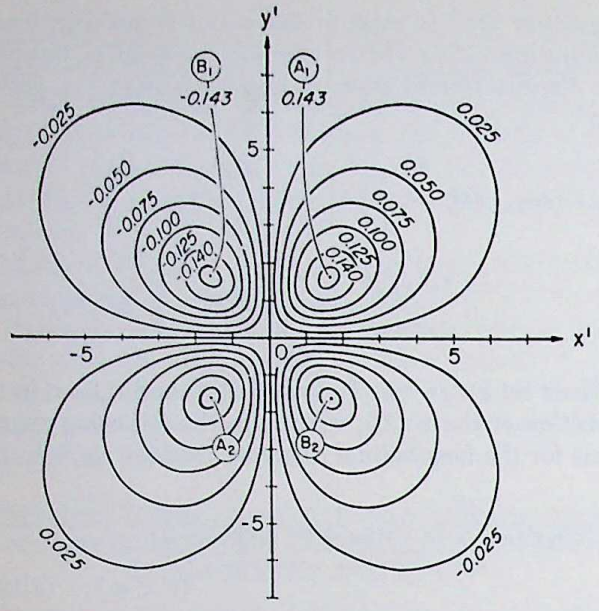

FIG. 1. Contours of $\gamma_{xy}(\mathbf{r}')$ in the xy plane. $\gamma_{xy}(\mathbf{r}')\equiv\gamma_{xy}(\mathbf{r},0)=(1/N)\,\mathcal{E}_{xy}(\mathbf{r},0)$; $N=\mathcal{E}_{xx}(0,0)=(64/45)(\pi^2/hc)^3K^4T^4$; $r=\alpha r'/\pi$; $\alpha=\hbar c/KT$.

the origin, this distance being of the order of half the mean wavelength of the radiation.[4] The variation of $\gamma_{xy}(\mathbf{r}')$ along the line $x=y$, $z=0$, is shown in Fig. 2. In Fig. 3, the contours of the surfaces $\gamma_{xy}(\mathbf{r}')$ in the plane $x=y$ are shown.

We see that the surfaces, $\gamma_{xy}(\mathbf{r}')=$constant, are closed surfaces, having the lines $x=\pm y$, $z=0$ as axes of symmetry. (Thus, any plane section through one of these lines will be symmetrical about that line.) Near the origin these surfaces are more or less hyperbolic cylinders as seen from Eq. (4.12b). The surfaces for peak values $|\gamma_{xy}(\mathbf{r}')|\simeq 0.143$, shrink to the four points A_1, A_2, B_1, B_2. The behavior of the other nondiagonal components, such as $\gamma_{yz}(\mathbf{r}')$ or $\gamma_{zx}(\mathbf{r}')$ is, of course, strictly similar.

For diagonal components of the correlation tensor, it is again sufficient to consider one of them, e.g., that

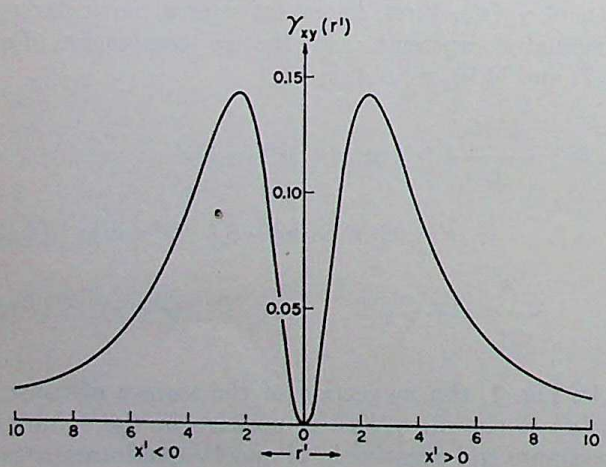

FIG. 2. Variation of $\gamma_{xy}(\mathbf{r}')$ with $\mathbf{r}'$, when $\mathbf{r}'$ is in the direction $x=y$ in the plane $z=0$.

corresponding to $i=j=z$. We have from (4.7) and (4.9)

$$\gamma_{zz}(r')=\frac{45}{4r'^4}\{(-r'\coth r'-r'^2\operatorname{csch}^2 r'-2r'^3\coth r'\operatorname{csch}^2 r'+4)+\frac{z'^2}{r'^2}(3r'\coth r'+3r'^2\operatorname{csch}^2 r'+2r'^3\coth r'\operatorname{csch}^2 r'-8)\},\quad (r'<\infty),\quad (4.13a)$$

$$=1-\frac{8}{21}r'^2+\frac{4}{21}z'^2+\cdots\qquad (r'<\pi).\quad (4.13b)$$

Eq. (4.13b) shows that for small spatial separation r' of the two points, the surfaces $\gamma_{zz}(\mathbf{r}')=$constant are the ellipsoids

$$2(x^2+y^2)+z^2=\text{constant}.$$

The contours of $\gamma_{zz}(\mathbf{r}')$ in the xy plane are circles, shown in Fig. 4. Figure 5 shows the contours in the

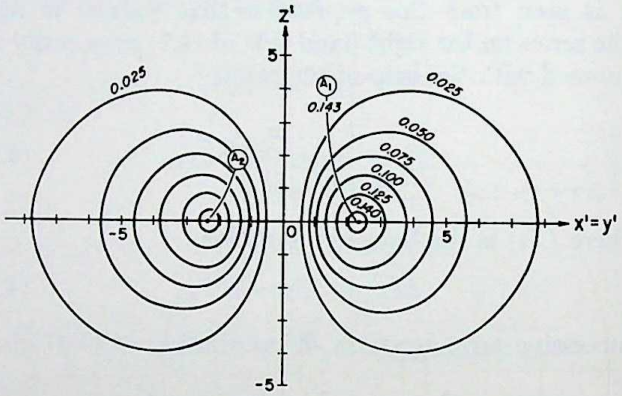

FIG. 3. Contours of $\gamma_{xy}(\mathbf{r}')$ in the plane $x=y$.

yz plane. The actual surfaces $\gamma_{zz}(\mathbf{r}')=$constant are just the surfaces of revolution generated by rotating these contours (Fig. 5) about the z axis.

For the sake of completeness the variation of γ_{zz} along the z axis (longitudinal coherence) and along the x axis (lateral coherence) are given in Figs. 6 and 7, respectively. These two curves are in agreement with Figs. 3 and 4 of Bourret.[1]

In the present section we have discussed only the case of spatial coherence characterized by $\gamma_{ij}(\mathbf{r}')\equiv\gamma_{ij}(\mathbf{r},0)$. In the general case, when τ is arbitrary, i.e., when the correlation is characterized by $\gamma_{ij}(\mathbf{r},\tau)$ rather than by $\gamma_{ij}(\mathbf{r},0)$, the value of the correlation, for any particular separation r of the two points may, of course, become appreciably larger (or smaller), provided τ is chosen appropriately.

5. THE SECOND-ORDER COMPLEX MAGNETIC AND MIXED CORRELATION TENSORS OF BLACKBODY RADIATION

Besides coherence effects associated with the electric field, coherence effects involving the magnetic field are

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

also of interest. Some of these effects are characterized by a magnetic correlation tensor $\mathcal{H}_{ij}$ and mixed correlation tensors $\mathcal{G}_{ij}$ and $\tilde{\mathcal{G}}_{ij}$, introduced in earlier publications.[16a,b] These tensors may be defined in a similar manner as the electric correlation tensor $\mathcal{E}_{ij}$. Assuming again that the field is stationary we have, in analogy with (1.3a),

$$\mathcal{H}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\langle H_i(\mathbf{r}_1,t+\tau)H_j^*(\mathbf{r}_2,t)\rangle\,, \tag{5.1}$$

$$\mathcal{G}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\langle E_i(\mathbf{r}_1,t+\tau)H_j^*(\mathbf{r}_2,t)\rangle\,, \tag{5.2}$$

$$\tilde{\mathcal{G}}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\langle H_i(\mathbf{r}_1,t+\tau)E_j^*(\mathbf{r}_2,t)\rangle\,, \tag{5.3}$$

where, as before $\mathbf{E}(\mathbf{r},t)$ denotes the complex analytic signal associated with the real electric field $\mathbf{E}^{(r)}(\mathbf{r},t)$ and $\mathbf{H}(\mathbf{r},t)$ denotes the complex analytic signal associated with the real magnetic field $\mathbf{H}^{(r)}(\mathbf{r},t)$.

We note that the tensors $\mathcal{G}$ and $\tilde{\mathcal{G}}$ are related as follows:

$$\tilde{\mathcal{G}}_{ij}(\mathbf{r}_1,\mathbf{r}_2,\tau)=\mathcal{G}_{ji}^*(\mathbf{r}_2,\,\mathbf{r}_1,\,-\tau)\,. \tag{5.4}$$

It is known[16a,17] that *in vacuo* each of these tensors

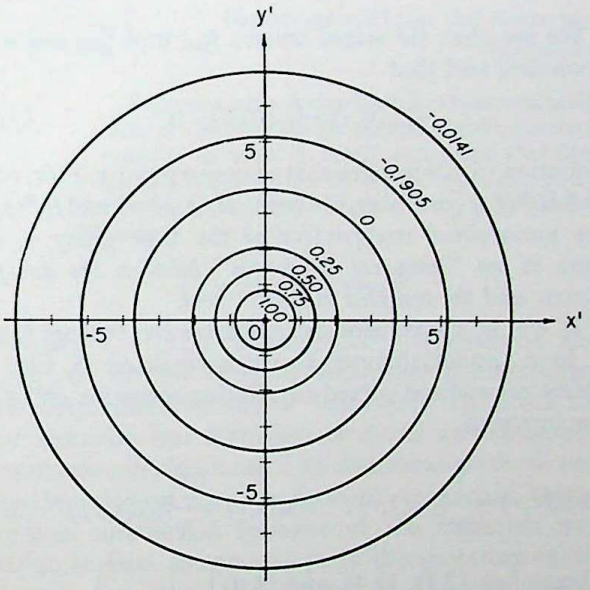

FIG. 4. Contours of $\gamma_{zz}(\mathbf{r}')$ in the xy plane.

satisfies two homogeneous wave equations. Also, that the tensors are not independent but satisfy differential equations of the form[16b,17]

$$\epsilon_{jkl}\partial_k{}^1\mathcal{E}_{lm}+\frac{1}{c}\frac{\partial}{\partial\tau}\tilde{\mathcal{G}}_{jm}=0\,, \tag{5.5}$$

$$\epsilon_{jkl}\partial_k{}^1\mathcal{G}_{lm}+\frac{1}{c}\frac{\partial}{\partial\tau}\mathcal{H}_{jm}=0\,, \tag{5.6}$$

[16] E. Wolf, (a) Nuovo Cimento **12**, 884 (1954); (b) in *Proceedings of the Symposium on Astronomical Optics*, edited by Z. Kopal (North-Holland Publishing Company, Amsterdam 1956), p. 177.
[17] P. Roman and E. Wolf, Nuovo Cimento **17**, 462 (1960).

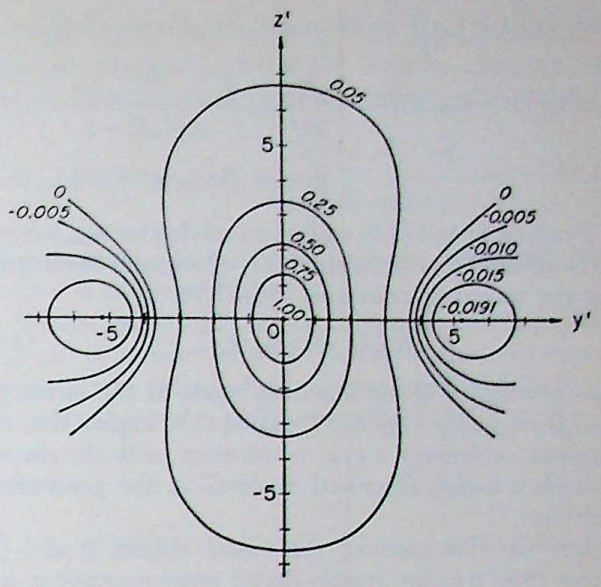

FIG. 5. Contours of $\gamma_{zz}(\mathbf{r}')$ in the yz plane. (Surfaces of constant γ_{zz} are the surfaces generated by rotation of these curves about the z axis).

etc., where $\partial_k{}^1$ $(k=x,\,y,\,z)$ are the components of the gradient, taken with respect to the coordinates of $\mathbf{r}_1$ and ϵ_{jkl} is the completely antisymmetric unit tensor of Levi-Civita. There is a similar set of differential equations involving the components $\partial_k{}^2$ of the gradient, taken with respect to the coordinates of $\mathbf{r}_2$. In the case of blackbody radiation, one has, on account of isotropy $\partial_k{}^1=-\partial_k{}^2=\partial/\partial r_k$ where r_k are components of the vector $\mathbf{r}=\mathbf{r}_1-\mathbf{r}_2$.

Now for blackbody radiation we have from (2.1)–(2.4)

$$\mathcal{E}_{ij}(\mathbf{r},\tau)=\frac{hc}{2\pi^3}\int\frac{k^2\delta_{ij}-k_ik_j}{k\{\exp(\alpha k)-1\}}\times\exp\{i(\mathbf{k}\cdot\mathbf{r}-kc\tau)\}d^3k\,. \tag{5.7}$$

On substituting from (5.7) into (5.5) and solving the resulting equation for $\tilde{\mathcal{G}}$, subject to the boundary condi-

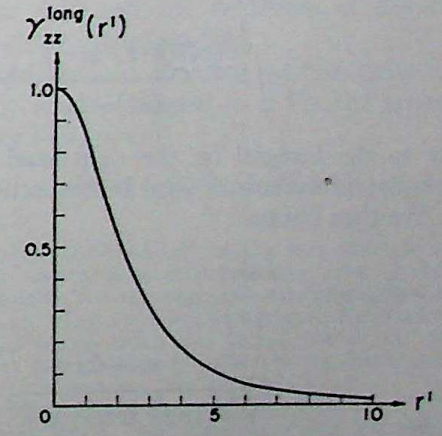

FIG. 6. Longitudinal coherence. Variation of $\gamma_{zz}{}^{\text{long}}(\mathbf{r}')\equiv\gamma_{zz}(\mathbf{r},0)$, with r', when $\mathbf{r}'$ is along the z axis.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tion $\tilde{\mathcal{G}}_{jm}(\mathbf{r},\infty)=0$, we obtain, if we also use (5.4),

$$\tilde{\mathcal{G}}_{jm}(\mathbf{r},\tau)=-\mathcal{G}_{jm}(\mathbf{r},\tau)=-\frac{hc}{2\pi^3}\epsilon_{jmk}\int\frac{k_k}{\exp(\alpha k)-1}\times\exp\{i(\mathbf{k}\cdot\mathbf{r}-kc\tau)\}d^3k\,. \quad (5.8)$$

From (5.8) and (5.6) we find on solving for $\mathfrak{C}_{jm}$ subject to the boundary condition $\mathfrak{C}_{lm}(\mathbf{r},\infty)=0$, and on comparing the resulting expression with (5.7),

$$\mathfrak{C}_{jm}(\mathbf{r},\tau)\equiv\mathcal{E}_{jm}(\mathbf{r},\tau)\,. \quad (5.9)$$

In deriving (5.9) use has been made of the identity[18] $\epsilon_{jkl}\epsilon_{mk'j}=\delta_{km}\delta_{lk'}-\delta_{kk'}\delta_{lm}$. Relation (5.9) implies that *the magnetic coherency tensor is identical with the electric coherency tensor*, discussed in detail in the preceeding sections.

Let us now consider the mixed tensors $\mathcal{G}$ and $\tilde{\mathcal{G}}$. From (5.8) we may readily derive series expansions for

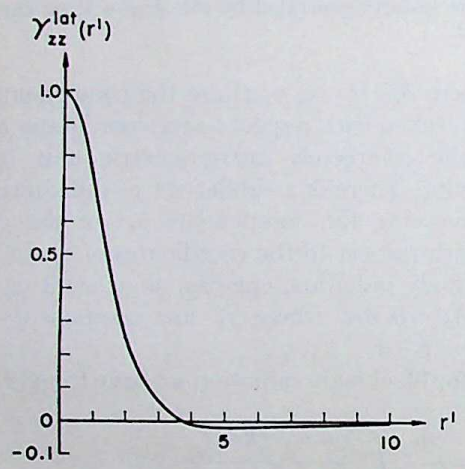

FIG. 7. Lateral coherence. Variation of $\gamma_{zz}{}^{lat}(\mathbf{r}')\equiv\gamma_{zz}(\mathbf{r},0)$, with r', when $\mathbf{r}'$ is along the x axis.

these tensors. For this purpose, we first rewrite (5.8) in the form

$$\mathcal{G}_{jm}(\mathbf{r},\tau)=-\tilde{\mathcal{G}}_{jm}(\mathbf{r},\tau)=\frac{hc}{2\pi^3}\epsilon_{jmk}(-i\partial_k)\int\frac{\exp\{i(\mathbf{k}\cdot\mathbf{r}-kc\tau)\}}{\exp(\alpha k)-1}d^3k \quad (5.10)$$

and apply to the integral on the right-hand side of (5.10) a similar procedure as used in connection with Eq. (2.5). We then obtain

$$\mathcal{G}_{jm}(\mathbf{r},\tau)=-\tilde{\mathcal{G}}_{jm}(\mathbf{r},\tau)=i\frac{16hc}{\pi^2}\epsilon_{jmk}r_k\times\sum_{n=1}^{\infty}\frac{n\alpha+ic\tau}{[(n\alpha+ic\tau)^2+r^2]^3}\,. \quad (5.11)$$

[18] H. Jeffreys and B. S. Jeffreys, *Methods of Mathematical Physics* (Cambridge University Press, New York, 1950), 2nd ed., p. 73.

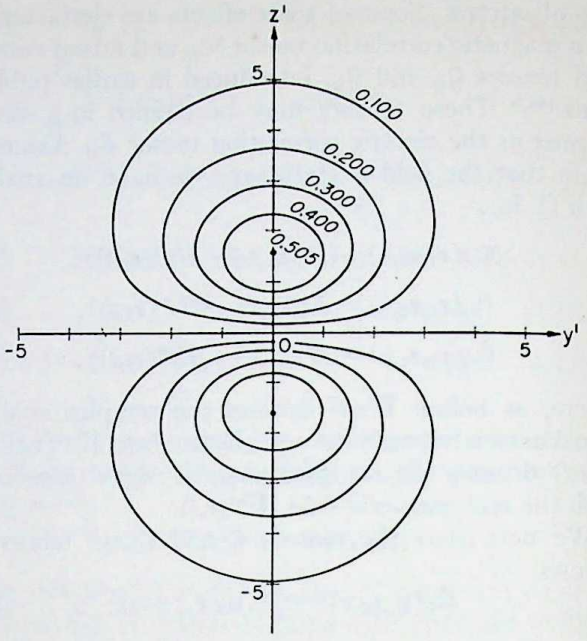

FIG. 8. Contours of $|\sigma_{xy}(\mathbf{r}')|\equiv|\sigma_{xy}(\mathbf{r},0)|$ in the yz plane. $\sigma_{xy}(\mathbf{r}')\equiv\sigma_{xy}(\mathbf{r},0)=(1/N)\mathcal{G}_{xy}(\mathbf{r},0)$; $N=(64/45)(\pi^2/hc)^3K^4T^4$.

We see that *the mixed tensors* $\mathcal{G}_{jm}$ and $\tilde{\mathcal{G}}_{jm}$ *are antisymmetric* and that

$$\mathcal{G}_{jm}(0,\tau)=\tilde{\mathcal{G}}_{jm}(0,\tau)=0\,. \quad (5.12)$$

Equation (5.12) implies that at every point $\mathbf{r}$, $E_i(\mathbf{r},t+\tau)$ and $H_j^*(\mathbf{r},t)$ [and also, of course $H_i(\mathbf{r},t+\tau)$ and $E_j^*(\mathbf{r},t)$] are *uncorrelated* irrespective of the time delay τ, i.e., *there is no "temporal coherence" between the complex electric and the complex magnetic field.*

It will be convenient to normalize the tensors $\mathcal{G}$ and $\tilde{\mathcal{G}}$ in a similar manner as we normalized $\mathcal{E}$, i.e., we define normalized mixed correlation tensors σ and $\tilde{\sigma}$ by the formulas

$$\sigma_{jm}(\mathbf{r},\tau)=\frac{1}{N}\mathcal{G}_{jm}(\mathbf{r},\tau)\,,\quad \tilde{\sigma}_{jm}(\mathbf{r},\tau)=\frac{1}{N}\tilde{\mathcal{G}}_{jm}(\mathbf{r},\tau)\,, \quad (5.13)$$

where [cf. (2.1), (2.4), and (5.9)]

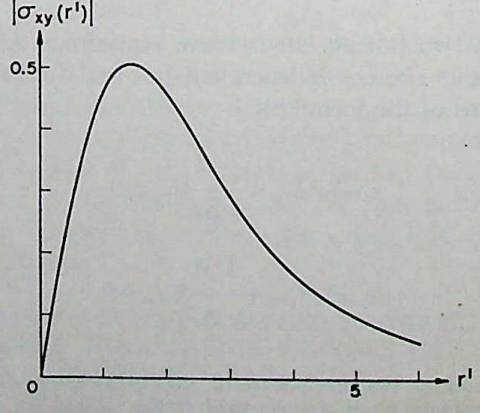

FIG. 9. Variation of $|\sigma_{xy}(\mathbf{r}')|$ with r', when $\mathbf{r}'$ is along the z axis.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$N=[\mathcal{E}_{jj}(0,0)]^{1/2}[\mathcal{H}_{jj}(0,0)]^{1/2}$$
$$=\mathcal{E}_{jj}(0,0)=\mathcal{H}_{jj}(0,0)=\frac{64\,\pi^6K^4T^4}{45\,(hc)^3}. \quad (5.14)$$

It follows from (5.13), (5.14), and (5.11) that σ and $\tilde{\sigma}$ may be represented in series form as follows:

$$\sigma_{jm}(\mathbf{r},\tau)=-\tilde{\sigma}_{jm}(\mathbf{r},\tau)=i\frac{180\alpha^4}{\pi^4}r_k\epsilon_{jmk}$$
$$\times\sum_{n=1}^{\infty}\frac{n\alpha+ic\tau}{[(n\alpha+ic\tau)^2+r^2]^3}. \quad (5.15)$$

Here the constant α is given by (2.3) as before.

From (5.15) we obtain in the special case $\tau=0$ (*spatial coherence* between the electric and magnetic fields), for typical nondiagonal elements of σ and $\tilde{\sigma}$,

$$\sigma_{xy}(\mathbf{r},0)=-\tilde{\sigma}_{xy}(\mathbf{r},0)=i\frac{180}{\alpha\pi^4}z\sum_{n=1}^{\infty}\frac{n}{(n^2+r^2/\alpha^2)^3}. \quad (5.16)$$

The diagonal elements are, of course, identically zero, since σ is antisymmetric.

We see from (5.16) that in the plane $z=0$ (xy plane) $\sigma_{xy}(\mathbf{r},0)$ is identically zero. In Fig. 8 the contours of $|\sigma_{xy}(\mathbf{r},0)|$ in the yz plane are presented and in Fig. 9 the variation of $|\sigma_{xy}(\mathbf{r},0)|$ along the z axis is shown.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Coherence Properties of Blackbody Radiation.* II. Correlation Tensors of the Quantized Field

C. L. MEHTA AND E. WOLF
Department of Physics and Astronomy, University of Rochester, Rochester, New York

(Received 9 December 1963)

Expressions are derived for the electromagnetic correlation tensors of blackbody radiation defined on the basis of the theory of the quantized field. Correlation functions of all order are considered, but second-order ones are discussed in detail; it is found that these are identical with those obtained on the basis of semiclassical theory in part I of this investigation. This result illustrates a recent theorem of E.C.G. Sudarshan relating to the equivalence between semiclassical and quantum mechanical description of statistical light beams.

1. INTRODUCTION

IN part I of this investigation,[1] expressions were derived for the complex second-order electromagnetic correlation tensors of blackbody radiation and their behavior was discussed in detail and illustrated by a number of diagrams. The statistical methods used were based entirely on classical concepts, though quantum mechanical features of the radiation were implicit in that treatment, since the spectrum of the radiation was taken to be given by Planck's law.

In the present paper the second-order correlation tensors introduced recently by Glauber[2] on the basis of the theory of the quantized field, are evaluated for blackbody radiation and are shown to be identical with those defined and evaluated on the basis of the semiclassical theory. This result illustrates a recent theorem of Sudarshan,[3] relating to the equivalence between semiclassical[4-6] and quantum mechanical description of statistical light beams.

In Sec. 4 higher-order correlation tensors of blackbody radiation are briefly discussed.

2. THE SECOND-ORDER CORRELATION TENSORS OF THE QUANTIZED FIELD

It will be useful to begin with some results which will be needed later, relating to quantization of the electromagnetic field and the definition of the correlation tensors of the quantized field.

The electric-field operator, at the space-time point $x\equiv(\mathbf{r},ct)$, when expanded in a Fourier series is given by[7] (with $i=x,\,y,\,z$)

$$\hat{E}_i(x)=\hat{E}_i^{(+)}(x)+\hat{E}_i^{(-)}(x), \quad (2.1)$$

[4] The term "semiclassical" implies here that the distribution functions characterizing statistical properties of the beam are not necessarily non-negative and may therefore not be true probabilities. They are essentially Wigner distribution functions (see Refs. 5 and 6), called also "quasiprobabilities." However, in the present case (blackbody radiation) the distribution function turns out to be positive. [See Eq. (3.1).]

where

$$\hat{E}_i^{(+)}(x)=i\left(\frac{2\pi\hbar c}{V}\right)^{1/2}\sum_{\mathbf{k}}(k)^{1/2}\{\sum_{\lambda=1}^{2}\epsilon_i^{(\lambda)}\hat{a}_\lambda(\mathbf{k})e^{i\kappa x}\}, \quad (2.2)$$

$$\hat{E}_i^{(-)}(x)=\{\hat{E}_i^{(+)}(x)\}^\dagger=-i\left(\frac{2\pi\hbar c}{V}\right)^{1/2}\sum_{\mathbf{k}}(k)^{1/2}$$
$$\times\{\sum_{\lambda=1}^{2}\epsilon_i^{(\lambda)}\hat{a}_\lambda^\dagger(\mathbf{k})e^{-i\kappa x}\}. \quad (2.3)$$

Here V represents the volume to which the field is confined and $\hat{a}_\lambda(\mathbf{k})$ and $\hat{a}_\lambda^\dagger(\mathbf{k})$ are the annihilation and creation operators, respectively, for a photon of momentum $\hbar\mathbf{k}$ and polarization λ; they satisfy the commutation relations

$$[\hat{a}_\lambda(\mathbf{k}),\hat{a}_{\lambda'}^\dagger(\mathbf{k}')]=\delta_{\lambda\lambda'}\delta_{\mathbf{k}\mathbf{k}'}, \quad (2.4)$$

$$[\hat{a}_\lambda(\mathbf{k}),\hat{a}_{\lambda'}(\mathbf{k}')]=[\hat{a}_\lambda^\dagger(\mathbf{k}),\hat{a}_{\lambda'}^\dagger(\mathbf{k}')]=0. \quad (2.5)$$

$\boldsymbol{\varepsilon}^{(1)}$ and $\boldsymbol{\varepsilon}^{(2)}$ are two unit vectors, such that $\boldsymbol{\varepsilon}^{(1)}$, $\boldsymbol{\varepsilon}^{(2)}$ and $\mathbf{k}/k$ (with $k=|\mathbf{k}|$) form a right-handed orthogonal triad and κx represents the usual four-vector product

$$\kappa x=\mathbf{k}\cdot\mathbf{r}-kct. \quad (2.6)$$

In writing down Eqs. (2.2) and (2.3), the modified Lorentz condition was used in the form introduced by Gupta and Bleuler,[8] employing an indefinite metric: Allowable states $|\psi\rangle$ are only those for which

$$\sum_{\mu=1}^{4}\frac{\partial\hat{A}_\mu^{(+)}}{\partial x_\mu}|\psi\rangle=0, \quad (2.7)$$

where $\hat{A}^{(+)}$ is the positive frequency part of the potential of the field. This condition justifies our restriction to transverse photons ($\lambda=1,2$) as long as only expectation values of products of field operators are considered.

The magnetic-field operator may be similarly written in the form

$$\hat{H}_i(x)=\hat{H}_i^{(+)}(x)+\hat{H}_i^{(-)}(x), \quad (2.8)$$

where

$$\hat{H}_i^{(+)}(x)=i\left(\frac{2\pi\hbar c}{V}\right)^{1/2}\sum_{\mathbf{k}}(k)^{1/2}$$
$$\times\left\{\sum_{\lambda=1}^{2}\frac{(\mathbf{k}\times\boldsymbol{\varepsilon}^{(\lambda)})_i}{k}\hat{a}_\lambda(\mathbf{k})e^{i\kappa x}\right\}, \quad (2.9)$$

$$\hat{H}_i^{(-)}(x)=\{\hat{H}_i^{(+)}(x)\}^\dagger=-i\left(\frac{2\pi\hbar c}{V}\right)^{1/2}\sum_{\mathbf{k}}(k)^{1/2}$$
$$\times\left\{\sum_{\lambda=1}^{2}\frac{(\mathbf{k}\times\boldsymbol{\varepsilon}^{(\lambda)})_i}{k}\hat{a}_\lambda^\dagger(\mathbf{k})e^{-i\kappa x}\right\}. \quad (2.10)$$

If $\hat{\rho}$ is the density operator of the field, the second-order correlation tensor of the electric field, introduced by Glauber[2a,b] may defined as

$$'\mathcal{E}_{ij}(x_1,x_2)=\mathrm{Tr}\{\hat{\rho}\hat{E}_i^{(-)}(x_1)\hat{E}_j^{(+)}(x_2)\}, \quad (2.11)$$

where the indices i, j specify Cartesian components of the tensor (i, $j=x$, y, z) and the prime on $\mathcal{E}$ is used to distinguish this tensor from the corresponding one defined in paper I in classical terms. In a similar way, one may define the second-order magnetic and mixed-correlation tensors

$$'\mathcal{H}_{ij}(x_1,x_2)=\mathrm{Tr}\{\hat{\rho}\hat{H}_i^{(-)}(x_1)\hat{H}_j^{(+)}(x_2)\}, \quad (2.12)$$

$$'\mathcal{G}_{ij}(x_1,x_2)=\mathrm{Tr}\{\hat{\rho}\hat{E}_i^{(-)}(x_1)\hat{H}_j^{(+)}(x_2)\}, \quad (2.13)$$

$$'\tilde{\mathcal{G}}_{ij}(x_1,x_2)='\mathcal{G}_{ji}^*(x_2,x_1)$$
$$=\mathrm{Tr}\{\hat{\rho}\hat{H}_i^{(-)}(x_1)\hat{E}_j^{(+)}(x_2)\}. \quad (2.14)$$

To evaluate the correlation tensors $'\mathcal{E}$, $'\mathcal{H}$, $'\mathcal{G}$, and $'\tilde{\mathcal{G}}$ for blackbody radiation, it will be useful first of all to express the density operator $\hat{\rho}$ in a representation in which the base vectors are the eigenvectors $|\{z\}\rangle$ of the annihilation operator $\hat{a}_\lambda(\mathbf{k})$:

$$\hat{a}_\lambda(\mathbf{k})|\{z\}\rangle=z_\lambda(\mathbf{k})|\{z\}\rangle. \quad (2.15)$$

Here $\{z\}$ denotes the set of $z_\lambda(\mathbf{k})$ for all λ's and $\mathbf{k}$'s, so that

$$|\{z\}\rangle=\prod_{\lambda,\mathbf{k}}|z_\lambda(\mathbf{k})\rangle. \quad (2.16)$$

Since the operator $\hat{a}_\lambda(\mathbf{k})$ is not Hermitian, its eigenvalues $z_\lambda(\mathbf{k})$ are in general complex,

$$z_\lambda(\mathbf{k})=x_\lambda(\mathbf{k})+iy_\lambda(\mathbf{k}), \quad (2.17)$$

($x_\lambda(\mathbf{k})$, $y_\lambda(\mathbf{k})$ real) and the eigenvectors belonging to different eigenvalues are not orthogonal. However, they obey a closure relation (cf. Ref. 9).

$$\frac{1}{\pi}\int\prod_{\lambda,\mathbf{k}}|z_\lambda(\mathbf{k})\rangle\langle z_\lambda(\mathbf{k})|\,d^2z_\lambda(\mathbf{k})=\hat{1}, \quad (2.18)$$

where $\hat{1}$ is the identity operator if, as we shall assume, they are normalized so that

$$\langle z_\lambda(\mathbf{k})|z_\lambda(\mathbf{k})\rangle=1. \quad (2.19)$$

The eigenstate $|z_\lambda(\mathbf{k})\rangle$ has the following expansion in the number representation[9]:

$$|z_\lambda(\mathbf{k})\rangle=\sum_{n_\lambda(\mathbf{k})=0}^{\infty}\exp(-\tfrac{1}{2}|z_\lambda(\mathbf{k})|^2)\frac{\{z_\lambda(\mathbf{k})\}^{n_\lambda(\mathbf{k})}}{[n_\lambda(\mathbf{k})!]^{1/2}}|n_\lambda(\mathbf{k})\rangle, \quad (2.20)$$

where the $|n_\lambda(\mathbf{k})\rangle$ form an orthonormal set of eigenvectors of the number operator $\hat{a}_\lambda^\dagger(\mathbf{k})\hat{a}_\lambda(\mathbf{k})$:

$$\hat{a}_\lambda^\dagger(\mathbf{k})\hat{a}_\lambda(\mathbf{k})|n_\lambda(\mathbf{k})\rangle=n_\lambda(\mathbf{k})|n_\lambda(\mathbf{k})\rangle. \quad (2.21)$$

The eigenvectors of the annihilation operator have been found very useful in the analysis of problems

[8] See, for example, S. S. Schweber, *An Introduction to Quantum Field Theory* (Harper & Row, New York, 1961), p. 242.

[9] J. R. Klauder, Ann. Phys. (N. Y.) 11, 123 (1960).

Digitized by Arya Samaj Foundation Chennai and eGangotri

relating to the statistical behavior of radiation.[2,3,10] An important property of these eigenvectors is expressed by a theorem established recently by Sudarshan[3] which we shall employ. According to this theorem, any operator and in particular the density operator $\hat{\rho}$ may be expressed in the "diagonal" form

$$\hat{\rho}=\int \phi(\{z\})\,|\{z\}\rangle\langle\{z\}|\,d^2\{z\}\,. \tag{2.22}$$

Using this representation of the density operator, it then follows from (2.2), (2.3), (2.11), (2.22) and (2.15) and its Hermitian adjoint that the second-order correlation tensor of the electric field may be expressed in the form

$$'\mathcal{E}_{ij}(x_1,x_2)$$

$$=\int \phi(\{z\})\langle\{z\}|\hat{E}_i^{(-)}(x_1)\hat{E}_j^{(+)}(x_2)|\{z\}\rangle d^2\{z\}$$

$$=\sum_{\lambda,\mathbf{k}}\sum_{\lambda',\mathbf{k}'}\epsilon_i^{(\lambda)}(\mathbf{k})\epsilon_j^{(\lambda')}(\mathbf{k}')\Phi_{\lambda\lambda'}(\mathbf{k},\mathbf{k}';x_1,x_2)\,, \tag{2.23}$$

where

$$\Phi_{\lambda\lambda'}(\mathbf{k},\mathbf{k}';x_1,x_2)=(2\pi\hbar c/V)(kk')^{1/2}\exp(-i\kappa x_1+i\kappa' x_2)$$

$$\times\int \phi(\{z\})z_\lambda^*(\mathbf{k})z_{\lambda'}(\mathbf{k}')d^2\{z\}\,. \tag{2.24}$$

The corresponding expressions for the second order magnetic and mixed correlation tensors defined by (2.12)–(2.14) can also readily be written down. We only need to use the expressions (2.9) and (2.10) in place of (2.2) and (2.3) where appropriate. We then obtain in place of (2.23) the following expressions for the other second-order correlation tensors of the quantized field:

$$'\mathcal{H}_{ij}(x_1,x_2)=\sum_{\lambda,\mathbf{k}}\sum_{\lambda',\mathbf{k}'}\left(\frac{\mathbf{k}\times\boldsymbol{\epsilon}^{(\lambda)}}{k}\right)_i\left(\frac{\mathbf{k}'\times\boldsymbol{\epsilon}^{(\lambda')}}{k'}\right)_j$$

$$\times\Phi_{\lambda\lambda'}(\mathbf{k},\mathbf{k}';x_1,x_2)\,, \tag{2.25}$$

$$'\mathcal{G}_{ij}(x_1,x_2)=\sum_{\lambda,\mathbf{k}}\sum_{\lambda',\mathbf{k}'}\epsilon_i^{(\lambda)}(\mathbf{k})\left(\frac{\mathbf{k}'\times\boldsymbol{\epsilon}^{(\lambda')}}{k'}\right)_j$$

$$\times\Phi_{\lambda\lambda'}(\mathbf{k},\mathbf{k}';x_1,x_2)\,, \tag{2.26}$$

$$'\tilde{\mathcal{G}}_{ij}(x_1,x_2)=\sum_{\lambda,\mathbf{k}}\sum_{\lambda',\mathbf{k}'}\left(\frac{\mathbf{k}\times\boldsymbol{\epsilon}^{(\lambda)}}{k}\right)_i\epsilon_j^{(\lambda')}(\mathbf{k}')$$

$$\times\Phi_{\lambda\lambda'}(\mathbf{k},\mathbf{k}';x_1,x_2)\,. \tag{2.27}$$

3. THE SECOND-ORDER CORRELATION TENSORS OF BLACKBODY RADIATION

We will now evaluate the correlation tensors $'\mathcal{E}$, $'\mathcal{H}$, $'\mathcal{G}$ and $'\tilde{\mathcal{G}}$ for the case of blackbody radiation. It would appear from a discussion of Glauber [Ref. 2c, Eq. (10.23)], based essentially on the central limit theorem, that the "phase-space" distribution function $\phi(\{z\})$ for blackbody radiation is given by

$$\phi(\{z\})=\prod_{\lambda,\mathbf{k}}\frac{1}{\pi\bar{n}_k}\exp\left\{-\frac{|z_\lambda(k)|^2}{\bar{n}_k}\right\}, \tag{3.1}$$

where $\bar{n}_k\equiv\bar{n}_{\mathbf{k},\lambda}$ $(\lambda=1,2)$ is the average number of photons with momentum $\mathbf{k}$ and polarization λ,

$$\bar{n}_k=1/(e^{\alpha k}-1)\,, \tag{3.2}$$

with

$$\alpha=\hbar c/KT\,. \tag{3.3}$$

That the "phase-space" distribution $\phi(\{z\})$ given by (3.1) does indeed lead to the well-known expression for the density operator $\hat{\rho}$ of a radiation field in thermal equilibrium at temperature T is verified directly in the Appendix to the present paper (see also Mandel[10]).

If we substitute from (3.1) into (2.24), and also use the relation

$$\int z_{\lambda'}^*(\mathbf{k}')z_{\lambda''}(\mathbf{k}'')\prod_{\lambda,\mathbf{k}}\frac{1}{\pi\bar{n}_k}\exp(-|z_\lambda(\mathbf{k})|^2/\bar{n}_k)d^2z_\lambda(\mathbf{k})$$

$$=\frac{1}{\pi\bar{n}_{k'}}\delta_{\lambda'\lambda''}\delta_{\mathbf{k}'\mathbf{k}''}\int|z_{\lambda'}(\mathbf{k}')|^2$$

$$\times\exp(-|z_{\lambda'}(\mathbf{k})|^2/\bar{n}_{k'})d^2z_{\lambda'}(\mathbf{k}')$$

$$=\bar{n}_{k'}\delta_{\lambda'\lambda''}\delta_{\mathbf{k}'\mathbf{k}''}\,, \tag{3.4}$$

where δ is the Kronecker symbol, we find that

$$\Phi_{\lambda,\lambda'}(\mathbf{k},\mathbf{k}';x_1,x_2)$$

$$=\frac{2\pi\hbar c}{V}k\bar{n}_k\delta_{\lambda\lambda'}\delta_{\mathbf{k}\mathbf{k}'}\exp\{-i\kappa(x_1-x_2)\}\,. \tag{3.5}$$

Next we assume that the linear dimensions of the enclosure are large compared with the mean wavelength of the radiation. Summation over $\mathbf{k}$ may then be replaced by integration over the whole $\mathbf{k}$ space, if use is made of the usual rules[11]

$$\frac{1}{(V)^{1/2}}\sum_{\mathbf{k}}f(\mathbf{k})\rightarrow\frac{1}{(2\pi)^{3/2}}\int d^3k f(\mathbf{k})\,, \tag{3.6}$$

$$\delta_{\mathbf{k}\mathbf{k}'}\rightarrow\delta(\mathbf{k}-\mathbf{k}')\,, \tag{3.7}$$

where f is an arbitrary function and $\delta(\mathbf{k}-\mathbf{k}')$ is the three-dimensional Dirac delta function. One then obtains from (3.5) and (2.23), the following expression for the correlation tensor $'\mathcal{E}$:

$$'\mathcal{E}_{ij}(x_1,x_2)=\frac{\hbar c}{4\pi^2}\int k\bar{n}_k\exp\{i\kappa(x_2-x_1)\}$$

$$\times\sum_{\lambda=1}^{2}\epsilon_i^{(\lambda)}(\mathbf{k})\epsilon_j^{(\lambda)}(\mathbf{k})d^3k\,. \tag{3.8}$$

[10] L. Mandel, Phys. Letters 7, 117 (1963).

[11] J. M. Jauch and F. Rohrlich, *The Theory of Photons and Electrons* (Addison Wesley Publishing Co., Cambridge, 1955), p. 38.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Next we substitute for $\bar{n}_k$ from (3.2) and also use the relation

$$\sum_{\lambda=1}^{2} \epsilon_i^{(\lambda)}(\mathbf{k})\epsilon_j^{(\lambda)}(\mathbf{k}) = \delta_{ij} - \frac{k_i k_j}{k^2}, \tag{3.9}$$

which follows from the fact that $\boldsymbol{\varepsilon}^{(1)}$, $\boldsymbol{\varepsilon}^{(2)}$, and $\mathbf{k}/k$ form a triad of mutually orthogonal unit vectors. We thus finally obtain the following expression for the second-order electric correlation tensor $'\mathcal{E}$ of the quantized field:

$$'\mathcal{E}_{ij}(x_1,x_2) = \frac{\hbar c}{4\pi^2}\int \frac{k^2\delta_{ij} - k_i k_j}{k(e^{ak}-1)} \times \exp\{i\kappa(x_2-x_1)\}d^3k. \tag{3.10}$$

For the magnetic second-order correlation tensor, we obtain in a strictly similar manner from (2.25)

$$'\mathcal{H}_{ij}(x_1,x_2) = \frac{\hbar c}{4\pi^2}\int k\bar{n}_k \exp\{i\kappa(x_2-x_1)\} \times \sum_{\lambda=1}^{2}\left(\frac{\mathbf{k}\times\boldsymbol{\varepsilon}^{(\lambda)}}{k}\right)_i\left(\frac{\mathbf{k}\times\boldsymbol{\varepsilon}^{(\lambda)}}{k}\right)_j d^3k. \tag{3.11}$$

Now the three vectors $\mathbf{k}\times\boldsymbol{\varepsilon}^{(1)}/k$, $\mathbf{k}\times\boldsymbol{\varepsilon}^{(2)}/k$ and $\mathbf{k}/k$ also form a triad of mutually orthogonal unit vectors, and hence a relation similar to (3.9) holds between them. In consequence, the right-hand side of (3.11) becomes identical with the right-hand side of (3.10) and hence we have

$$'\mathcal{H}_{ij}(x_1,x_2) = '\mathcal{E}_{ij}(x_1,x_2). \tag{3.12}$$

For the mixed second-order correlation tensor $'\mathcal{G}$ we obtain from (2.26) in a similar manner

$$'\mathcal{G}_{ij}(x_1,x_2) = \frac{\hbar c}{4\pi^2}\int k\bar{n}_k \exp\{i\kappa(x_2-x_1)\} \times \sum_{\lambda=1}^{2}\epsilon_i^{(\lambda)}(\mathbf{k})\left(\frac{\mathbf{k}\times\boldsymbol{\varepsilon}^{(\lambda)}}{k}\right)_j d^3k. \tag{3.13}$$

It may readily be verified that

$$\sum_{\lambda=1}^{2}\epsilon_i^{(\lambda)}(\mathbf{k})\left(\frac{\mathbf{k}\times\boldsymbol{\varepsilon}^{(\lambda)}}{k}\right)_j = \epsilon_{ijl}k_l/k, \tag{3.14}$$

where ϵ_{ijl} is the completely antisymmetric unit tensor of Levi Civita. Hence, if also (2.14) is used, (3.13) reduces to

$$'\mathcal{G}_{ij}(x_1,x_2) = -'\tilde{\mathcal{G}}_{ij}(x_1,x_2) = \frac{\hbar c}{4\pi^2}\epsilon_{ijl}\int \frac{k_l}{e^{ak}-1} \times \exp\{i\kappa(x_2-x_1)\}d^3k. \tag{3.15}$$

Noting that $\kappa(x_2-x_1)$ is the four-vector product

$$\kappa(x_2-x_1) = kc\tau - \mathbf{k}\cdot\mathbf{r}, \tag{3.16}$$

where $\tau = t_1 - t_2$ and $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$, it follows on comparing Eqs. (3.10), (3.12), and (3.15) with Eqs. (5.7), (5.9), and (5.8) of paper I that

$$\begin{aligned} '\mathcal{E}_{ij}(x_1,x_2) &= \tfrac{1}{4}\mathcal{E}_{ij}^*(x_1,x_2), \\ '\mathcal{H}_{ij}(x_1,x_2) &= \tfrac{1}{4}\mathcal{H}_{ij}^*(x_1,x_2), \\ '\mathcal{G}_{ij}(x_1,x_2) &= \tfrac{1}{4}\mathcal{G}_{ij}^*(x_1,x_2), \\ '\tilde{\mathcal{G}}_{ij}(x_1,x_2) &= \tfrac{1}{4}\tilde{\mathcal{G}}_{ij}^*(x_1,x_2). \end{aligned} \tag{3.17}$$

The relations (3.17) show that the second-order electromagnetic correlation tensors of blackbody radiation defined for the quantized field by Eqs. (2.11), (2.12), (2.13), and (2.14) are proportional to the complex conjugates of the corresponding tensors defined for the classical field by Eqs. (1.3a), (5.1), (5.2), and (5.3) of paper I.[12–14]

4. HIGHER ORDER CORRELATION TENSORS

Up to now we have considered correlation tensors of second order only. For the sake of completeness, we will now briefly consider electromagnetic correlation tensors of higher orders for the case of blackbody radiation. Again these correlation tensors may be defined either as appropriate averages of products involving the field vectors of the complex classical field at a number of space-time points,[15,16,17] or as quantum mechanical expectation values involving the corresponding field operators.[2] Since the equivalence of these different definitions has been demonstrated by Sudarshan,[3] Mandel[10] and Mehta and Wolf,[18] we may restrict our discussion to correlation tensors defined on the basis of the theory of the quantized field. The electric correlation tensor of order $m+n$ is then defined by the equation

$$\begin{aligned} &\mathcal{E}^{(m,n)}_{j_1,j_2,\cdots j_{m+n}}(x_1,x_2,\cdots x_m;\, x_{m+1},\cdots x_{m+n}) \\ &\quad = \mathrm{Tr}\{\hat{\rho}\hat{E}_{j_1}^{(-)}(x_1)\hat{E}_{j_2}^{(-)}(x_2)\cdots\hat{E}_{j_m}^{(-)}(x_m) \\ &\qquad \times \hat{E}_{j_{m+1}}^{(+)}(x_{m+1})\cdots\hat{E}_{j_{m+n}}^{(+)}(x_{m+n})\}, \end{aligned} \tag{4.1}$$

where $\hat{E}_j^{(-)}(x)$, $\hat{E}_j^{(+)}(x)$ are Cartesian components of the operators $\hat{E}^{(-)}(x)$, $\hat{E}^{(+)}(x)$ at the space-time point

---

[12] The correlation tensors of the classical field could readily be redefined without any loss of generality, so as to lead to strict identities $'\varepsilon_{ij} = \varepsilon_{ij}$, etc. In particular, the factor $\frac{1}{4}$ could be suppressed by employing a slightly different normalization in defining the analytic signal (Refs. 13 and 14) by means of which the complex fields are associated with the real fields. However, we preferred to retain the customary definitions throughout this investigation.

x, defined by Eqs. (2.2) and (2.3). It follows from Sudarshan's discussion[3] that the expectation value on the right of (4.1) may be expressed as a phase-space average of the products of the components of the complex classical field, in the form

$$\mathcal{G}^{(m,n)}_{j_1,j_2,\cdots j_{m+1}}(x_1,x_2,\cdots x_m;\, x_{m+1},\cdots x_{m+n})$$

$$=\int \phi(\{z\})E_{j_1}{}^*(x_1)E_{j_2}{}^*(x_2)\cdots E_{j_m}{}^*(x_m)$$

$$\times E_{j_{m+1}}(x_{m+1})\cdots E_{j_{m+n}}(x_{m+n})d^2\{z\}\,, \quad (4.2)$$

where $\phi(\{z\})$ is the "phase space" distribution function associated with the density operator $\hat{\rho}$ [cf. (2.22)] and

$$E_j(x)=i\left(\frac{2\pi\hbar c}{V}\right)^{1/2}\sum_{\mathbf{k},\lambda}(k)^{1/2}\epsilon_j{}^{(\lambda)}(\mathbf{k})z_\lambda(\mathbf{k})e^{ikx}; \quad (4.3)$$

$(j=x,y,z)$ is the eigenvalue of the operator $\hat{E}_j{}^{(+)}(x)$ corresponding to the eigenstate $|\{z\}\rangle$.

In the case of blackbody radiation, the phase-space distribution $\phi(\{z\})$ is given by (3.1), which is a multivariate Gaussian distribution. Now since according to (4.3) the field components $E_{j_\mu}(x_\mu)$, $E_{j_\mu}{}^*(x_\mu)$ are linear combinations of the $z_\lambda(\mathbf{k})$ and $z_\lambda{}^*(\mathbf{k})$, they will, according to a well-known theorem on the Gaussian random process, be also distributed as Gaussian variates[19] and hence all moments involving them may completely be expressed in terms of the second-order moments[20] as follows:

If $m=n$

$$\mathcal{G}^{(m,n)}_{j_1,j_2,\cdots j_{m+n}}(x_1,x_2,\cdots x_m;\, x_{m+1},\cdots x_{m+n})$$

$$=\sum\nolimits_\pi \mathcal{G}^{(1,1)}_{j_1,j_p}(x_1;\,x_p)\,\mathcal{G}^{(1,1)}(x_2;\,x_q)\cdots$$

$$\times\,\mathcal{G}^{(1,1)}_{j_m,j_s}(x_m;\,x_s)\,. \quad (4.4)$$

If $m\neq n$

$$\mathcal{G}^{(m,n)}_{j_1,j_2,\cdots j_{m+n}}(x_1,x_2,\cdots x_m;\, x_{m+1},\cdots x_{m+n})=0. \quad (4.5)$$

The second-order coherence tensor $\mathcal{G}^{(1,1)}_{j_1,j_p}(x_1;\,x_p)$, etc. on the right of (4.4) is precisely the second order electric correlation tensors given by (3.10) and π denotes all permutations p, q, $\cdots s$ of the non-negative integers $m+1$, $m+2$, $\cdots 2m$.

Strictly similar expressions can readily be written down for the magnetic and mixed tensors of an arbitrary order.

Finally, it should be mentioned that the expression (4.4) for the electric correlation tensor of blackbody radiation has also recently been derived by Glauber.[20a]

[19] Proof of this result for a real Gaussian random process is given, for example, in Wang and Uhlenbeck, Rev. Mod. Phys. 17, 323 (1945). Generalization to a complex Gaussian random process is straightforward.

[20] See, for example, I. S. Reed, Inst. Radio Engrs. Trans. Inform. Theory IT8, 194 (1962).

APPENDIX

In this Appendix we will verify that the phase-space distribution (3.1), namely,

$$\phi(\{z\})=\prod_{\lambda,\mathbf{k}}\frac{1}{\pi\bar{n}_k}\exp\left\{-\frac{|z_\lambda(\mathbf{k})|^2}{\bar{n}_k}\right\} \quad (A1)$$

corresponds to the density operator $\hat{\rho}$ for radiation field in thermal equilibrium at temperature T.

On substituting from (A1) and (2.20) into (2.22), we obtain

$$\hat{\rho}=\prod_{\lambda,\mathbf{k}}\sum_{n_\lambda(\mathbf{k})=0}^{\infty}\sum_{m_\lambda(\mathbf{k})=0}^{\infty}\int\frac{1}{\pi\bar{n}_k}$$

$$\times\exp\left\{-\frac{|z|^2}{\bar{n}_k}\right\}\frac{z^{n_\lambda(\mathbf{k})}z^{*m_\lambda(\mathbf{k})}}{(n_\lambda(\mathbf{k})!m_\lambda(\mathbf{k})!)^{1/2}}$$

$$\times\exp\{-|z|^2\}|n_\lambda(\mathbf{k})\rangle\langle m_\lambda(\mathbf{k})|\,d^2z. \quad (A2)$$

Next we set $z=r\exp(i\theta)$, $d^2z=rdrd\theta$ and note that the integration over θ gives $2\pi\delta_{n_\lambda(\mathbf{k}),m_\lambda(\mathbf{k})}$. We then obtain

$$\hat{\rho}=\prod_{\lambda,\mathbf{k}}\sum_{n_\lambda(\mathbf{k})}\int_0^\infty\frac{1}{\bar{n}_k}\exp\left\{-r^2\left(1+\frac{1}{\bar{n}_k}\right)\right\}$$

$$\times(r^2)^{n_\lambda(\mathbf{k})}\frac{|n_\lambda(\mathbf{k})\rangle\langle n_\lambda(\mathbf{k})|}{n_\lambda(\mathbf{k})!}d(r^2)$$

$$=\prod_{\lambda,\mathbf{k}}\sum_{n_\lambda(\mathbf{k})}\frac{1}{\bar{n}_k+1}\left(1+\frac{1}{\bar{n}_k}\right)^{-n_\lambda(\mathbf{k})}|n_\lambda(\mathbf{k})\rangle\langle n_\lambda(\mathbf{k})|\,. \quad (A3)$$

Next we substitute for $\bar{n}_k$ from (3.2) and find that

$$\hat{\rho}=\prod_{\lambda,\mathbf{k}}\frac{\exp(\alpha k-1)}{\exp(\alpha k)}\sum_{n_\lambda(\mathbf{k})}\exp\{-n_\lambda(\mathbf{k})\alpha k\}$$

$$\times|n_\lambda(\mathbf{k})\rangle\langle n_\lambda(\mathbf{k})|\,, \quad (A4)$$

where α is given by (3.3). But

$$\sum_{n_\lambda(\mathbf{k})}\exp\{-n_\lambda(\mathbf{k})\alpha k\}|n_\lambda(\mathbf{k})\rangle\langle n_\lambda(\mathbf{k})|$$

$$=\exp\{-\hat{a}_\lambda{}^\dagger(\mathbf{k})\hat{a}_\lambda(\mathbf{k})\alpha k\}\sum_{n_\lambda(\mathbf{k})}|n_\lambda(\mathbf{k})\rangle\langle n_\lambda(\mathbf{k})| \quad (A5)$$

and we have also the completeness relation

$$\sum_{n_\lambda(\mathbf{k})}|n_\lambda(\mathbf{k})\rangle\langle n_\lambda(\mathbf{k})|=\hat{1}. \quad (A6)$$

Using (A5) and (A6) in (A4), we finally obtain the following expression for the density operator $\hat{\rho}$ corresponding to the phase-space distribution function (A1):

$$\hat{\rho}=\prod_{\lambda,\mathbf{k}}\frac{\exp\{-\alpha k\hat{a}_\lambda{}^\dagger(\mathbf{k})\hat{a}_\lambda(\mathbf{k})\}}{\exp(\alpha k)/[\exp(\alpha k)-1]}. \quad (A7)$$

This is precisely the density operator for a radiation field in thermal equilibrium at temperature T.[21]

Effect of Magnetic Field on Thermal Conductivity and Energy Gap of Superconducting Films*

D. E. Morris† and M. Tinkham
Department of Physics, University of California, Berkeley, California

(Received 9 January 1964)

We have measured the change in the thermal conductivity of superconducting tin, indium, and lead films upon application of a magnetic field in the plane of the film. These experiments were undertaken to explore the dependence of the energy gap upon magnetic field and to determine the thermodynamic order of the field-induced transition in films. Within the range of temperatures available to us ($0.35\ T_c$ to $0.65\ T_c$) the thermal conductivity of indium and tin films increases nearly as H^2. In films of thickness $d \geqq 2800$ Å the thermal conductivity jumps at H_c to the normal state value, indicating a first-order phase transition in thin films, consistent with the Ginzburg-Landau (GL) theory. If the effect of a field upon the superconducting state can be adequately represented as a change of the ϵ_0 of BCS, we may use the theory of Bardeen, Rickayzen, and Tewordt to compute $\epsilon_0(H)$ from our data. At $T=0.65\ T_c$ we find $\epsilon_0(H)/\epsilon_0(H=0)=[1-(H/H_c)^2]^{1/2}$ in agreement with the GL prediction. At $T=0.35\ T_c$ however, $\epsilon_0(H)/\epsilon_0(0)=1-(H/H_c)^2$ provides a more satisfactory fit to our data. Orientation of the field $\perp$ and $\parallel$ to the direction of heat flow produces the same effect on the thermal conductivity to $\pm 1\%$. This is interesting in view of Bogoliubov's prediction of a $\mathbf{p}_F \cdot \mathbf{v}_{\text{drift}}$ term in the excitation spectrum of a current-carrying superconductor. When the field is not parallel to the surface of the film the thermodynamic transition is still sharply defined, but H_c is reduced. Thin lead films gave results similar to those of indium and tin films except that at low fields the field-dependent conductivity increased more slowly than H^2 at low temperatures.

I. INTRODUCTION

IT is now well accepted on both experimental[1,2] and theoretical[3,4] grounds that near T_c the superconducing transition of a thin film in a magnetic field is of second order. The predictions of the Ginzburg-Landau-Gor'kov theory[3–6] (GLG), applicable here, are in good agreement with experimental results. At reduced temperatures $t=T/T_c \ll 1$, however, the GLG theory is inapplicable.[7] Bardeen[8] has made a calculation which leads to a first-order transition at very low temperatures, while Nambu and Tuan[9] find a second-order transition for a very thin film at all temperatures.

The elegant experimental measurements of the field dependence of the energy gap employing the tunnel effect[1,2] have generally been limited to a few metals at moderately high reduced temperatures and to the case of fields applied parallel to the film surface. Only recently, while this report was in preparation, have measurements been extended to lead films at low reduced temperatures by Douglass and Meservy.[10] The seexperiments support our findings, to be reported here, that the transition for a thin film remains second order even at very low temperatures, and they also find a similar field dependence of the energy gap at low temperatures. It should perhaps be noted that the tunnel-effect measurements selectively indicate the effective energy gap at the film surface for electrons moving normal to the surface.

We have developed an independent experimental method to study the thermodynamic parameters of a superconducting film in a magnetic field. This method consists of measuring the effect of an externally applied magnetic field on the thermal conductivity of a superconducting thin film. A preliminary report of our results on tin and indium films has been published elsewhere.[11] The experiments were then extended[12] to a wider range of experimental conditions and to another metal, lead. We report these more extensive experiments here. The experimental data reveal the thermodynamic order of the transition by inspection. By using the relation derived by Bardeen, Rickayzen, and Tewordt[13] (BRT) the data may be inverted point by point to give $\epsilon_0(H)$, the field-dependent energy gap averaged through the film.

The external field has been applied at various angles with respect to the plane of the film with unexpected results, and the relative directions of the field and the heat flow in the plane of the film have been varied in a search for vestiges of the anisotropy of the energy gap

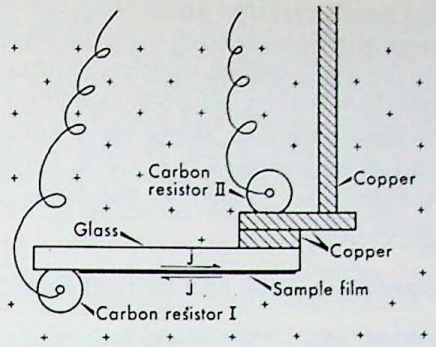

FIG. 1. Sample and thermometer mounting arrangement.

in a current-carrying superconductor predicted by Bogoliubov.[14]

II. EXPERIMENTAL METHOD

A. Low-Temperature Arrangement

The use of carbon resistance thermometers,[15] with their low thermal inertia and high sensitivity, makes it possible to measure the low-temperature thermal conductivity of thin metal films deposited on glass substrates. During our experiments, the temperature drop along the film is typically 0.1°K with 10^{-7} W total heat transport along the sample film and substrate. Under these conditions a change of 2 μdeg in the temperature drop along the film is detectable.

The sample and thermometer arrangement is shown in Fig. 1. A $\frac{1}{2}$-W carbon-composition resistor is prepared for use as a thermometer-heater (I) by grinding a flat surface until the resistance material just becomes visible. The lead wires are cut off short, and lengths of No. 42 Formvar insulated manganin wire are attached with nonsuperconducting solder. The thermal conductivity of these lead wires is negligible in our experiments. The flattened surface of the resistor is glued with GE-7031 cement at one end of the glass sample-film substrate. Using the same cement, the opposite end of the substrate is attached to a copper heat sink, which is in turn connected to the lid of the experimental chamber. A similarly prepared second resistor, to be used as a reference thermometer (II), is similarly glued to the copper heat sink.

The experimental chamber is placed in the lowest part of the interior of a conventional, liquid-nitrogen shielded, glass Dewar for liquid helium use. A thin-walled stainless-steel tube extends from the experimental chamber to the top of the Dewar. This tube is used to evacuate the chamber; it also carries No. 40 manganin wires for connection to the thermometers. Since the usual power input to the heater-thermometer during the experiments is only $\sim 10^{-7}$ W, thermal anchoring of the manganin leads to the inside of the chamber lid and radiation baffling in the pumping tube above the chamber are both essential. The chamber is sealed to its copper lid with a Woods metal joint. When this alloy is cooled below ~8°K, it becomes superconducting.[16] In order to prevent the superconducting diamagnetism and trapped flux at the joint from disturbing the magnetic field applied to the sample film, the sample is suspended near the bottom of the $4\frac{1}{2}$-in.-long chamber from a copper rod directed downward from the copper lid.

B. Thermometry

The thermometers used were Allen-Bradley $\frac{1}{2}$-W nominal 100-Ω resistors, connected in a wheatstone-bridge circuit. Satisfactory cancellation of temperature drifts was achieved without special matching of the reference and heater resistors. The resistance of the reference thermometer was measured as a function of the vapor pressure of the helium bath over the range 1.2–4.2°K at a small enough current to prevent appreciable heating above the bath temperature. The results could be approximated closely by a relation of the form $\ln R = A + B/T$, where $A = 2.89$ and $B = 3.26°$.

The insensitivity of the resistance thermometers to magnetic fields was checked during several experimental runs. If the magnetic field is increased to several times the critical field of the experimental film, any changes in the thermometer bridge balance above the critical field may be attributed to magnetoresistance in the thermometers. This is so because any effect of the magnetic field on the thermal resistance of the experimental films, which have electron mean free paths ~800 Å, would in the normal state be negligible even at the maximum field applied. In the case of a film of relatively low critical field the resistance bridge balance was unaffected by an increase from $H = 400$ Oe to $H = 800$ Oe. In another experiment, increase of the field from 7500 to 15 000 Oe produced only a small shift in the resistance thermometer bridge balance. These results are consistent with the behavior of similar resistors as determined by Clement and Quinnell.[15] They found that magnetoresistance effects were small and proportional to H^2. Further, we expect the small magnetoresistance of the thermometer heater and the reference thermometer to nearly cancel in measurements of resistance bridge balance.

The relation between power input and resistance change was measured separately for the heater thermometer and the reference thermometer in several experiments. The temperature rise of the reference thermometer at a given power input was only about 10% of that of the heater thermometer at the same power level. We may conclude that the thermal resistance of the re-

sistors themselves and of the glue used to fasten them in place amounts to $\sim\frac{1}{10}$ of the thermal resistance of the sample film and substrate. For example, at 1.2° and a power input of 0.09×10^{-6} W, the temperature rise of the heater thermometer was ~0.060° and of the reference ~0.006°. This gives a value of $dP/dT=1.5\times10^{-5}$ W/deg for the reference thermometer. Berman[17] established that in the 100-Ω ½-W Allen-Bradley resistor (the same type and value as we have used) $dP/dT=5.2\times10^{-5}$ W/deg. The difference is accounted for by the fact that thermal contact was made to only a fraction of the surface of the resistor in our experiments.

C. Temperature Stability

The initial (unsuccessful) experiments were attempted at 1.3°K, without a reference thermometer. A monotonic, but not perfectly uniform, decrease of the bath temperature at the rate of ~1 mdeg/min during the measurements resulted from the decreasing helium film creep as the liquid-helium level declined. The resulting drift in the thermometer resistance overwhelmed the temperature changes expected from the desired effect of a magnetic field. Attempts were made to stabilize the bath temperature with an electronic regulator consisting of a separate resistance thermometer in a 33-cps ac bridge, followed by a tuned amplifier, lock-in detector, and dc heater in the liquid helium. Although satisfactory long-term stability was achieved, amplifier noise in the heater produced objectionable variations over periods shorter than a minute. Since the total experimental effect is ~5 mdeg, the noise level should be less than 50 μdeg to ensure an adequate signal/noise ratio.

With the introduction of the reference thermometer in a bridge circuit with the thermometer heater, the effective drift rate was decreased by a factor of 10, even without special matching of the resistors. This permitted data to be taken without the use of any noise-producing feedback stabilization schemes.

Temperatures of 1.2°K were reached by pumping at 300 liters/min with a conventional rotary vacuum pump. Operation at 1.7°K was attained by adjustment of a valve in the pumping line until the temperature drift rate at the desired temperature was reasonably low. When operation near 2.1°K was desired, a Cartesian manostat was connected in the helium vapor pumping line. A 1-cu-ft ballast tank was connected in the pumping line between the Dewar and the manostat to reduce fluctuations in the pressure above the helium bath which were caused by the oscillation of the manostat throttle.

Spatial nonuniformity of the bath temperature and bubbling of the helium usually results in intolerable temperature fluctuations of the sample if operation is attempted above the λ point of the helium bath. However, it was possible to conduct experiments at the normal boiling point (4.22°K) by leaving the bath completely undisturbed and isolated from vibration for three hours after the liquid-helium transfer. By that time, the bubbling produced only a relatively small rapid fluctuation of the signal; however, the temperature drop along the film had to be increased to ~0.6°K (several times the low-temperature values) to obtain an adequate signal-to-noise ratio.

D. Temperature Drop and Critical Field Spread

The approximate temperature drop along the film during the experiments at various temperatures is shown in Table I. The increase in ΔT at higher temperatures was necessary to maintain the signal/noise ratio in the presence of greater uncontrolled temperature fluctuations and decreasing thermometer sensitivity. The percentage difference in the critical fields at the hot and cold ends of the film which result from the difference of temperature is also shown in Table I. These values were determined from the appropriate bulk critical field curves.

TABLE I. Temperature drop along experimental films and corresponding spread in critical fields.

Mean temperature	ΔT	$\Delta H_c/H_c$ Indium	Tin	Lead
1.2°	0.06°	1.5%	1.0%	0.2%
1.7°	0.1°	4%	3.5%	0.6%
2.1°	0.15°	10%	7%	1.3%
4.5°	0.6°			15%

E. Magnetic Field

A high-power water-cooled Helmholtz pair produced fields up to 1000 Oe. This relatively high-field, iron-free system was employed to permit precise control of the direction of the field by using auxiliary trimming coils, in order that the effect of applying the field slightly out of the plane of the sample film could be investigated. The terminals of the trimming coils could be connected by a rotary switch to taps on a low-resistance nichrome strip wired in series with the main coil pair. In this way the angle of the resultant field, independent of amplitude, could be adjusted in 0.02° steps up to ±4°. In experiments on films with critical fields greater than 1000 Oe, conventional iron-core electromagnets were used. The resulting uncontrolled angle of the field with respect to the plane of the film is less than 1° and apparently it has no major effect upon the experimental results for these very thin films, as may be seen in Fig. 11.

F. Sample Films

Sample films were produced by rapid evaporation onto glass substrates held at 77°K, after thorough ion-bombardment cleaning of the substrate surface.

[17] R. Berman, Rev. Sci. Instr. 25, 94 (1954).

The substrates were No. 0 microscope-cover glasses about 0.11 mm thick which had been broken into pieces about 5 mm×15 mm, suitable for our experiments. The substrates were washed in a saturated solution of detergent, rinsed in hot tap water, and air dried. The substrate was then clamped against the surface of an unfilled cold trap inside the vacuum chamber. The chamber was evacuated and an intense (20 mA) high-voltage (5000 V) glow discharge was operated for 5 min to heat and clean the substrate by ion bombardment. Then the pressure was reduced to 3×10^{-6} mm Hg and the substrate was cooled to 77°K by filling the attached cold trap. The vacuum pumping line contained a liquid nitrogen cooled baffle to rule out contamination of the vacuum chamber by condensation of oil vapor.

A tantalum evaporation boat containing the preweighed and pre-fused sample charge was rapidly heated to about 1400°C and the film evaporation took place in a period ranging from 1 sec for a 3-mg charge (giving a 1300-Å film) to 6 sec for a 30-mg charge. The source-to-substrate distance was only 2 in. The deposition rate of over 1000 Å/sec, along with the residual gas pressure of less than 10^{-5} mm Hg, ensured that the flux of residual gas molecules was a great deal smaller than that of the metal atoms during the evaporation. Films prepared under these conditions should therefore be quite pure. Cooling of the substrate during the evaporation is necessary to prevent migration of the metal atoms after they first strike the surface.[18] After the films were warmed to room temperature and removed from the vacuum, they were annealed at room temperature for at least one week. (The lead films were annealed in vacuum to retard oxidation.)

The sources and purities of the metals used in evaporation of the experimental films are given in Table II.

TABLE II. Metal sources and purities.

Metal	Supplier	Stated purity
Indium	Indium Corporation of America	99.999%
Lead	A. D. Mackay	99.999%
Tin	Johnson, Matthey	99.999%

Films ranging in thickness from 250 to 12 000 Å were prepared. Thickness was estimated from the measured critical field and published data relating the critical field to film thickness. As described above, all films were deposited on substrates cooled to 77°K. In all cases it was possible to prepare films which were mirror-like in appearance with very little diffuse reflectivity, in contrast to results of room-temperature evaporations.[18] No structure was visible under magnification of 1500 diameters except a fine granularity.

A 250-Å indium film showed no noticeable deterioration after seven months exposure to the atmosphere. A 700-Å tin film similarly exposed for four months showed no visible deterioration. Oxidation of lead films, however, was more rapid. The experimental film designated Pb I was exposed to the atmosphere for approximately 5 h while Pb II was exposed approximately ½ h. In order to determine the durability of lead films and the extent of deterioration produced by atmospheric exposure while preparing for an experiment, measurements have been made of the transmission of 0.9-μ radiation through a lead film of about 180-Å thickness, as a function of the duration of exposure to the atmosphere. The results may be roughly interpreted as a decrease in thickness of the metallic film due to oxidation, resulting in decreased reflection and increased transmission. We assume that Z, the impedance per square, is inversely proportional to d, the film thickness. Then, for transmission $T\ll1$, $T\sim Z^2\sim1/d^2$. On this basis, during the period between 15-min and 2 h after the beginning of exposure to the atmosphere, Δd was ~7 Å. After one day Δd was ~20 Å, and the oxidation of the film proceeded at ~7 Å per day for the next week. Now, PbO is a semiconductor, not an insulator as the above analysis has assumed; also, the estimation of d_0 from the weight of the evaporated Pb charge may be somewhat in error. Nevertheless we may safely conclude that the atmospheric oxidation of the Pb films used in our experiments was of negligible importance.

III. EXPERIMENTAL RESULTS AND ANALYSIS

A. Electron Mean Free Path

An estimate of the electron mean free path Λ_e in the experimental films will be useful in the interpretation of our data. According to BRT[13] the mean free path of the electronic excitations is unaffected by the transition to superconductivity. We may determine Λ_e in the normal state from the relation for thermal conductivity $K_n=\frac{1}{3}C_{en}v_F\Lambda_e$ where the electronic specific heat $C_{en}\approx4\times10^{-4}\times T$ cal/mole-deg for both tin and indium,[19] and $v_F\approx10^8$ cm/sec is the Fermi velocity. A direct measurement of K_n is impractical because of the dominant thermal conductance of the glass substrate. It is possible, however, to determine experimentally the ratio of the thermal conductivity of the films to that of the substrate and combine this information with published values of the thermal conductivity of glass, K_{gl}, in order to find K_n. We will denote by r the fractional change in the total conductance of the film plus substrate combination when the film is driven into the normal state by a field $H\geq H_c$. The quantity r is measured experimentally as the change in the thermometer bridge balance position upon application of $H\geq H_c$ (i.e., the total "signal") divided by the shift in bridge balance position resulting from increase in the bridge power in-

put from a small value up to the full operating current. When r is combined with the published values[20] of the temperature dependent ratio K_s/K_n of the thermal conductivities of the superconducting and normal states,[16] and with d and D, the thickness of the film and of the substrate, we may determine $K_n/K_{gl}=rD/(1-K_s/K_n)d$. Then $\Lambda_e=3K_n/C_{en}v_F$. The thermal conductivity of the glass, K_{gl}, needed in this calculation, is estimated from a value[19] of $K_{gl}=5\times10^{-4}$ W/cm-deg at 2°K, and the assumption that $K_{gl}\sim T^{1.3}$ at liquid-helium temperatures.[21] The resulting values for K_{gl} were used in the computation of the Λ_e values quoted in Table III.

TABLE III. Data leading to estimates of electronic mean free paths Λ_e in the experimental films. Symbols are defined in text. In all cases thickness of glass substrate $D=0.11$ mm.

Sample	d (Å)	T (°K)	Heater power (μW)	r	$\frac{K_s}{K_n}$	K_{gl} (mW/cm-deg)	K_{gl}' (mW/cm-deg)	Λ_e (Å)
SnII	2600	1.2°	0.09	0.2	0.1	0.26	0.11	600
SnIII	700	1.2°	0.08	0.046	0.1	0.26	0.07	500
InII	1600	1.7°	0.3	0.07	0.39	0.40	0.18	600
		1.8°	0.1	0.07	0.45	0.40	0.20	600
		2.1°	0.22	0.11	0.61	0.55	0.73	1600
		2.14°	0.85	0.07	0.64	0.58	0.5	800
InIII	650	1.25°	0.14	0.05	0.16	0.26	0.2	600
		1.7°	0.11	0.07	0.33	0.40	0.12	1000
		2.1°	1.3	0.016	0.65	0.55	0.58	600
InIV	4000	1.2°	0.09	0.41	0.14	0.26	0.26	800
		2.1°	1.3	0.10	0.67	0.55	0.44	600

[a] From Ref. 16, p. 83, Fig. 29.

Note that Λ_e has a value of 600–900 Å, and seems to be constant with increasing film thickness between 650 Å (InIII) and 4000 Å (InIV). This indicates that Λ_e is limited by imperfection and impurity scattering rather than boundary scattering in these films. In either case, Λ_e would be independent of temperature. Thus, the range of calculated values of Λ_e at different temperatures in the same film gives an indication of the lack of precision in the determination of Λ_e.

Phonon scattering of the electrons is negligible in our films. The phonon-limited K_{eg} would be $2.56\times10^3/T^2$ W/cm-deg in tin, according to the compilation of Klemens.[22] From $K_e=(1/3)\gamma T v_F\Lambda_e$ we may calculate at 1.2°K, $\Lambda_{eg}\approx0.4$ cm, and at 2.1°K, $\Lambda_{eg}\approx0.075$ cm.

An independent experimental estimate of the thermal conductivity of the glass substrate, K_{gl}', also listed in Table III, was made from the power input to the heater, the resulting temperature change in the thermometer resistance, and the approximate dimensions of the substrate. We ascribe the difference between K_{gl} and K_{gl}' at the lower temperatures to poor calibration of the thermometer resistance as a function of temperature. This calibration does not affect the normalization or interpretation of the experimental data; it was used only in the computation of K_{gl}' and in the estimation of the temperature difference between the ends of the film during the experiments (Table I).

B. Temperature Variation of H_c/H_{cb}

We note an increase in H_c/H_{cb} with temperature in all of the experimental films, (see Figs. 2, 5–8). This may be anticipated as a result of the increase in λ with temperature, since H_c/H_{cb} is determined by the ratio λ/d. The effect has been studied in detail by Appleyard *et al.*[23] and by Alekseyevsky[24]; their results are discussed by Shoenberg.[16] Our measurements of H_c are limited to temperature $T<0.7\ T_c$ where the changes of λ are relatively small, and our results are only of sufficient accuracy to show an agreement in sign and order of magnitude with the expected effect. Our results fall between $(H_c-H_{cb})/H_{cb}\sim\lambda(T)\sim[1-(T/T_c)^4]^{-1/2}$, which applies for thick films ($d\gg\lambda$), and $H_c/H_{cb}(T)\sim[1-(T/T_c)^2]^{1/2}$, predicted by Pippard[25] for very small specimens.

Pippard[25] and Ginzburg[6] have predicted substantial superheating and supercooling effects in films a few penetration depths thick. In several experiments we approached the transition from above and also from below and found no detectable hysteresis. This may be a result of the thermal gradient along our films, or of their crystalline imperfection.

C. Behavior of Very Thin Films

The results of our experiments are easiest to interpret in the case of very thin films ($d<\lambda$). The applied field penetrates almost uniformly, and ϵ_0 is also expected to be essentially uniform.

Figure 2 shows results for thin (~700 Å) films of tin and indium. For both metals, the thermal conductivity K increases nearly as H^2 up to the critical field, the thermal conductivity in the superconducting state joins smoothly onto the field-independent conductivity of the normal metal. The location of the shoulder at this point fixes H_c for the pruposes of normalizing the data. The absence of any discontinuity at H_c indicates that the superconducting transition in a magnetic field is second order for films of this thickness, in contrast to the first-order transition of bulk superconductors in a field. In other words, since K is related

[20] For tin and indium, K_s/K_n as a function of T/T_c, measured in bulk samples, is in good agreement with the theoretical calculation of BRT for the case of electronic thermal conductivity with lattice-defect scattering dominant. Boundary scattering would give essentially similar results. In the films we have studied, even if we neglect defect scattering, the electronic mean free path would be limited by boundary scattering to a few thousand angstroms at most, and thus we can have considerable confidence in the applicability of the experimental and theoretical bulk metal values of K_s/K_n.

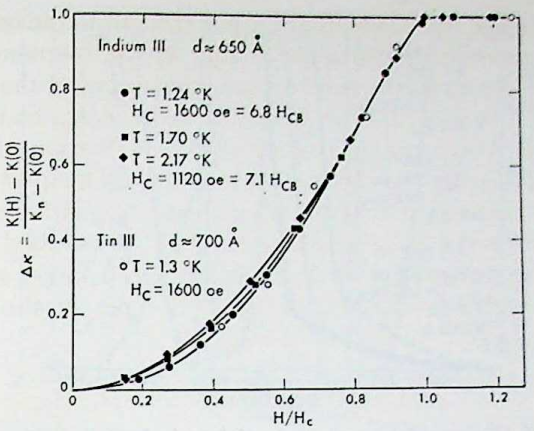

FIG. 2. Change of thermal conductivity of thin superconducting films with field. Note that the phase transition is of second order for films of this thickness.

directly to the gap width, we can infer that the gap closes continuously to zero when a field is applied to a thin film, whereas in a bulk sample it drops discontinuously from nearly the full value (~98% even at the surface) to zero.

The measured dependence of K upon H may be used to compute a dependence of the energy gap upon field in a simple way if the electronic term K_e is primarily limited by scattering of electrons by lattice imperfections. Under these conditions the ratio of the thermal conductivity in the superconducting state K_{es} to that in the normal state K_{en} is given by Bardeen, Rickayzen, and Tewordt[13] as their Eq. (3.6). This may be written

$$\frac{K_{es}}{K_{en}} = G(\epsilon_0/kT) = \int_{\epsilon_0}^{\infty} E^2(\partial f/\partial E)dE \Big/ \int_0^{\infty} E^2(\partial f/\partial E)dE,$$

where $f(E/kT)$ is the Fermi function. The function $G(\epsilon_0/kT)$ is plotted in Fig. 3. If we assume that the effect of a field upon the superconducting state can be adequately represented as a change of the ϵ_0 of BCS, then the observed quantity $\Delta\kappa$ plotted in Fig. 2 should be given by

$$\Delta\kappa = \frac{K_{es}(H)-K_{es}(0)}{K_{en}-K_{es}(0)} = \frac{G[\epsilon_0(H)/kT]-G[\epsilon_0(0)/kT]}{1-G[\epsilon_0(0)/kT]}.$$

This relation was used to invert the experimental data on indium III, point-by-point, to yield $\epsilon_0(H)$, with the result shown in Fig. 4. Because $G(\epsilon_0/kT)$ initially drops only cubically as ϵ_0/kT increases from zero (see Fig. 3), the gap must drop more steeply to zero near H_c than the approach of $K_{es}(H)$ to K_{en} there. A rather steep final drop $\sim(H_c-H)^{1/2}$ in the gap near H_c is necessary to reproduce the almost linear approach of K_{es} to K_{en} observed at that point.

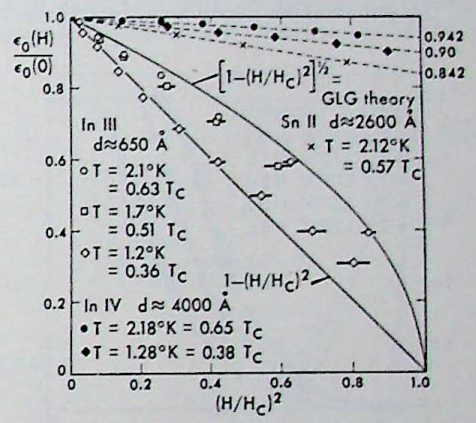

FIG. 4. Magnetic field dependence of superconducting energy gap for several tin and indium films computed from the data in Figs. 2, 6, 7, and 8, assuming that the energy gap is independent of position in the film. The curve $[1-(H/H_c)^2]^{1/2}$ is that given by the GLG theory in the limit of very thin films.

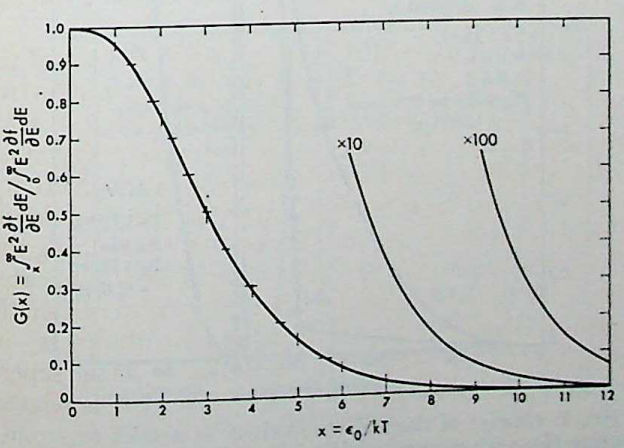

FIG. 3. The function $G(\epsilon_0/kT)$ relates the normalized thermal conductivity to the energy gap, according to the theory of Bardeen, Rickayzen, and Tewordt.

The difficulty of distinguishing between a broadened transition because of film inhomogeneity and a truly rounded approach to K_{en} because of the form of $G(\epsilon_0/kT)$ results in an uncertainty in the choice of H_c. The bars on the plotted experimental points in Fig. 4 indicate the size of this uncertainty.

Our results for the dependence of the energy gap upon magnetic field in a thin film are qualitatively similar to those from the more direct tunnel experiments of Giaever and Megerle[1] and of Douglass,[2] although their data were taken at higher reduced temperature and in a different metal (aluminum). From our data shown in Fig. 4, we see that $\epsilon_0(H)/\epsilon_0(0)$ seems to approach $1-h^2$, where $h=H/H_c$, at low temperatures, but it is moderately well fitted at $T/T_c=0.63$ by $(1-h^2)^{1/2}$. The latter form is that given by Douglass[4] based on the Ginzburg-Landau-Gor'kov (GLG) theory, which is expected to hold near T_c. We also note that our data at $T/T_c=0.36$ deviate from $1-h^2$ and approach $(1-h^2)^{1/2}$ when the gap has dropped so that $\epsilon_0(H)<kT$. This behavior indicates that the GLG approach becomes successful, as expected,

when there is a large amount of thermal excitation present.

We may find the approximate value of d/λ for In III from the GLG theory. Ginzburg[6] has shown that the solution of the Ginzburg-Landau equations, in the limit $d<\lambda$, leads to $H_c=(24)^{1/2}(\lambda/d)H_{cb}$. For In III, $H_c/H_{cb}\approx 7$, so that $d\approx 0.7\lambda$. The sevenfold increase in critical field over the bulk value shows that the field penetration must be very nearly complete, so that we are in this case observing the effect of a field in the thin film limit.

D. Behavior of Thicker Films

The film indium II (Fig. 5) of intermediate thickness $d\approx 1800$ Å, is still thin enough to display a second-order transition, but the increase of K near H_c is much faster than H^2. This behavior may be explained in terms of an increase of the penetration depth λ as the gap decreases,

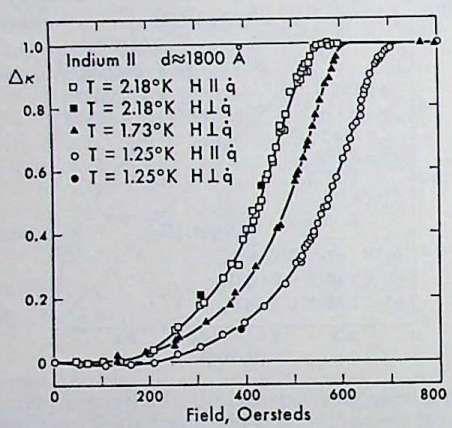

FIG. 5. Change of thermal conductivity of a superconducting film of intermediate thickness with magnetic field.

as would be expected on the basis of sum-rule arguments.[26] Since the film thickness is comparable to the electron mean free path (≈ 600 Å in this sample according to Table III) which determines the coherence length ξ, we expect the energy gap to be only weakly dependent on position in the film. We may then apply the approach of Pippard,[25] considering the balance between condensation energy and magnetic energy to determine the gap (or order parameter) as a function of field. Taking into account the dependence of film susceptibility on (d/λ) and the dependence of λ on ϵ_0, one is led to expect a change in the form of $\epsilon_0(H/H_c)$ of the observed sense for films with $d>\lambda$. A similar conclusion follows from the GLG theory, as discussed by Douglass.[4]

In Fig. 6 we see the experimental results on a moderately thick film, tin II. The data taken at 2.12° shows a variation of K with H which is purely quadratic (within 1%) up to the critical field. At this point $\Delta\kappa=24\%$. With a further increase of field, K increases rapidly

[26] M. Tinkham and R. A. Ferrell, Phys. Rev. Letters 2, 331 (1959).

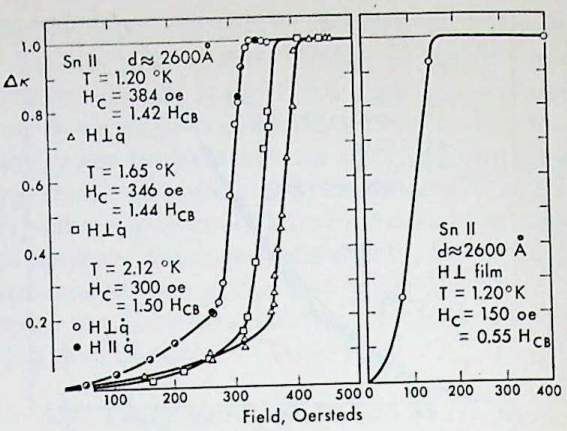

FIG. 6. Change of thermal conductivity of a 2600-Å tin film with magnetic field at various temperatures. Because of poor temperature stabilization, we have little confidence in the 1.20 and 1.65°K curves except for the determination of critical fields. The right-hand curve is for H perpendicular to the film plane.

up to the normal-state conductivity. The breadth of the transition can be accounted for partly, but not completely, by the difference in temperature of the ends of the film. We do not have much confidence in the 1.2 and 1.65° curves, except for the points which determine the transition, because the temperature stabilization was poor during those particular runs.

When we apply our method for calculation of the energy gap as a function of field to the 2.12° data, assuming a uniform gap throughout the film, we find the energy gap decreasing exactly as H^2 to $\epsilon_0(H)/\epsilon_0(0)=0.842$ at the critical field (Fig. 4). If we apply the GLG theory we find that the observed critical field ratio $H_c/H_{cb}=1.50$ implies that $d/\lambda=3.6$ and $\epsilon_0(H_c)/\epsilon_0(0)=0.78$. The agreement with the above value of 0.842 is quite good considering that at H_c the gap in the interior of the film should be depressed somewhat less than that at the surface, because in this film the coherence length is limited by Λ_e to a value less than the film thickness.

We next consider the data for In IV (Figs. 7, 8, 9, 10).

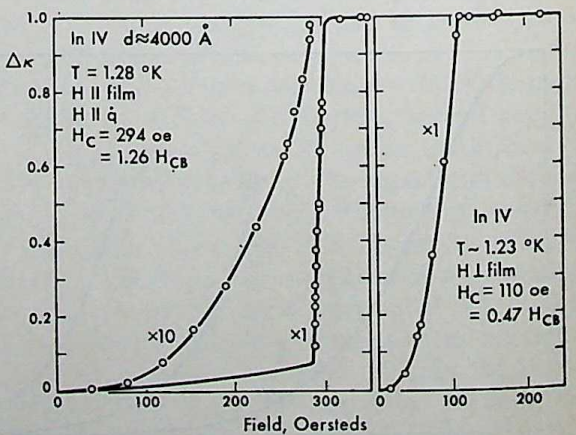

FIG. 7. Change of thermal conductivity of a thick superconducting film with magnetic field, at $T\approx 0.38\ T_c$. The first points are shown on an expanded scale for greater clarity. At the right is the result of applying the field perpendicular to the surface of the film.

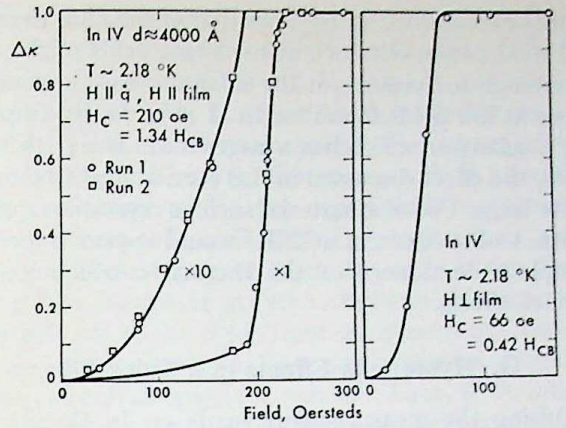

FIG. 8. Change of thermal conductivity of a thick superconducting film with magnetic field, at $T \approx 0.64\ T_c$.

Because of the large film thickness the change in thermal conductivity does not exceed about 10% up to the critical field, and the calculated energy gap variation assuming ϵ_0 is independent of position, i.e., $\xi \gg d$ (Fig. 4) is correspondingly small. The numbers at the right-hand margin of Fig. 4 are found by extrapolating the computed values of the energy gap to H_c at the points shown. These points fall almost exactly on straight lines until we reach the transition region, so we may be confident of the extrapolation. There seems to be a very slight curvature to the $0.38\ T_c$ curve, probably reflecting a trace of the peculiar hysteresis effects which are so prominent in this sample with a field orientation **H** perpendicular to $\dot{\mathbf{q}}$, the direction of heat flow (Figs. 9, 10).

E. Initial Decrease of $\Delta\kappa$

In indium II (Fig. 5) at the lowest temperature we see an apparent initial decrease of thermal conductivity with field. This may be a spurious effect arising from a slow approach to the equilibrium distribution of any trapped flux. We note from Table III that the heater power in our experiments is only about 10^{-6}–10^{-7} W and that r, the total change in thermal conductance of the metal and glass-sample sandwich with magnetic field is between 5 and 40%. Thus, evolution of heat at a rate of only 10^{-10} W (<4 erg/h!) when the field is applied could produce a spurious effect of 1% of the total. Such an evolution of heat could result from induction heating of the film during a slow approach to the equilibrium distribution of trapped flux. In many cases during the experiments, a small effect with a time constant on the order of minutes was noticed in addition to the ordinary thermal relaxation time constant, when the field was increased. This effect did not appear upon decreasing the field or upon increasing H from zero to a value previously exceeded. If indeed this is related to a slow approach to equilibrium in the flux distribution and associated induction heating, the sign of the bridge unbalance produced by the heating would give an apparent depression of $\Delta\kappa$, consistent with the sign of the observed effect.

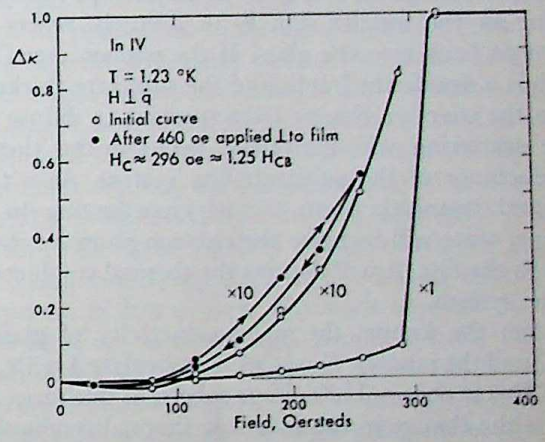

FIG. 10. Hysteresis effects observed in a thick superconducting film.

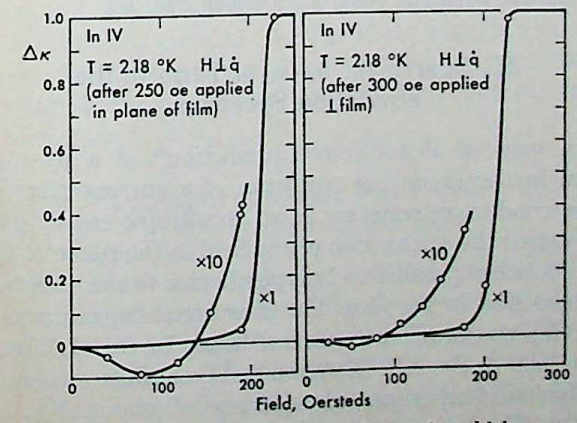

FIG. 9. Change of thermal conductivity of a thick superconducting film with magnetic field applied perpendicular to $\dot{\mathbf{q}}$, the direction of heat flow. At the right, the effect of prior exposure of sample to a large field perpendicular to the film is shown.

Another possible explanation of the long time constant term is heat released during adsorption of helium gas on the thermometer or sample surface when the equilibrium temperature of the heater-thermometer changes. It would be difficult, however, to explain the absence of the effect with decreasing field on this basis.

Yet another explanation might be depression of phonon conductivity by scattering from excitations as the gap decreases. It may be easily shown that the phonon conductivity of the experimental films, if we neglect the substrate, is very small in comparison with the electronic contribution.[27] However, diffuse scattering of the substrate phonons by the electronic excitations in the film when the substrate phonons cross the boundary into the film may lead to an effective "modu-

[27] $K_{\text{electron}} = \frac{1}{3} C_e v_F \Lambda_e$ while $K_{\text{phonon}} = \frac{1}{3} C_p v_p \Lambda_p$. C_e and C_p are comparable in the range 1–4°K in lead, tin, and indium, while $v_F/v_p \approx 10^2$. If $\Lambda_e \approx \Lambda_p \approx d$, then $K_p/K_e \approx 10^{-2}$.

Digitized by Arya Samaj Foundation Chennai and eGangotri

lation" of the phonon conductivity of the substrate. The resultant effect may be comparable to that of the electronic thermal conductivity of the film. This possibility is examined in the following section.

F. Modulation of Phonon Conductivity of Dielectric Substrate

The wavelength of thermal phonons in glass at 1°K is approximately 2000 Å. Thus we may expect almost perfect specular reflection at the optically polished surfaces of our film substrates. Thermal phonons at 1°K have $\nu \approx 1/400$ of the Debye cutoff frequency, and therefore behave essentially as ordinary ultrasonic phonons. Experiment and theory indicate that the acoustical match between quartz and indium is quite good and leads to less than 1% reflection. Therefore, thermal phonons from the glass substrate pass quite freely into an indium surface film. Neglecting electron-phonon scattering in the film, the phonons will be specularly reflected at the smooth film-vacuum surface, and pass back into the glass. The effect of electron-phonon scattering in the indium film is to diffusely reflect the phonons back into the glass. If the phonon mean free path is a significant fraction of the substrate thickness, then the effective change from specular to diffuse surface scattering will materially decrease the thermal conductance of the substrate-film system. As a field-induced transition from the superconducting to the normal state will increase the electron-phonon interaction in the film, it will depress the thermal conductance of the system.

From the known thermal conductivity of glass at 2°K, and the relation $K=\frac{1}{3}Cv\Lambda$, we calculate $\Lambda \approx 5\times10^{-4}$ cm. This is only $\sim 1/20$ of our substrate thickness, and limits the change in the substrate thermal conductance which may be produced by surface scattering to less than $\sim 5\%$.

The degree of diffuse phonon scattering in the film depends, of course, upon the size of Λ_{pe}, the phonon mean free path as limited by electron scattering, compared with the film thickness. We may estimate Λ_{pe} by using the principle of detailed balance and the measured values of K_{ep}, the phonon-scattering limited electronic thermal conductivity, and its temperature dependence. Kittel[19] has done this in the high-temperature limit. Carrying out a similar analysis in the low-temperature limit, one finds $\Lambda_{pe} \approx 10^{-5}$ cm for tin and 10^{-6} cm for lead at 1.2°K. Since our experimental films range from 5×10^{-6} to 4×10^{-5} cm in thickness, substantial diffuse scattering of phonons may occur within the film in the normal state. When the film becomes superconducting, this diffuse scattering will nearly vanish, since most of the electrons in a superconductor at temperatures far below T_c are in the superconducting ground state and thus unable to scatter phonons. Even though the total modulation of the conductance of the substrate is limited to 5% in our case, since the substrate conductance is typically 2 to 10 times that of the film, the partial modulation obtained at moderate fields might well be enough to account for the small decrease in conductance at low fields found for In II (Fig. 5). By employing a substrate which has a larger mean free path than glass, the effect discussed in this section might be made quite large. Use of a material such as crystalline quartz (with Λ of several cm at 2°K) would appear to permit complete dominance of the thermal conductance by surface effects.

G. Hysteresis Effects in a Thick Film

During the measurements made on In IV ($d=8\lambda$) rather peculiar hysteresis effects were observed (see Figs. 9 and 10). These effects appeared only when $\mathbf{H}$ was perpendicular to $\dot{\mathbf{q}}$, the direction of heat flow. There was no detectable hysteresis when $\mathbf{H}$ was parallel to $\dot{\mathbf{q}}$, nor was any comparable hysteresis observed in any experiments with the other (thinner) experimental films. We consider the most reasonable explanation to be scattering of the heat-carrying electronic excitations at normal-superconducting boundaries.

We may assume that field inhomogeneity and film curvature make necessary small normal-state strips to carry flux through the film. If the super and normal regions have the shape of narrow lamina lying parallel to the direction of $\mathbf{H}$, then when $\mathbf{H}\perp\dot{\mathbf{q}}$ a large number of interfaces would obstruct the heat flow when a moderate field is applied.[16] Hysteresis would be a result of trapped flux affecting the arrangement of domains. Saturation of the film with trapped flux by application of a large field perpendicular to the film surface before a measurement will ensure that the maximum amount of scattering at S-N boundaries occurs before the measurement field is applied. This procedure does appear to suppress the initial decrease of $K(H)$, as we see in Fig. 9. Following saturation of the film with trapped flux, application of a subcritical field parallel to the plane of the film would sweep out some of the previously trapped flux and partially restore the original behavior, consistent with the results shown in Fig. 10.

H. Search for $p_F \cdot v_{drift}$ Term in the Excitation Spectrum

In view of Bogoliubov's prediction[14] of a $\mathbf{p}_F \cdot \mathbf{v}_{drift}$ term in the excitation spectrum of a current-carrying superconductor, resulting in an anisotropic energy gap, we varied the orientation of the field in the plane of the film between parallel and perpendicular to the direction of heat flow in the film. The directional dependence of $\Delta K(H)$ was studied in several films. In tin II, Fig. 6 ($d=2600$ Å, $T=2.12$°K, $\Lambda_e \approx 600$ Å), no effect was found within the experimental accuracy of about 1%. In indium II, as may be seen in Fig. 5, the result is not so clear-cut. Nevertheless, the apparent deviation of the $\mathbf{H}\perp\dot{\mathbf{q}}$ points from those for $\mathbf{H}\|\dot{\mathbf{q}}$ is not of significant

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

magnitude, and the deviations may be explained by poor control of the alignment of $\mathbf{H}$ in the plane of the film during the experiments. An experiment was conducted at 2.1°K on film Pb I, which was similar to Pb II (Fig. 11) except for an unexplained initial negative portion of its $\Delta\kappa(H)$ curve. The curves with $\mathbf{H}\perp\hat{\mathbf{q}}$ and $\mathbf{H}\parallel\hat{\mathbf{q}}$ were identical within the experimental uncertainties, except for a shift in H_c probably arising from a difference in the accuracy of alignment of H in the plane of the film. Since the induced diamagnetic currents are orthogonal to the field, these measurements also show the absence of a dependence on the angle between heat current and diamagnetic current. Thus, if we interpret our results in terms of a decrease of the energy gap with increasing field, the modified gap appears to remain essentially isotropic. Of course, even if there were a $\mathbf{p}\cdot\mathbf{v}$ term, first-order effects would cancel in a transport property such as K, which involves an average of excitations over the entire Fermi surface. However, as the change of ϵ_0 with H approaches 100%, noncancelling second-order effects would be expected to appear, and these would be expected to differ by a factor of several for the parallel and perpendicular cases, because of a different angular average. Thus, another factor must enter to explain the lack of anisotropy. It may well have to do with the fact that in these films, the two equal and opposite surface currents are separated by a distance comparable to ξ_0. Alternately, the short mean free path ($\sim$800 Å) in these samples would be expected to average out anisotropies as in the dirty superconductor theory of Anderson.[28] Both of these characteristics of the experimental situation contrast strongly with the Bogoliubov idealization, which corresponds to a spatially uniform current arising from a displaced sphere of momentum eigenfunctions characteristic of an ideal sample.

The apparent lack of anisotropy is important in evaluating the results of tunnel effect measurements on the magnetic field dependence of the energy gap since, for specular tunneling, this method determines the energy gap normal to the surface of the film, this direction being perpendicular to the directions of both the applied magnetic field and the induced current. This directional aspect of the tunneling experiment would also interfere with any attempt to observe the $\mathbf{v}\cdot\mathbf{p}$ effect in the presence of an externally introduced uniform current flow.

I. Magnetic Fields Not Parallel to the Surface of the Film

We have measured the thermal conductivity of several of our experimental films with field intentionally applied at an angle to the surface. The results were quite striking and unexpected.

Tin II and indium IV are films thick enough to show first-order transitions in fields parallel to the surface; that is, the energy gap is only slightly depressed from its zero field value even just below the transition. This may be seen by inspection of Fig. 4. Application of a field perpendicular to the film might be expected to produce an intermediate state configuration with the fraction of the material in the normal state approximately given by H/H_c.[29] Thus, we might expect $\Delta\kappa(H)$ to increase linearly from zero at $H=0$ to 1.0 at $H=H_c$, although the curve might "sag" somewhat as a result of both additional scattering of the electrons at S-N boundaries and the partial flux penetration of the superconducting regions.

Our measurements contrast strikingly with the above prediction. As we see in the right-hand portions of Figs. 6–8, $\Delta\kappa(H)$ apparently increases exactly as H^2 up to the normal-state value, which is reached in these samples at a field between 42% and 55% of the bulk critical field. Our results suggest that the transition is essentially complete when $K(H)$ first reaches K_n, as there is no change in K with further increase of H (see Fig. 7).

A possible explanation of the above behavior lies in the fact that for these films d is comparable with λ, ξ_0, and Λ_e, in contrast to the usual case of a thick plate in the intermediate state with a transverse field. In the latter case the superconducting and normal domains are arranged as thin lamina parallel to the field in order to minimize the free energy.[16] This is not possible in our thin film samples, since domains shaped as thin lamina parallel to the field would require adjacent S-N boundaries to be closer together than a coherence length ξ_0, and this would contribute an excessively large positive term to the free energy. We might suppose that, when our films are in a moderate magnetic field, the superconducting domains are blunt lamina whose width is determined so as to minimize the sum of the free energy terms arising from the demagnetizing factor of a blunt superconducting domain and from close spacing of the S-N domain boundaries.[30] On general grounds, one might expect an array of vortices[31] about normal lines to be more favorable energetically than lamina involving normal surfaces. Such a structure would have qualitative properties very similar to the laminar structure.

We have measured $\Delta\kappa(H)$ for Pb II with the field applied at angles θ of 0, 1.3 ($\pm$0.4), 5, 10, 20, and 90° with respect to the plane of the film at $T=2.16°$, as

[28] P. W. Anderson, Phys. Chem. Solids 11, 26 (1959).

[29] This is expected because the field at a superconducting-normal interface in a bulk sample must be equal to H_c; then H will be close to H_c throughout the small normal domains, while in the interior of the superconducting domains $H\approx 0$ (if the domains are much larger than the penetration depth λ). Thus, the flux HA which passes through area A of the film penetrates normal regions of total area $A_n=HA/H_c$.

[30] Since our domains will have dimensions of the same order as the coherence length, the energy gap may be nonzero nearly everywhere. In this case we may imagine the energy gap to oscillate as a function of position, with the magnetic flux density being greater in the regions where the gap is small. The remainder of the argument is qualitatively unchanged.

[31] M. Tinkham, Phys. Rev. 129, 2413 (1963).

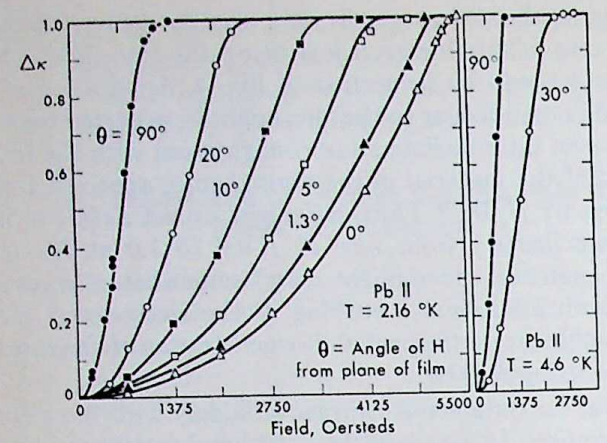

FIG. 11. Change of thermal conductivity of a superconducting lead film with the field applied at various angles with respect to the plane of the film.

well as at 0, 30, and 90° for $T=4.5°$. The results are shown in Fig. 11. We see that as θ is increased from zero the apparent critical field decreases, but the transition appears to remain well defined. The general shape of $\Delta\kappa(H)$ does not change rapidly with θ, but for large θ, $\Delta\kappa(H)$ becomes more nearly linear in H. At $\theta=90°$, the apparent critical field has decreased to a value of the order of H_{cb}.

An attempt has been made to fit the experimental values of $H_c(\theta)$ with various analytical interpolation functions. These are based on the assumption that the parallel and perpendicular components of the magnetic field produce additive contributions to the free energy, and that when the sum of these effects reaches a critical value the film is driven normal. Assuming the contributions to the energy to increase as simple powers of the components of the field, this leads to a form

$$\left(\frac{H_c\cos\theta}{H_{c\parallel}}\right)^m+\left(\frac{H_c\sin\theta}{H_{c\perp}}\right)^n=1.$$

Since magnetic field energies normally are proportional to H^2, one might expect that $m=n=2$. However, this gives a very poor fit at small angles. In fact, a considerably better fit was found to result from the choice $m=n=1$. Subsequently, it was shown[31] by detailed consideration of the vortex model for the perpendicular field case that one would expect $n=1$, but $m=2$. A comparison of the degree of fit of these three interpolation formulas to the critical field data on Pb II has been given previously.[31] A similar comparison with data of White on a thin indium film has also been given.[32] Both of these comparisons favor the theoretically based function, with $m=2$ and $n=1$.

J. Behavior of Thin Lead Films

As we have discussed previously, the predictions of the GLG theory fail at low temperatures. The low-temperature limiting behavior of $\epsilon_0(H)/\epsilon_0(0)$ would be of interest in guiding theoretical efforts. Since facilities for producing stabilized temperatures below 1.2°K were not available to us, experiments were undertaken on lead since 1.2°K equals only 0.18 T_c for this metal. Our detailed results are not easy to interpret and may be a reflection of the peculiarities of superconducting lead, rather than characteristic of superconductors in general. However, we may assert with some confidence that the superconducting transition in a field is of second order for thin films ($d<\lambda$) over the range of temperatures from 0.63 T_c at least down to 0.18 T_c. This conclusion follows from the observed absence of any discontinuity in $\Delta\kappa$ at H_c, as was discussed in Sec. IIIC.

Experimental results for Pb II, a lead film about 500 Å thick, are shown in Fig. 12. Another film,[33] Pb I, gave similar results except for an unexplained initial decrease in $\Delta\kappa$ which appeared at 4.2, 2.1, and 1.2°. The initial decrease of $\Delta\kappa$ for Pb I at 2.1°K was the same for $\mathbf{H}\perp\dot{\mathbf{q}}$ and $\mathbf{H}\|\dot{\mathbf{q}}$. Because of this divergence of results between Pb I and Pb II, we have less confidence in the data in the low-field region than we have near H_c. In Fig. 12, the rounded approach of the 4.5° data to the normal-state conductivity may be accounted for quantitatively by the 0.6° temperature drop along the film, and the consequent 15% critical field spread (Table I). In contrast, at 2.16 and 1.27° the critical field spreads are small (see Table I), and the rounding of the curves at the transition results from the form for small ϵ_0/kT of the G function (Fig. 3) connecting K and ϵ_0/kT, as discussed in the analysis of the In III data.

If we naively invert the data of Fig. 12 point-by-point in the usual manner we find the apparent relations between ϵ_0 and H which are given in Fig. 13 for the various temperatures. At each temperature, the upper curve follows from assuming the zero-field gap

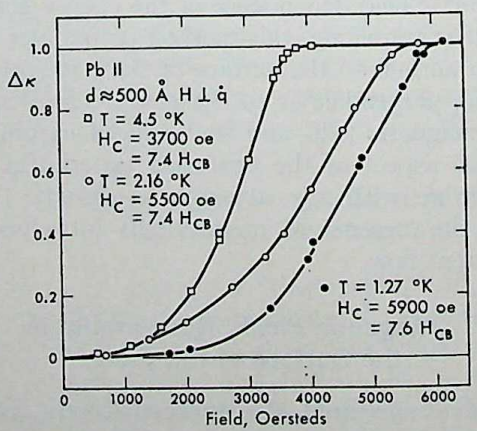

FIG. 12. Change of thermal conductivity of a superconducting film with magnetic field at several temperatures.

[32] M. Tinkham, Rev. Mod. Phys. **36**, 268 (1964).

[33] This film was prepared in a similar manner to Pb II, and has a similar critical field, but it was exposed to the atmosphere for 5 h before mounting, compared to an exposure of ½ h for Pb II. However, we expect that this duration of exposure would have produced negligible oxidation (Sec. IIF).

value based on the BCS result $\epsilon_0=1.75\ kT_c$ at $T=0°K$. If we take instead the value 2.1 kT_c as suggested by several experiments[34–36] the lower curves result.

If one were to take Fig. 13 at face value, one would be forced to conclude that the variation of ϵ_0 with H is different in lead and indium at the same reduced temperature $t(=T/T_c)$. Although the 4.5° lead curve and 2.1° indium curve (Fig. 4), both with $t\approx\frac{2}{3}$, seem to be consistent with the GLG result $\epsilon_0(H)/\epsilon_0(0)=[1-(H/H_c)^2]^{1/2}$, we see that lead at 2.16° seems to be incompatible with indium at 1.2° even though the reduced temperatures are nearly the same ($t\approx0.35$). It is just possible that the experimental curves for Pb II reflect some spurious effect of the sort that produced the initial negative curve for Pb I, although the deviation would have to be of opposite sign from that observed in Pb I in order to make the Pb II and In III results compatible. Inversion of the Pb I data produces an $\epsilon_0(H)/\epsilon_0(0)$ versus H^2 curve with the same qualitative deviation from the indium curve, once the field is greater than about $(H/H_c)^2=0.3$, [so that we are well above the region where $K(H)$ decreases from the zero-field value].

An alternative, and probably more sound, explanation of the discrepancy is that the relation derived from BRT which we have used to connect the thermal conductivity variations with changes in the energy gap is not completely valid, at least in the case of lead.

It is well known that the thermal and electrodynamic properties of lead and mercury deviate considerably from the law of corresponding states. It has not been possible to accurately test the applicability of Sec. 3 of the BRT theory to these metals, because phonon scattering contributes to the thermal resistance as a result of the low values of θ_{Debye}. But, since $K_e=\frac{1}{3}C_e v_F\Lambda_e$ and the experimentally determined[37] $C_e(T)$ is different from that predicted by BCS, on which the BRT theory is based, we may expect that the BRT calculation will not account satisfactorily for the thermal conductivity of lead and mercury.

Upon comparison of Figs. 4 and 13, we note that if the effective value of the energy gap of lead were to decrease from the usual value at 4.5° to about 1.4 kT_c at 2.16° and about 1.0 kT_c at 1.27°, both of the low curves for lead could be made to coincide with the 1.3° indium III curve. This suggests that we might combine the $\Delta\kappa(H)$ curves of Pb II with the $\epsilon_0(H)/\epsilon_0(0)$ result found for In III at 1.3°, and find the function $G_1(x)$ which would be necessary to connect them. If we now subtract $G(x)$ from $G_1(x)$, we find that the difference, $\Delta G(x)$, is a function which is zero at $x=0$, increases to a maximum of about 0.35 for x between 4 and 6, and then decreases with further increase of x. Let us generalize $G(x)$ to include an "effective density of states"

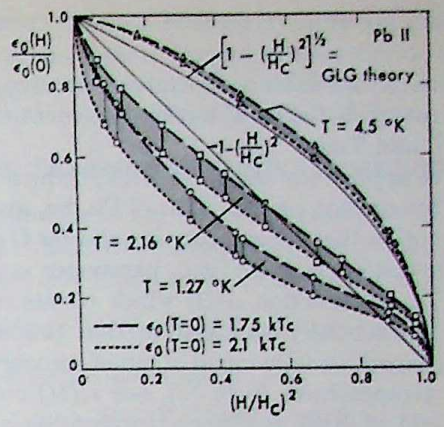

FIG. 13. Dependence of energy gap of a lead film on field as calculated from the data of Fig. 12 using the $G(\epsilon_0/kT)$ function from Fig. 3. For each experimental point, two gaps are computed as shown: one assuming the gap ($2\epsilon_0$) approaches 3.5 kT_c at $T=0$ as found by BCS; and one assuming the gap goes to 4.2 kT_c as found experimentally.

$\rho[E/\epsilon_0(H)]$. Note that this brings us completely outside the BRT theory, and thus we can have no confidence in the result except as a phenomenological description. Let

$$G_1(x)=\int_0^\infty \rho(E/\epsilon_0)E^2(\partial f/\partial E)dE \Big/ \int_0^\infty E^2(\partial f/\partial E)dE$$

and take $\rho(E/\epsilon_0)=1$ for $E\geq\epsilon_0$ (the usual BRT form). Then

$$\Delta G(x)=\int_0^{\epsilon_0} \rho(E/\epsilon_0)E^2(\partial f/\partial E)dE \Big/ \int_0^\infty E^2(\partial f/\partial E)dE.$$

We have attempted to fit $\Delta G(x)$ with several simple forms of $\rho(E/\epsilon_0)$. Within our very limited accuracy of ΔG, we find a satisfactory fit for the delta function $\rho(E/\epsilon_0)=\frac{2}{3}\delta[(E/\epsilon_0)-\frac{1}{2}]$, or for the parabolic function $\rho(E/\epsilon_0)=\frac{3}{2}(E/\epsilon_0)^2$. We emphasize that we do not take the above to be conclusive evidence for the existence of "states in the gap" of lead, or for the location of any such hypothetical states. Rather, these considerations are intended to indicate the major scale of the departure of the data on lead from that on indium at low reduced temperatures. We conclude that lead behaves in some respects differently from other superconductors even at the same reduced temperatures, but the cause is not at present fully understood.

IV. CONCLUSIONS

From the results of the preceeding sections we may draw several conclusions: First, the thermodynamic transition in a field may be quite sharp and well-defined even for films sufficiently thin (700 Å) that $H_c>7\,H_{cb}$. The thermodynamic transition appears to be reversible and without hysteresis for typical films up to 2500 Å thick. Our experiments give direct evidence that the superconducting transition is of second order in

films which are thin (compared with the penetration depth) for temperatures ranging from T_c down to 0.18 T_c, the lowest available temperature, in disagreement with the theory of Bardeen[8] but in agreement with that of Nambu and Tuan.[9]

We have applied the theory of BRT,[13] which is based on BCS, to our data on thin films of Pb, Sn, and In, on the assumption that their theory is valid for $H \neq 0$ with a suitable field-dependent gap parameter $\epsilon_0(H)$. At $T=0.65\ T_c$, the function $\epsilon_0(H)$ which results from our analysis is essentially identical to that predicted by GLG and experimentally found in tunnel measurements. At lower temperatures ($0.36\ T_c$), our $\epsilon_0(H)$ computed with the aid of BRT is different, indicating a breakdown of the GLG theory for $T \ll T_c$, or possibly a failure of the method of data analysis via BRT.

By varying the relative orientation of the direction of heat flow and the applied magnetic field in the plane of the experimental films, we unsuccessfully sought evidence for vestiges of the $\mathbf{p}_F \cdot \mathbf{v}$ term in the excitation spectrum of a current-carrying superconductor, predicted by Bogoliubov.[14] Since the experimental conditions differed radically from those envisioned by Bogoliubov, this negative result is not surprising.

Application of magnetic fields at various angles up to 90° with respect to the film plane still produced surprisingly well defined thermodynamic transitions, although H_c was reduced considerably below the parallel field value. The transition in a perpendicular field appeared to be second-order even for films of thickness up to 4000 Å, whose parallel field transition was definitely first order. The perpendicular critical field values and the angular dependence of H_c seem to be explained satisfactorily by the theory of Tinkham.[31]

Lead films gave results qualitatively similar to indium and tin films, but quantitatively the form of the derived $\epsilon_0(H)$ at low temperatures was different from that of tin and indium. We suspect that this is connected with the well-known peculiarities in the thermal properties of superconducting lead.

ACKNOWLEDGMENTS

Thanks are due to I. F. Silvera for measuring the effect of atmospheric oxidation on the optical transmissivity of our Pb films. One of us (D.M.) would like to thank Dr. K. G. Ramanathan for the hospitality of the National Physical Laboratory of India during the preparation of the manuscript.

Higher Order Coherent Raman Effects*

C. L. Tang
Raytheon Research Division, Waltham, Massachusetts
(Received 8 January 1964)

With the recently available very intense coherent maser light, interesting higher order coherent Raman effects have been observed in solids, liquids, and gases. Garmire, Pandarese, and Townes have given a phenomenological theory of these higher order coherent Raman effects. In this paper a somewhat more detailed theory of these effects is given. The analysis is based on a perturbation solution of the Boltzmann equation for the density matrix of the Raman active medium. General expressions for all the relevant induced dipole moments and absorbed or emitted Stokes and anti-Stokes radiations in the ordinary or higher order coherent Raman processes are given. These cover a great variety of possible experimental situations. Several specific simple examples are studied in some detail and the results of the phenomenological theory are reproduced from the general results given here.

I. INTRODUCTION

THE first-order Raman effects have been investigated extensively in the past both experimentally and theoretically. With the recently available very intense maser light, interesting higher order coherent Raman effects in solids,[1] liquids,[2] and gases[3] have also been observed. Garmire, Pandarese, and Townes[4] give a detailed macroscopic theory of these higher order coherent Raman effects, particularly those through excitation of intense coherent molecular oscillations at infrared frequencies. Many interesting conclusions were drawn from the theory and some of these have already been observed experimentally. In this paper an attempt is made to give a somewhat more detailed analysis of the same effects on the basis of the quantum-mechanical Boltzmann equation for the density matrix characterizing the Raman-active medium and to include in the theory the effects of various relaxation processes.

The effects of spatial dispersion[5] are not, however, explicitly taken into account in the calculations here. This may be a serious omission in some cases involving liquids and solids, but in the cases of gases it is most likely not. When spatial dispersion effects are neglected, a local description of the Raman-active dielectric medium is possible. The study of the various higher order coherent Raman effects can then be carried out in several steps.

In the first step, we consider a volume of the dielectric with linear dimensions large compared with the intermolecular spacings but small compared with the wavelengths of the interacting photons and the coherent molecular vibrational waves (or other polarization waves). Within a volume of this size, the radiation fields can be assumed coherent and uniform, and the medium can be characterized by a spatially independent density matrix. The quantum-mechanical Boltzmann equation governs the time response of the density matrix due to the applied fields. The average induced dipole moment per molecule or molecular oscillations in the medium produced in various Raman processes can be obtained from the corresponding higher order terms in the perturbation solution of the Boltzmann equation. From these one can determine the frequencies of the Raman-scattered Stokes and anti-Stokes radiations and the rate at which they are absorbed or emitted locally. In Sec. II an explicit formulation of the problem in terms of the density matrix is given along with a formal procedure for obtaining the appropriate perturbation solution.

In the second step, we consider a volume of the dielectric medium with linear dimensions large compared with the wavelengths of all the waves of interest but still small compared with the distances over which the amplitudes and phases of the waves change appreciably. The harmonic spatial dependences of all the waves can therefore be directly introduced into the various expressions obtained in the previous step. When macroscopic spatially coherent effects are considered, one assumes a fixed phase for each of the electromagnetic waves. Upon averaging the resulting expressions over such a volume, one obtains the conditions under which each Stokes or anti-Stokes radiation will be absorbed or amplified on the average. These include the so-called phase-matching conditions which give the propagation vectors of the Stokes and anti-Stokes radiations.

In the final step, one may consider questions which are only significant on dimensional scales over which the amplitudes and phases of the various waves vary appreciably. These involve questions such as energy transport, boundary effects, geometrical effects, etc.

In the present study we do not, however, go beyond the second step in any detail. The primary concern here is in the intrinsic properties of the higher order coherent Raman processes as discussed by Garmire, Pandarese, and Townes.

The above assumptions and basic steps are implicit in the calculations and discussions given below.

II. THE DENSITY-MATRIX EQUATION

We ignore first the spatial dependence in all the variables. Under the usual assumptions,[6] the quantum-mechanical Boltzmann equation for the density matrix is

$$\partial\rho/\partial t=-(i/\hbar)[H,\rho]-\tfrac{1}{2}[\Gamma(\rho-\bar{\rho})+(\rho-\bar{\rho})\Gamma], \quad (2.1)$$

where the total Hamiltonian

$$H=H_0+V=H_0-\mathbf{p}\cdot\mathbf{E} \quad (2.1a)$$

is the sum of the unperturbed Hamiltonian of the molecule, H_0, and the interaction energy of the molecules with the total electric field, $\mathbf{E}$. In a representation in which H_0 is diagonal, Γ, which characterizes phenomenologically the effects of various relaxation processes, is a diagonal matrix $\Gamma_{mn}=\gamma_m\delta_{mn}\cdot 1$, where 1 is a unit matrix with the dimensionality of the corresponding eigenvalue of H_0. The matrix $\bar{\rho}$ is diagonal, and the diagonal elements are proportional to the thermal equilibrium populations of the corresponding energy levels at a given temperature T in the absence of V, or

$$\bar{\rho}=\exp(-H_0/kT)/\mathrm{Trace}[\exp(-H_0/kT)]. \quad (2.1b)$$

$\rho(t)$ determines the average induced electric dipole moment, $\mathbf{p}(t)$, per molecule:

$$\mathbf{p}(t)=\mathrm{Tr}[\mathbf{p}\rho(t)], \quad (2.2)$$

where $\mathbf{p}$ is the electric dipole operator.

In studying Raman effects we consider three energy levels, ϵ_1, ϵ_2, and ϵ_3, of the molecules (Fig. 1) where level 1 is the ground state and level 2 could be a vibrational level, a rotational level, or an electronic level if electronic Raman effects are considered. Level 3 is the intermediate state. All these levels will in general be degenerate. For the basic first-order Raman process, it is sufficient to assume that the total electric field consists of two components:

$$\mathbf{E}(t)=[\mathbf{E}_a e^{i\omega_a t}+\mathbf{E}_a^* e^{-i\omega_a t}]+[\mathbf{E}_b e^{i\omega_b t}+\mathbf{E}_b^* e^{-i\omega_b t}]. \quad (2.3a)$$

The elements of interest in the perturbation term V of the total Hamiltonian are assumed to be:

$$\begin{aligned} &V_{1\alpha,1\beta}=V_{2\alpha,2\beta}=V_{3\alpha,3\beta}=V_{1\alpha,2\beta}=0,\\ &V_{1\alpha,3\beta}=V_{1\alpha,3\beta}^{(a)}e^{i\omega_a t}+V_{1\alpha,3\beta}^{(a)*}e^{-i\omega_a t}, \quad (2.3b)\\ &V_{2\alpha,3\beta}=V_{2\alpha,3\beta}^{(b)}e^{i\omega_b t}+V_{2\alpha,3\beta}^{(b)*}e^{-i\omega_b t}, \end{aligned}$$

for ω_a and ω_b sufficiently close to the correspond-

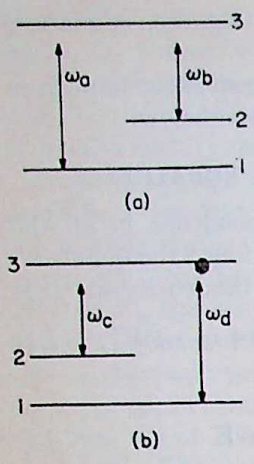

FIG. 1. Schematic diagram of energy levels and fields involved in (a) ordinary and (a), (b) higher order Raman processes.

ing transition frequencies $\omega_{31}=\hbar^{-1}(\epsilon_3-\epsilon_1)$ and $\omega_{32}=\hbar^{-1}(\epsilon_3-\epsilon_2)$, and

$$V_{m\alpha,n\beta}^{(a,b)}=-\langle m,\alpha|\mathbf{p}\cdot\mathbf{E}_{a,b}|n,\beta\rangle. \quad (2.3c)$$

In Eqs. (2.3b) and (2.3c), α and β designate the degenerate states of the energy levels ϵ_m and ϵ_n, respectively. We also assume that

$$\omega_a-\omega_b\approx\hbar^{-1}(\epsilon_2-\epsilon_1)=\omega_{21}, \quad (2.3d)$$

but ω_a and ω_b are not so near the corresponding transition frequencies that the direct processes become important.

As in the usual theory[7] of ordinary Raman effects for a single molecule, which is based on the perturbation solution of Schrödinger's equation, we obtain the steady-state solution of the Boltzmann equation (2.1) by perturbation techniques.[8] Specifically, we formally expand the elements of the density matrix:

$$\rho_{m\alpha,n\beta}=\rho_{m\alpha,n\beta}^{(0)}+\rho_{m\alpha,n\beta}^{(1)}+\cdots+\rho_{m\alpha,n\beta}^{(j)}+\cdots \quad (2.4)$$

in successive orders of approximation corresponding to ascending powers of the amplitude of the electric field. The lowest order term

$$\rho_{m\alpha,n\beta}^{(0)}=\frac{1}{T_{mn}}\int^t\exp\left(i\omega_{mn}+\frac{1}{T_{mn}}\right)\times(t'-t)\bar{\rho}_{m\alpha,n\beta}dt', \quad (2.5)$$

which would simply be equal to $\bar{\rho}_{m\alpha,n\beta}$ if the latter is purely diagonal and time-independent. In Eq. (2.5)

$$T_{mn}^{-1}=\tfrac{1}{2}(\gamma_m+\gamma_n), \quad (2.6)$$

which is independent of the degeneracy indices α and β.

The successive terms, i.e., $j\geq 1$:

$$\rho_{m\alpha,n\beta}^{(j)}=-\frac{i}{\hbar}\sum_{l,\gamma}\int^t\exp\left(i\omega_{mn}+\frac{1}{T_{mn}}\right)(t'-t)\times[V_{m\alpha,l\gamma}\rho_{l\gamma,n\beta}^{(j-1)}-\rho_{m\alpha,l\gamma}^{(j-1)}V_{l\gamma,n\beta}]dt'. \quad (2.7)$$

This series solution, (2.4)–(2.7), is formally identical to that used in the study of nonlinear interaction of oscillating modes in a gas maser, or in similar problems, where the nonlinearity is due to multiple successive single-photon processes.[6,8,9] Raman processes are true multiple-photon processes.

Mathematically, the distinction is quite simple, and it lies in how the intermediate steps in the iterations implied in (2.7) are carried out, apart from the resonance conditions. Very briefly, in the successive single-photon process, one calculates alternately the off-diagonal and the diagonal elements in the successive steps of (2.7) (see Ref. 8). In the ordinary Raman process, as in the situation depicted in Fig. 1(a), in which simultaneous absorption of a photon at ω_a and emission of a photon at ω_b occur, one calculates, for example, the second-order term $\rho_{1\alpha,2\beta}^{(2)}$ directly from $\rho_{1\alpha,3\gamma}^{(1)}$ and $\rho_{3\gamma,2\beta}^{(1)}$. This will become clearer in the following sections.

III. ORDINARY COHERENT RAMAN EFFECTS

In the ordinary Raman process, only two photons are involved as shown in Fig. 1(a). Following the usual procedure,[8] we obtain from Eqs. (2.7), (2.5), (2.3b), and (2.1b) the lowest order terms in the perturbation expansions of the off-diagonal elements of the density matrix

$$\rho_{1\alpha,3\gamma}^{(1)}=-\frac{i\Delta\bar{\rho}_{31}T_{13}V_{1\alpha,3\gamma}^{(a)}e^{i\omega_a t}}{\hbar[1+i(\omega_a-\omega_{31})T_{13}]}, \quad (3.1a)$$

$$\rho_{2\beta,3\gamma}^{(1)}=-\frac{i\Delta\bar{\rho}_{32}T_{23}V_{2\beta,3\gamma}^{(b)}e^{i\omega_b t}}{\hbar[1+i(\omega_b-\omega_{32})T_{23}]}, \quad (3.1b)$$

where

$$\Delta\bar{\rho}_{mn}\equiv\bar{\rho}_{m\alpha,m\alpha}-\bar{\rho}_{n\beta,n\beta}\equiv\bar{\rho}_{mm}-\bar{\rho}_{nn} \quad (3.2)$$

for any α and β. $\Delta\bar{\rho}_{mn}$ is diagonal and is independent of the degeneracy indices by virtue of (2.1b). Substituting (3.1a) and (3.1b) into (2.7), we obtain for the second-order term in the off-diagonal matrix element

$$\rho_{1\alpha,2\beta}^{(2)}=\sum_{\gamma}\frac{V_{1\alpha,3\gamma}^{(a)}V_{3\gamma,2\beta}^{(b)*}T_{12}e^{i(\omega_a-\omega_b)t}}{\hbar^2[1+i(\omega_a-\omega_b-\omega_{21})T_{12}]}\times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1-i(\omega_b-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1+i(\omega_a-\omega_{31})T_{13}}\right]. \quad (3.3)$$

In the proper limits this term corresponds to the second-

Digitized by Arya Samaj Foundation Chennai and eGangotri

order term in the perturbed wave function of the Schrödinger equation in the theory of ordinary Raman effects for a single molecule.[7] It contains all the necessary information for calculating the coherent molecular oscillations excited by the light waves. If electronic Raman processes are being considered and dipole transitions between levels 1 and 2 are allowed, it describes the induced dipole moment oscillating at $\omega_{21}=\omega_a-\omega_b$ produced by the light waves at ω_a and ω_b.

This coherently driven molecular oscillation described by $\rho_{1\alpha,2\beta}^{(2)}$ gives rise to a third-order term $\rho_{1\alpha,3\gamma}^{(3)}$, which results in an oscillating dipole moment per molecule at ω_a:

$$\mathbf{p}_a^{(3)}=\sum_{\alpha,\gamma}[\mathbf{p}_{3\gamma,1\alpha}\rho_{1\alpha,3\gamma}^{(3)}+\rho_{3\gamma,1\alpha}^{(3)}\mathbf{p}_{1\alpha,3\gamma}]$$
$$=\sum_{\gamma,\alpha,\gamma',\beta}i\chi_a\mathbf{p}_{3\gamma,1\alpha}V_{1\alpha,3\gamma'}^{(a)}V_{3\gamma',2\beta}^{(b)*}V_{2\beta,3\gamma}^{(b)}\times e^{i\omega_a t}+\text{c.c.}, \quad (3.4a)$$

where

$$\chi_a=\frac{T_{12}T_{13}}{\hbar^3[1+i(\omega_a-\omega_b-\omega_{21})T_{12}][1+i(\omega_a-\omega_{31})T_{13}]}\times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1-i(\omega_b-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1+i(\omega_a-\omega_{31})T_{13}}\right], \quad (3.4b)$$

and an oscillating dipole moment at ω_b:

$$\mathbf{p}_b^{(3)}=\sum_{\beta,\gamma}[\mathbf{p}_{3\gamma,2\beta}\rho_{2\beta,3\gamma}^{(3)}+\rho_{3\gamma,2\beta}^{(3)}\mathbf{p}_{2\beta,3\gamma}]$$
$$=\sum_{\gamma,\beta,\gamma',\alpha}i\chi_b\mathbf{p}_{3\gamma,2\beta}V_{2\beta,3\gamma'}^{(b)}V_{3\gamma',1\alpha}^{(a)*}V_{1\alpha,3\gamma}^{(a)}\times e^{i\omega_b t}+\text{c.c.}, \quad (3.4c)$$

where

$$\chi_b=\frac{T_{12}T_{23}}{\hbar^3[1-i(\omega_a-\omega_b-\omega_{21})T_{12}][1+i(\omega_b-\omega_{32})T_{23}]}\times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1+i(\omega_b-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1-i(\omega_a-\omega_{31})T_{13}}\right], \quad (3.4d)$$

with the help of (3.3), (2.7), (2.3b), and (2.2). Not all the terms in the sums over the degeneracy indices in (3.4a) and (3.4c), as well as (3.3), are nonzero. Many will vanish of course due to selection rules or other special circumstances.

These dipole moments at frequencies ω_a and ω_b, $\mathbf{p}_a^{(3)}$ and $\mathbf{p}_b^{(3)}$, induced in the Raman process will lead to energy exchange between the molecules and the oscillating electric fields at the corresponding frequencies. The average absorbed power is equal to the time average of the scalar product of the rate of decrease of the dipole moment and the corresponding oscillating component of the electric field. We obtain from (3.4a) for the average power absorbed per molecule at the frequency ω_a

$$P_a=\text{Re}\{\sum_{\gamma,\alpha,\gamma',\beta}2\omega_a\chi_a V_{3\gamma,1\alpha}^{(a)*}V_{1\alpha,3\gamma'}^{(a)}\times V_{3\gamma',2\beta}^{(b)*}V_{2\beta,3\gamma}^{(b)}\}. \quad (3.5)$$

Similarly, from (3.4c) the average absorbed power per molecule at ω_b is

$$P_b=\text{Re}\{\sum_{\gamma,\beta,\gamma',\alpha}2\omega_b\chi_b V_{3\gamma,2\beta}^{(b)*}V_{2\beta,3\gamma'}^{(b)}\times V_{3\gamma',1\alpha}^{(a)*}V_{1\alpha,3\gamma}^{(a)}\}. \quad (3.6)$$

We next introduce the spatial dependence of the perturbation terms $V^{(a)}$ and $V^{(b)}$ into (3.5) and (3.6) and obtain the absorbed power averaged over a volume large compared with all the wavelengths of interest but small compared with the distances over which the amplitudes and phases of the waves vary appreciably. We consider homogeneous plane waves:

$$V_{1\alpha,3\beta}^{(a)}=\bar{V}_{1\alpha,3\beta}^{(a)}e^{-i\mathbf{k}_a\cdot\mathbf{r}},$$
$$V_{2\alpha,3\beta}^{(b)}=\bar{V}_{2\alpha,3\beta}^{(b)}e^{-i\mathbf{k}_b\cdot\mathbf{r}}, \quad (3.7)$$

where $\mathbf{r}$ is the position vector of the average molecules characterized by the density matrix and $\bar{V}_{m\alpha,n\beta}^{(a,b)}$ is spatially independent but complex.

Substituting (3.7) into (3.5) and (3.6) and averaging over $\mathbf{r}$, we obtain the average power per unit volume absorbed at the frequency ω_a:

$$\langle P_a\rangle_{\mathbf{r}}=\text{Re}\{\sum_{\gamma,\alpha,\gamma',\beta}2N\omega_a\chi_a\bar{V}_{3\gamma,1\alpha}^{(a)*}\bar{V}_{1\alpha,3\gamma'}^{(a)}\times\bar{V}_{3\gamma',2\beta}^{(b)*}\bar{V}_{2\beta,3\gamma}^{(b)}\}, \quad (3.8a)$$

and that at ω_b:

$$\langle P_b\rangle_{\mathbf{r}}=\text{Re}\{\sum_{\gamma,\beta,\gamma',\alpha}2N\omega_b\chi_b\bar{V}_{3\gamma,2\beta}^{(b)*}\bar{V}_{2\beta,3\gamma'}^{(b)}\times\bar{V}_{3\gamma',1\alpha}^{(a)*}\bar{V}_{1\alpha,3\gamma}^{(a)}\}, \quad (3.8b)$$

where N is the density of the active molecules coupled to the fields. In both cases the final results are independent of the propagation vectors. Unlike the higher order Raman effects which will be considered in the following section, there are no phase matching conditions here. The average absorptions per unit volume, (3.8a) and (3.8b), are always directly proportional to the local absorptions (3.6a) and (3.6b).

On the other hand, substituting (3.7) into (3.3), we have

$$\rho_{1\alpha,2\beta}^{(2)}=\sum_{\gamma}\frac{\bar{V}_{1\alpha,3\gamma}^{(a)}\bar{V}_{3\gamma,2\beta}^{(b)*}T_{12}}{\hbar^2[1+i(\omega_a-\omega_b-\omega_{21})T_{12}]}\times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1-i(\omega_b-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1+i(\omega_a-\omega_{31})T_{13}}\right]\times\exp i[(\omega_a-\omega_b)t-(\mathbf{k}_a-\mathbf{k}_b)\cdot\mathbf{r}], \quad (3.9)$$

which means the molecular-oscillation wave (or other polarization waves) produced in the coherent Raman process has a propagation vector equal to $\mathbf{k}_a-\mathbf{k}_b$.

If ω_a designates the primary light, say the maser light at ω_l, then (3.8b) describes the first Stokes radiation at

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$\omega_{S_1}=\omega_b$:

$$\langle P_{S_1}\rangle_r=\mathrm{Re}\{\sum_{\gamma,\beta,\gamma',\alpha} 2N\omega_{S_1}\chi_{S_1}\bar{V}_{3\gamma,2\beta}{}^{(S_1)*}\bar{V}_{2\beta,3\gamma'}{}^{(S_1)} \times\bar{V}_{3\gamma',1\alpha}{}^{(l)*}\bar{V}_{1\alpha,3\gamma}{}^{(l)}\}, \quad (3.10a)$$

where

$$\chi_{S_1}=\frac{T_{12}T_{23}}{\hbar^3[1-i(\omega_l-\omega_{S_1}-\omega_{21})T_{12}][1+i(\omega_{S_1}-\omega_{32})T_{23}]} \times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1+i(\omega_{S_1}-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1-i(\omega_l-\omega_{31})T_{13}}\right]. \quad (3.10b)$$

If ω_b designates the primary light, say the maser light at ω_l, then (3.8a) describes the anti-Stokes radiation at $\omega_{AS}=\omega_a$:

$$\langle P_{AS}\rangle_r=\mathrm{Re}\{\sum_{\gamma,\alpha,\gamma',\beta} 2N\omega_{AS}\chi_{AS}\bar{V}_{3\gamma,1\alpha}{}^{(AS)*}\bar{V}_{1\alpha,3\gamma'}{}^{(AS)} \times\bar{V}_{3\gamma',2\beta}{}^{(l)*}\bar{V}_{2\beta,3\gamma}{}^{(l)}\}, \quad (3.10c)$$

where

$$\chi_{AS}=\frac{T_{12}T_{13}}{\hbar^3[1+i(\omega_{AS}-\omega_l-\omega_{21})T_{12}][1+i(\omega_{AS}-\omega_{31})T_{13}] \times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1-i(\omega_l-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1+i(\omega_{AS}-\omega_{31})T_{13}}\right]. \quad (3.10d)$$

Equations (3.10a)–(3.10d) contain all the information about the Stokes and anti-Stokes radiations in the ordinary Raman process. These expressions are very general though somewhat complicated. In order to see the physical interpretations of these results better, we consider some simple limiting cases.

We first simplify the χ's. Let us assume that

$$T_{13},T_{23}\to\infty \quad (3.11)$$

and

$$\Delta\bar{\rho}_{32}\approx-\bar{\rho}_{22}, \quad \Delta\bar{\rho}_{31}\approx-\bar{\rho}_{11}. \quad (3.12)$$

Therefore, we have from (3.10b):

$$\lim_{T_{13},T_{23}\to\infty}\chi_{S_1}=\frac{1}{\hbar^3}\left[\frac{T_{12}+iT_{12}{}^2(\omega_l-\omega_{S_1}-\omega_{21})}{1+(\omega_l-\omega_{S_1}-\omega_{21})^2T_{12}{}^2}\right] \times\left[\pi\delta(\omega_{S_1}-\omega_{32})-iP\frac{1}{\omega_{S_1}-\omega_{32}}\right] \times\left[-\bar{\rho}_{22}\pi\delta(\omega_{S_1}-\omega_{32})+i\bar{\rho}_{22}P\frac{1}{\omega_{S_1}-\omega_{32}} -\bar{\rho}_{11}\pi\delta(\omega_l-\omega_{31})-i\bar{\rho}_{11}P\frac{1}{\omega_l-\omega_{31}}\right], \quad (3.13a)$$

where P in (3.13a) designates principal values. The δ-functions' contributions correspond to the effects of the single-photon processes between levels 1 or 2 and 3. These effects are usually not considered as a part of the Raman process. One should note, however, that a clear-cut distinction can easily be made only in the case T_{13}, $T_{23}\to\infty$. Experimentally, in the cases where the Raman processes are important, the direct single-photon processes usually are not, so that one does not have to make a distinction and both the δ-function contributions and the principal value signs in (3.13a) can be omitted:

$$\chi_{S_1}=-\frac{1}{\hbar^3(\omega_{S_1}-\omega_{32})}\left[\frac{T_{12}}{1+(\omega_l-\omega_{S_1}-\omega_{21})^2T_{12}{}^2} +i\frac{(\omega_l-\omega_{S_1}-\omega_{21})T_{12}{}^2}{1+(\omega_l-\omega_{S_1}-\omega_{21})^2T_{12}{}^2}\right] \times\left[\frac{\bar{\rho}_{11}}{\omega_l-\omega_{31}}-\frac{\bar{\rho}_{22}}{\omega_{S_1}-\omega_{32}}\right]. \quad (3.13b)$$

We also assume that the primary light is linearly polarized in, say the $\hat{z}$ direction

$$\mathbf{E}_l=\hat{z}E_le^{-i\mathbf{k}_l\cdot\mathbf{r}}, \quad (3.14a)$$

and that the Stokes radiation is

$$\mathbf{E}_{S_1}=[\sin\theta_{S_1}\hat{x}+\cos\theta_{S_1}\hat{z}]\bar{E}_{S_1} \times\exp(-i\mathbf{k}_{S_1}\cdot\mathbf{r}+i\psi_{S_1}). \quad (3.14b)$$

With (3.13b), (3.14a) and (3.14b), (3.10a) and (3.10b) can be readily evaluated if, for example, levels 1 and 2 are nondegenerate; one obtains for the Stokes radiation the familiar result[4]:

$$\langle P_{S_1}\rangle_r=-\frac{2N(\bar{\rho}_{11}-\bar{\rho}_{22})\omega_{S_1}T_{12}}{9\hbar^3\Delta_1{}^2[1+(\omega_l-\omega_{S_1}-\omega_{21})^2T_{12}{}^2]} \times|p_{13}|^2|p_{23}|^2\bar{E}_l{}^2\bar{E}_{S_1}{}^2\cos^2\theta_{S_1}, \quad (3.15a)$$

where $\Delta_1=\omega_{31}-\omega_l\approx\omega_{32}-\omega_{S_1}$ near the resonance peak at $\omega_l-\omega_{S_1}\approx\omega_{21}$ and $|p_{mn}|$ is the magnitude of the reduced matrix element of the operator $\mathbf{p}$. Since $\bar{\rho}_{11}>\bar{\rho}_{22}$, $\langle P_{S_1}\rangle_r\leq0$, and Stokes radiation is emitted. It is emitted in all directions with the radiation pattern determined by the angle, θ_{S_1}, between the polarizations of the maser light and the Stokes light according to $\cos^2\theta_{S_1}$.

Similarly, one obtains for the absorbed anti-Stokes radiation per unit volume[4]:

$$\langle P_{AS}\rangle_r=\frac{2N(\bar{\rho}_{11}-\bar{\rho}_{22})\omega_{AS}T_{12}}{9\hbar^3\Delta_2{}^2[1+(\omega_l-\omega_{S_1}-\omega_{21})^2T_{12}{}^2]} \times|p_{13}|^2|p_{23}|^2\bar{E}_l{}^2\bar{E}_{AS}{}^2\cos^2\theta_{AS}, \quad (3.15b)$$

where $\Delta_2=\omega_{31}-\omega_{AS}\approx\omega_{32}-\omega_l$. It is clear from (3.15b) that anti-Stokes radiation is always absorbed.

These are only some special cases. A great variety of more complicated situations may arise in experiments and the general expressions (3.10a)–(3.10d) must then be used.

IV. HIGHER ORDER COHERENT RAMAN PROCESSES

A. General Theory

In the higher order Raman processes more than two photons are involved simultaneously. Let there be photons at angular frequencies ω_c and ω_d as shown in Fig. 1(b) in addition to the photons at ω_a and ω_b as shown in Fig. 1(a).

Physically, a light wave at ω_c, propagating through a medium which is being modulated by coherent molecular oscillations, excited by two other light waves at ω_a and ω_b as described by the second order off-diagonal density matrix element $\rho_{1\alpha,2\beta}^{(2)}$, (3.3), will induce an oscillating dipole moment at $\omega_d=\omega_c+(\omega_a-\omega_b)$. Similarly, the light wave at ω_d can induce an oscillating dipole moment at $\omega_c=\omega_d-(\omega_a-\omega_b)$. Both are higher order Raman effects. This is not unlike the double-resonance effects[10] where the coherence between levels 1 and 2 is induced directly by an applied field of angular frequency ω_{21}. In the present case, this coherence is induced by two applied fields at ω_a and ω_b, where $\omega_a-\omega_b\approx\omega_{31}-\omega_{32}=\omega_{21}$.

Mathematically, the presence of two additional oscillating fields adds new elements in the perturbation term, V, in the total Hamiltonian for the density-matrix equation:

$$V_{1\alpha,3\beta}^{(d)}e^{i\omega_d t}+V_{1\alpha,3\beta}^{(d)*}e^{-i\omega_d t}, \tag{4.1a}$$

and

$$V_{2\alpha,3\beta}^{(c)}e^{i\omega_c t}+V_{2\alpha,3\beta}^{(c)*}e^{-i\omega_c t}. \tag{4.1b}$$

In the perturbation solution of the density-matrix equation, a third-order term in the off-diagonal density-matrix element $\rho_{1\alpha,3\gamma}^{(3)}$ appears which comes from substituting into (2.7) the second-order off-diagonal elements $\rho_{1\alpha,2\beta}^{(2)}$ and $\rho_{2\beta,1\alpha}^{(2)}$ and the new perturbation terms given in (4.1b). Similarly, a third-order term $\rho_{2\beta,3\gamma}^{(3)}$ appears. These give rise to new induced dipole terms.

From (2.2), (2.7), (3.3), and (4.1a), we then obtain the average induced dipole moment per molecule at $\omega_d-(\omega_a-\omega_b)$:

$$\mathbf{p}_{d-a+b}^{(3)}=\sum_{\gamma,\beta,\gamma',\alpha} i\chi_{d-a+b}\mathbf{p}_{3\gamma,2\beta}V_{2\beta,3\gamma'}^{(b)}V_{3\gamma'1\alpha}^{(a)*}V_{1\alpha,3\gamma}^{(d)}e^{i(\omega_d-\omega_a+\omega_b)t}+\text{c.c.}, \tag{4.2a}$$

where

$$\chi_{d-a+b}=\frac{T_{12}T_{23}}{\hbar^3[1-i(\omega_a-\omega_b-\omega_{21})T_{12}][1+i(\omega_d-\omega_a+\omega_b-\omega_{32})T_{23}]}\left[\frac{\Delta\tilde{\rho}_{32}T_{23}}{1+i(\omega_b-\omega_{32})T_{23}}+\frac{\Delta\tilde{\rho}_{31}T_{13}}{1-i(\omega_a-\omega_{31})T_{13}}\right], \tag{4.2b}$$

and the induced dipole moment per molecule at $\omega_c+(\omega_a-\omega_b)$:

$$\mathbf{p}_{c+a-b}^{(3)}=\sum_{\gamma,\alpha,\gamma',\beta} i\chi_{c+a-b}\mathbf{p}_{3\gamma,1\alpha}V_{1\alpha,3\gamma'}^{(a)}V_{3\gamma',2\beta}^{(b)*}V_{2\beta,3\gamma}^{(c)}e^{i(\omega_c+\omega_a-\omega_b)t}+\text{c.c.}, \tag{4.3a}$$

where

$$\chi_{c+a-b}=\frac{T_{12}T_{13}}{\hbar^3[1+i(\omega_a-\omega_b-\omega_{21})T_{12}][1+i(\omega_c+\omega_a-\omega_b-\omega_{31})T_{13}]}\left[\frac{\Delta\tilde{\rho}_{32}T_{23}}{1-i(\omega_b-\omega_{32})T_{23}}+\frac{\Delta\tilde{\rho}_{31}T_{13}}{1+i(\omega_a-\omega_{31})T_{13}}\right]. \tag{4.3b}$$

Let the primary light be the maser light at ω_l; we can study all the higher order Stokes and anti-Stokes radiations with the help of (4.2a), (4.2b), (4.3a), and (4.3b).

1. First Stokes Radiation

The following combination of frequencies can lead to the first Stokes radiation in the higher order Raman process involving four photons:

$$\omega_a=\omega_{AS},\quad \omega_b=\omega_l,\quad \omega_d=\omega_l,$$
$$\text{and} \tag{4.4}$$
$$\omega_c=\omega_d-\omega_a+\omega_b=\omega_l-\omega_{AS}+\omega_l=\omega_{S_1}.$$

Substituting (4.4) into (4.2a) and (4.2b), we obtain the induced dipole moment per molecule at ω_{S_1} produced in the process:

$$\mathbf{p}_{S_1}{}'^{(3)}=\sum_{\gamma,\beta,\gamma',\alpha} i\chi_{S_1}{}'\mathbf{p}_{3\gamma,2\beta}V_{2\beta,3\gamma'}^{(l)}V_{3\gamma',1\alpha}^{(AS)*}\times V_{1\alpha,3\gamma}^{(l)}e^{i\omega_{S_1}t}+\text{c.c.}, \tag{4.5a}$$

where

$$\chi_{S_1}{}'=\frac{T_{12}T_{23}}{\hbar^3[1-i(\omega_{AS}-\omega_l-\omega_{21})T_{12}][1+i(\omega_{S_1}-\omega_{32})T_{23}]}\times\left[\frac{\Delta\tilde{\rho}_{32}T_{23}}{1+i(\omega_l-\omega_{32})T_{23}}+\frac{\Delta\tilde{\rho}_{31}T_{13}}{1-i(\omega_{AS}-\omega_{31})T_{13}}\right] \tag{4.5b}$$

and use is made of the fact that $\omega_{AS}-\omega_l=\omega_l-\omega_{S_1}$.

Following exactly the same steps as used in the previous section, we find the average absorbed power per molecule:

$$P_{S_1}{}'=\text{Re}\{\sum_{\gamma,\beta,\gamma',\alpha} 2\omega_{S_1}\chi_{S_1}{}'V_{3\gamma,2\beta}^{(S_1)*}V_{2\beta,3\gamma'}^{(l)}\times V_{3\gamma',1\alpha}^{(AS)*}V_{1\alpha,3\gamma}^{(l)}\}. \tag{4.6}$$

By introducing the plane-wave spatial dependence of the fields, (3.7) and

$$V_{1\alpha,3\gamma'}^{(AS)}=\bar{V}_{1\alpha,3\gamma'}^{(AS)}\exp(-i\mathbf{k}_{AS}\cdot\mathbf{r}) \tag{4.7}$$

into (4.6) and then averaging over $\mathbf{r}$, we obtain the

[10] F. Bitter, Phys. Rev. 76, 833 (1949).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

average absorbed power per unit volume:

$$\langle P_{S_1}'\rangle_r = \mathrm{Re}\{\sum_{\gamma,\beta,\gamma',\alpha} 2N\omega_{S_1}\chi_{S_1}'\bar{V}_{3\gamma,2\beta}^{(S_1)*}\bar{V}_{2\beta,3\gamma'}^{(l)} \times \bar{V}_{3\gamma',1\alpha}^{(AS)*}\bar{V}_{1\alpha,3\gamma}^{(l)}\}\delta_{k_l+k_{l'}-k_{S1}-k_{AS}}. \quad (4.8)$$

In contrast to the ordinary Raman processes, in the present case there is a phase matching condition[4]:

$$\mathbf{k}_l+\mathbf{k}_{l'}-\mathbf{k}_{S_1}-\mathbf{k}_{AS}=0 \quad (4.8a)$$

in order for the higher order coherent Raman process to take place. Whether (4.8) corresponds to absorption or emission will depend upon the detailed nature of the molecular states and the relative phases of the fields involved, as expressed in the bracketed factor in (4.8). We shall examine some special cases later.

2. *First Anti-Stokes Radiation*

For the first anti-Stokes radiation we take the following combination of frequencies in (4.3a) and (4.3b):

$$\omega_a=\omega_l,\quad \omega_b=\omega_{S_1},\quad \omega_c=\omega_l,$$
$$\text{and} \quad \omega_d=\omega_l+\omega_l-\omega_{S_1}=\omega_{AS}. \quad (4.9)$$

The induced dipole moment per molecule at ω_{AS} produced in the higher order Raman process is

$$\mathbf{p}_{AS'}^{(3)} = \sum_{\gamma,\alpha,\gamma',\beta} i\chi_{AS}'\mathbf{p}_{3\gamma,1\alpha}V_{1\alpha,3\gamma'}^{(l)}V_{3\gamma',2\beta}^{(S_1)*} \times V_{2\beta,3\gamma}^{(l)}e^{i\omega_{AS}t}+\text{c.c.}, \quad (4.10a)$$

where

$$\chi_{AS}' = \frac{T_{12}T_{13}}{\hbar^3[1+i(\omega_l-\omega_{S_1}-\omega_{21})T_{12}][1+i(\omega_{AS}-\omega_{31})T_{13}]} \times\left[\frac{\Delta\bar{\rho}_{32}T_{23}}{1-i(\omega_{S_1}-\omega_{32})T_{23}}+\frac{\Delta\bar{\rho}_{31}T_{13}}{1+i(\omega-\omega_{31})T_{13}}\right] \quad (4.10b)$$

from (4.9) and (4.3a) and (4.3b). The average absorbed power per molecule is then

$$P_{AS}' = \mathrm{Re}\{\sum_{\gamma,\alpha,\gamma',\beta} 2\omega_{AS}\chi_{AS}'V_{3\gamma,1\alpha}^{(AS)*}V_{1\alpha,3\gamma'}^{(l)} \times V_{3\gamma',2\beta}^{(S_1)*}V_{2\beta,3\gamma}^{(l)}\}. \quad (4.11)$$

Upon introducing the spatial dependence of the fields, (3.7) and (4.7), and averaging over $\mathbf{r}$, we obtain the absorbed power per unit volume:

$$\langle P_{AS}'\rangle_r = \mathrm{Re}\{\sum_{\gamma,\alpha,\gamma',\beta} 2N\omega_{AS}\chi_{AS}'\bar{V}_{3\gamma,1\alpha}^{(AS)*}\bar{V}_{1\alpha,3\gamma'}^{(l)} \times \bar{V}_{3\gamma',2\beta}^{(S_1)*}\bar{V}_{2\beta,3\gamma}^{(l)}\}\delta_{k_l+k_{l'}-k_{S1}-k_{AS}}. \quad (4.12)$$

Again, one has the phase matching condition, (4.8a).[4]

3. *Higher Order Stokes and Anti-Stokes Radiations*

By taking suitable combinations of frequencies, properties of successive higher orders of Stokes and anti-Stokes radiations can be studied in much the same way using (4.2a), (4.2b), (4.3a), and (4.3b).

For example, for the second Stokes radiation, one takes the following independent combinations of frequencies:

$$\omega_a=\omega_l,\quad \omega_b=\omega_{S_1},\quad \omega_d=\omega_{S_1},$$
$$\omega_c=\omega_d-\omega_a+\omega_b=\omega_{S_1}-(\omega_l-\omega_{S_1})=\omega_{S_2}; \quad (4.13a)$$

and

$$\omega_a=\omega_{AS},\quad \omega_b=\omega_l,\quad \omega_d=\omega_{S_1},$$
$$\omega_c=\omega_{S_1}-(\omega_{AS}-\omega_l)=\omega_{S_2}. \quad (4.13b)$$

Physically, these correspond to the cases where a light wave at ω_{S_1} propagates in a medium which is modulated by the coherent molecular oscillations excited by two other light waves at ω_l and ω_{S_1}, (4.13a), or ω_{AS} and ω_l, (4.13b). As a result, absorption or emission at ω_{S_2} may take place. It is now obvious how the absorbed powers could be calculated. It may be of interest to look at the phase matching conditions.

It can be shown readily that for the first case, (4.13a), the phase matching condition is[4]

$$\mathbf{k}_{S_1}+\mathbf{k}_{S_1'}-\mathbf{k}_l-\mathbf{k}_{S_2}=0; \quad (4.14a)$$

and for the second case, (4.13b), it is

$$\mathbf{k}_{AS}-\mathbf{k}_l-\mathbf{k}_{S_1}+\mathbf{k}_{S_2}=0. \quad (4.14b)$$

It is clear that the general results given can be readily applied to a great variety of interesting experimental situations. We now study some specific simple cases.

B. Special Examples

Consider the first Stokes radiation in the higher order process. As in Sec. III, let us assume again that all the light waves are linearly polarized:

$$\bar{V}^{(l)}=p_z\bar{E}_l, \quad (4.15a)$$

$$\bar{V}^{(S_1)}=(p_x\sin\theta_{S_1}+p_z\cos\theta_{S_1})\bar{E}_{S_1}e^{i\psi_{S_1}}, \quad (4.15b)$$

$$\bar{V}^{(AS)}=(p_x\sin\theta_{AS}\cos\phi_{AS}+p_y\sin\theta_{AS}\sin\phi_{AS} +p_z\cos\theta_{AS})\bar{E}_{AS}e^{i\psi_{AS}}, \quad (4.15c)$$

in a suitably chosen coordinate system. With (4.15a)–(4.15c), we can evaluate the sums in (4.8), assuming that level 2 is a vibrational level; for example,

$$\Sigma=\sum_{\gamma,\beta,\gamma',\alpha}\bar{V}_{3\gamma,2\beta}^{(S_1)*}\bar{V}_{2\beta,3\gamma'}^{(l)}\bar{V}_{3\gamma',1\alpha}^{(AS)*}\bar{V}_{1\alpha,3\gamma}^{(l)}$$
$$=\sum_{\alpha,\beta}\bar{E}_l^2\bar{E}_{S_1}\bar{E}_{AS}e^{-i\psi_{S_1}-i\psi_{AS}}\langle 2,\beta|T(1,0)|3,\beta\rangle\langle 1,\alpha|T(1,0)|3,\alpha\rangle$$
$$\times[\langle 3,\alpha|T(1,0)|2,\beta\rangle\cos\theta_{S_1}+(1/\sqrt{2})(\langle 3,\alpha|T(1,-1)|2,\beta\rangle-\langle 3,\alpha|T(1,1)|2,\beta\rangle)\sin\theta_{S_1}]$$
$$\times[\langle 3,\beta|T(1,0)|1,\alpha\rangle\cos\theta_{AS}-(1/\sqrt{2})\langle 3,\beta|T(1,1)|1,\alpha\rangle(\sin\theta_{AS}\cos\phi_{AS}+i\sin\theta_{AS}\sin\phi_{AS})$$
$$+(1/\sqrt{2})\langle 3,\beta|T(1,-1)|1,\alpha\rangle(\sin\theta_{AS}\cos\phi_{AS}-i\sin\theta_{AS}\sin\phi_{AS})], \quad (4.16)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where the tensor operators are

$$T(1,0)=p_z,\quad T(1,-1)=\frac{1}{\sqrt{2}}p_x+\frac{i}{\sqrt{2}}p_y,\quad T(1,1)=-\frac{1}{\sqrt{2}}p_x+\frac{i}{\sqrt{2}}p_y. \tag{4.16a}$$

If, furthermore, levels 1 and 2 are nondegenerate, Eq. (4.16) simplifies to

$$\sum=\tfrac{1}{9}|p_{13}|^2|p_{23}|^2\bar{E}_l{}^2\bar{E}_{S_1}\bar{E}_{AS}e^{-i\psi_{S_1}-i\psi_{AS}}\cos\theta_{S_1}\cos\theta_{AS}. \tag{4.16b}$$

Assuming in addition that T_{13}, $T_{23}\to\infty$ and none of the single-photon frequencies are very near any of the transition frequencies, substituting (4.16b) into (4.8) and (4.5b), and taking the proper limits, we obtain for the average absorbed first Stokes radiation per unit volume:

$$\langle P_{S_1}{}'\rangle_r=-\frac{2N(\tilde{\rho}_{11}-\tilde{\rho}_{22})\omega_{S_1}T_{12}|p_{13}|^2|p_{23}|^2\bar{E}_l{}^2\bar{E}_{S_1}\bar{E}_{AS}}{9\hbar^3[1+(\omega_{AS}-\omega_l-\omega_{21})^2T_{12}{}^2]\Delta_1\Delta_2}\cos\theta_{S_1}\cos\theta_{AS}$$
$$\times[\cos(\psi_{S_1}+\psi_{AS})+T_{12}(\omega_{AS}-\omega_l-\omega_{21})\sin(\psi_{S_1}+\psi_{AS})]\delta_{k_l+k_{l'}-k_{Sl}-k_{AS}}, \tag{4.17}$$

where in the denominator, as before,

$$\Delta_1=\omega_{32}-\omega_{S_1}\quad\text{and}\quad\Delta_2=\omega_{32}-\omega_l\approx\omega_{31}-\omega_{AS}.$$

On resonance,[4] one has absorption of the first Stokes radiation, or $\langle P_{S_1}{}'\rangle_r\geq 0$, if $\pi/2<(\psi_{S_1}+\psi_{AS})<3\pi/2$, and emission of the first Stokes radiation, or $\langle P_{S_1}{}'\rangle_r\leq 0$, if $-\pi/2<(\psi_{S_1}+\psi_{AS})<\pi/2$.

Under similar circumstances, one finds the absorbed anti-Stokes radiation per unit volume:

$$\langle P_{AS}{}'\rangle_r=\frac{2N(\tilde{\rho}_{11}-\tilde{\rho}_{22})\omega_{AS}T_{12}|p_{13}|^2|p_{23}|^2\bar{E}_l{}^2\bar{E}_{S_1}\bar{E}_{AS}}{9\hbar^3[1+(\omega_{AS}-\omega_l-\omega_{21})^2T_{12}{}^2]\Delta_1\Delta_2}\cos\theta_{S_1}\cos\theta_{AS}$$
$$\times[\cos(\psi_{S_1}+\psi_{AS})-T_{12}(\omega_{AS}-\omega_l-\omega_{21})\sin(\psi_{S_1}+\psi_{AS})]\delta_{k_l+k_{l'}-k_{Sl}-k_{AS}}, \tag{4.18}$$

where, in the denominator, use is made of the fact that

$$\omega_l-\omega_{31}\approx\omega_{S_1}-\omega_{32}\quad\text{and}\quad\omega_{AS}-\omega_{31}\approx\omega_l-\omega_{32}.$$

Therefore, on resonance, when $\pi/2<(\psi_{S_1}+\psi_{AS})<3\pi/2$, $\langle P_{AS}{}'\rangle_r\leq 0$, and one has emission of anti-Stokes radiation; when $-\pi/2<(\psi_{S_1}+\psi_{AS})<\pi/2$, $\langle P_{AS}{}'\rangle_r\geq 0$ and one has absorption of anti-Stokes radiation.[4]

It follows also from (4.17) and (4.18) that on resonance and when the phase matching condition is satisfied

$$\langle P_{AS}{}'\rangle_r\cdot\omega_{AS}{}^{-1}=-\langle P_{S_1}{}'\rangle_r\cdot\omega_{S_1}{}^{-1}, \tag{4.19}$$

which is similar to the so-called Manley-Row relation, well-known in the theory of parametric amplifiers in microwave tube work and derived classically.[11]

One should note also that when, for example, three photons are simultaneously involved in the higher order Raman process, the net absorption of the first Stokes radiation is not just $\langle P_{S_1}{}'\rangle_r$. It should be $\langle P_{S_1}{}'\rangle_r$ plus $\langle P_{S_1}\rangle_r$, since both terms could be of the same order of magnitude. Similarly, the net absorption of anti-Stokes radiation is the sum of $\langle P_{AS}{}'\rangle_r$ and $\langle P_{AS}\rangle_r$. An examination of these expressions shows that when $\bar{E}_{S_1}>\bar{E}_{AS}$ one could have coherent amplification of anti-Stokes radiation of the right phase.

It is clear that specific results for other higher order Stokes and anti-Stokes radiations can be obtained in much the same way.

Most of the results and conclusions obtained in these simple examples, as well as those given in the previous section, have been given and discussed in detail in Ref. 4 on the basis of a phenomenological theory. In more complicated cases, the general results given in Sec. IIIA, as well as those given in Sec. II, will have to be used.

Interpretation of Frequency Shifts Due to Electron Exchange Collisions

P. L. BENDER
Joint Institute for Laboratory Astrophysics, Boulder, Colorado

(Received 6 January 1964)

Experiments by Hobart and Franken in 1961 demonstrated a shift in the free-electron spin-resonance frequency due to collisions with sodium atoms whose electron spins were polarized. The results have been interpreted on the assumptions that the S-wave phase shifts were proportional to the wave number k and that higher partial waves were not important. The triplet and singlet electron-sodium scattering lengths of Salmona and Seaton were used, but no check on the calculation was made since the sodium polarization was not known. Recently Balling, Hanson, and Pipkin have measured the shift for collisions with highly polarized rubidium atoms. They have also derived complete formulas for the frequency shift and line broadening in terms of the phase shifts with all partial waves included. In the present paper, an alternate derivation of the frequency shift and line broadening formulas is given and the experimental results are discussed on the basis of the phase-shift information that is available for hydrogen, sodium, and cesium. The small size of the observed ratio of frequency shift to line broadening for rubidium appears somewhat surprising in view of the larger ratios calculated for other alkalis.

1. INTRODUCTION

A MEASUREMENT of the free-electron g factor has been reported by Dehmelt.[1] His method involves polarization of the electrons by exchange collisions with sodium atoms which in turn have been polarized by optical pumping.[2,3] An exchange broadening cross section of $260\pi a_0^2$ or larger at 400°K was also measured. Salmona and Seaton[4] discussed this result on the basis of their calculated S-wave scattering lengths and found that the zero-energy-exchange cross section is large because the triplet and singlet scattering lengths are of opposite sign and are both large.

Hobart and Franken have repeated the electron g-factor experiment using a more homogeneous magnetic field.[5,6] During the experiment, they discovered a shift in the electron-spin-resonance frequency with the sodium polarization and density. The sample temperature was about 410°K and the magnetic field about 3.7 G. The pulsed discharge which produced the electrons was short and uncorrelated with the modulation frequency used to observe the electron resonance. An argon buffer gas at pressures of between a few Torr and about 50 Torr was present, so the electrons were presumably thermal. The frequency shift was interpreted as due to phase shifts in the off-diagonal elements of the electron-spin density matrix introduced by the electron-sodium exchange collisions. Maximum shifts of about 100 cps were observed under conditions where the electron resonance broadening by electron-sodium exchange collisions was about 2000 cps (half-width at half-maximum).[7]

The expected ratio of frequency shift to line broadening for the conditions of the Hobart and Franken experiment has been estimated[8] using Salmona and Seaton's triplet and singlet S-wave scattering lengths. The formula obtained, including only the S-wave contribution to the shift and broadening, was

$$(d'/w')=-P_{Na}\langle(\sin 2\Delta_0)\rangle_{\rm av}/\langle(1-\cos 2\Delta_0)\rangle_{\rm av}. \qquad (1)$$

Here d' and w' are the frequency shift and half-width, P_{Na} is the sodium electron polarization, $\Delta_0=\delta_0(1)-\delta_0(0)$ is the difference of the triplet and singlet S-wave phase shifts, and the average is over the thermal distribution of electron energies. If the scattering length approximation for the S-wave phase shifts is adequate and higher partial waves are not important, the observed ratio of shift to broadening requires a sodium polarization of about 10%. However, since the sodium polarization was not measured, the observations do not provide a check on the correctness of Eq. (1) or of the assumptions which were made.

Recently Balling, Hanson, and Pipkin[9] have measured shifts in the free-electron spin-resonance frequency due to collisions with polarized rubidium atoms. In this work the rubidium polarization was 90% or higher and the electrons were believed to be well thermalized. They also derived complete theoretical formulas for the shift and broadening of the electron spin resonance due to electron-atom exchange collisions in terms of the differences between the triplet and singlet scattering phase shifts for all partial waves. Their interpretation of the observed ratio of shift to half-width of -0.05 ± 0.01 was that the S-wave phase-shift difference was near some multiple of $(\pi/2)$ for electrons of the average energy, with $(\pi/2)$ itself most likely, and that higher partial waves were probably not important.

In Sec. 2 of the present paper an alternate derivation of the frequency shift and line broadening formulas for electron-atom exchange collisions is given. This deri-

vation is based on the expressions one would obtain from Baranger's general impact theory[10] if the triplet and singlet states were energy eigenstates during the time between collisions. The proof that the resulting formulas hold for arbitrary alkali nuclear spin is given in the Appendix.

In Sec. 3 the available theoretical information on phase shifts for electron-alkali scattering is reviewed. The modified effective range theory expansions of the S-wave phase shifts in terms of the wave number k appear useful for hydrogen and sodium but break down for cesium in the temperature range of interest. Phase-shift calculations as a function of energy for hydrogen and cesium and the scattering lengths for sodium are used in discussing the frequency-shift ratio for rubidium. The experimentally observed result is not easy to understand in this way, and thus more extensive phase-shift calculations as well as further frequency-shift experiments with cesium and sodium appear to be desirable.

2. ALTERNATE DERIVATION OF ELECTRON SPIN RESONANCE FREQUENCY SHIFT

For the experimental conditions of Hobart and Franken[5] and of Balling, Hanson, and Pipkin,[9] the alkali and buffer gas densities are low enough so that the impact approximation is very good. The number of electrons is much less than the number of alkali atoms, and we thus consider only electron-alkali collisions. Magnetic interaction energies are small enough to be neglected during collisions. We take the axis of quantization as along the magnetic-field direction. The components of the free-electron spin and the valence-electron spin along the axis are labeled as m_e and m_J, respectively, while the total electron spin and its component along the axis are S and m_S. We assume that the alkali nuclear spin is zero for simplicity and show in the Appendix that the result is independent of the nuclear spin. However, we do require that the off-diagonal elements of the alkali atom density matrix in the energy (i.e., F, M_F) representation between collisions be negligible.

If the triplet and singlet states of the coupled free electron and alkali-valence electron were nondegenerate energy eigenstates between collisions, we could use the general impact theory results of Baranger[10] to obtain the shift and broadening of the transition between these levels in terms of the scattering phase shifts $\delta_l(1)$ and $\delta_l(0)$ for the triplet and singlet states, respectively. The subscript refers to the lth partial wave. Taking the triplet as the higher level, the half-width and the shift are given, respectively, in angular frequency by

$$W=\left\langle \frac{1}{2}nv\int d\Omega|f_1(\Omega)-f_0(\Omega)|^2\right\rangle_{\rm av}, \tag{2}$$

$$d=\Big\langle -(2\pi nv/k)R[f_1(0)-f_0(0)]$$

$$+\tfrac{1}{2}nvi\int d\Omega[f_0^*(\Omega)f_1(\Omega)-f_0(\Omega)f_1^*(\Omega)]\Big\rangle_{\rm av}. \tag{3}$$

Here $f_1(\Omega)$ and $f_0(\Omega)$ are the triplet and singlet elastic scattering amplitudes as a function of direction, R means the real part, n is the number of scatterers per a_0^3, v is the electron velocity in a_0/sec, a_0 is the Bohr radius for hydrogen, and k^2 is the electron energy in units of 13.6 eV. The average is over the electron-velocity distribution, which is assumed to be Maxwellian. Since

$$f_S(\theta)=(2ik)^{-1}\sum_l(2l+1)(e^{2i\delta_l(S)}-1)P_l(\cos\theta), \tag{4}$$

where $S=1$ and 0 correspond to the triplet and singlet amplitudes, we find

$$w=\langle(\pi nv/k^2)\sum_l(2l+1)[1-\cos2\Delta_l]\rangle_{\rm av}, \tag{5}$$

$$d=\langle-(\pi nv/k^2)\sum_l(2l+1)[\sin2\Delta_l]\rangle_{\rm av}, \tag{6}$$

where $\Delta_l=\delta_l(1)-\delta_l(0)$. Converting n and v to cgs units and labeling the most probable electron velocity as v_m and the corresponding value of k as k_m, we have

$$w=\left(\frac{\pi a_0^2nv_m}{k_m^2}\right)\sum_l(2l+1)\langle(1-\cos2\Delta_l)/(v/v_m)\rangle_{\rm av}, \tag{7}$$

$$d=-\left(\frac{\pi a_0^2nv_m}{k_m^2}\right)\sum_l(2l+1)\langle(\sin2\Delta_l)/(v/v_m)\rangle_{\rm av}. \tag{8}$$

This is equivalent to the following collisional rates of change of the density matrix elements ${}^e\sigma_{ij}$ in the electron-spin-coupled representation:

$$(d{}^e\sigma_{ij}/dt)_{\rm Col.}=-(w-id){}^e\sigma_{ij} \tag{9}$$

for i corresponding to a singlet state and j to a triplet state, and

$$(d{}^e\sigma_{ij}/dt)_{\rm Col.}=0 \tag{10}$$

for i and j both corresponding to singlet or both to triplet states.

In reality, the states between which transitions are observed are the free-electron spin states. We will let ρ be the free-electron spin density matrix in the usual representation. Ignoring the off-diagonal elements for the alkali spin density matrix u and also ignoring correlations between the free-electron and alkali-electron density matrices, we can write the total spin

Finally, by contracting we obtain

$$(d\rho/dt)_{\text{Col.}}=\begin{array}{c|cc} M_e \backslash M_e & \frac{1}{2} & -\frac{1}{2} \\ \hline \frac{1}{2} & -\frac{1}{2}w(\rho_{11}-A) & -[\frac{1}{2}w+\frac{1}{2}id(A-B)]\rho_{12} \\ -\frac{1}{2} & -[\frac{1}{2}w-\frac{1}{2}id(A-B)]\rho_{21} & \frac{1}{2}w(\rho_{11}-A) \end{array}. \tag{18}$$

The above collisional rates of change for the off-diagonal elements of ρ correspond to the following half-width and frequency shift for the free-electron spin resonance:

$$w'=\tfrac{1}{2}w, \tag{19}$$

$$d'=\tfrac{1}{2}P_A d, \tag{20}$$

where $P_A=A-B$ is the alkali electron spin polarization. These formulas are the same as those obtained by Balling, Hanson, and Pipkin[9] by essentially repeating Baranger's calculation for the case of electron exchange collisions. They have been rederived here mainly for pedagogic reasons. The ratio of shift to broadening for the case where only S-wave collisions are important agrees with our earlier estimated value except that the velocity averaging procedure is now specified.

3. LOW-ENERGY ELECTRON-ALKALI ELASTIC SCATTERING

We are now ready to review the available information on low-energy electron-alkali elastic scattering phase shifts. The only calculations available which extend over the necessary energy range are for hydrogen and cesium. For sodium, only the S-wave scattering lengths are available.

We define

$${}^sI_l\equiv\langle(\sin 2\Delta_l)/(v/v_m)\rangle_{\text{av}}, \tag{21}$$

$${}^cI_l\equiv\langle(1-\cos 2\Delta_l)/(v/v_m)\rangle_{\text{av}}, \tag{22}$$

$$R\equiv(-d'/P_A w'), \tag{23}$$

$$x\equiv(v/v_m)=(k/k_m). \tag{24}$$

Then,

$$R=[\sum_l(2l+1){}^sI_l]/[\sum_l(2l+1){}^cI_l], \tag{25}$$

where

$${}^sI_l=(4/\sqrt{\pi})\int_0^\infty x[\sin 2\Delta_l(k)]e^{-x^2}dx, \tag{26}$$

$${}^cI_l=(4/\sqrt{\pi})\int_0^\infty x[1-\cos 2\Delta_l(k)]e^{-x^2}dx. \tag{27}$$

For hydrogen and cesium, we will use $T=290°\text{K}$, corresponding to the rubidium experiments of Balling, Hanson, and Pipkin,[9] while for sodium we will also use $T=410°\text{K}$, corresponding roughly to the sodium experiments of Hobart and Franken[5,6] and of Dehmelt.[1] We have $k_m(290°\text{K})=0.0429$ and $k_m(410°\text{K})=0.0510$.

For the hydrogen S wave, we take the results of Schwartz.[11] However, his lowest points are for $k^2=0.01$ and 0.02. We must therefore use an interpolation formula. O'Malley, Spruch, and Rosenberg[12,13] have shown that the normal effective range theory expansion is not valid in the presence of a long-range potential such as the polarization potential $V(r)=-\alpha/r^4$. However, a modified effective range theory expansion which is valid for atoms which have spherically symmetric ground states has been given by these authors. From Eq. (2.3) of O'Malley,[14] we obtain

$$\Delta_0=[A(1)-A(0)]k+\tfrac{4}{3}[A(1)-A(0)](\alpha/a_0^3)k^3\ln k+0(k^3), \tag{28}$$

$$\Delta_1=0(k^3). \tag{29}$$

Here $A(1)$ and $A(0)$ are the triplet and singlet S-wave scattering lengths and α is the atomic polarizability. From Schwartz's paper $[A(1)-A(0)]=4.196$. Using the hydrogen polarizability[15] of $4.5a_0^3$ to calculate the coefficient of $k^3\ln k$ and including a k^3 term, we obtain

$$\Delta_0=4.196k+25.2k^3\ln k+24k^3, \tag{30}$$

where the coefficient of k^3 has been fit to Schwartz's value at $k=0.1$. With this interpolation formula, ${}^sI_0=0.339$ and ${}^cI_0=0.066$.

For the P wave we use the results of Burke and Schey.[16] Including only a k^3 term and fitting to their lowest point, we find $\Delta_1=3.8k^3$, ${}^sI_1=0.001$, ${}^cI_1=0.000$. Also from Burke and Schey, higher partial waves are negligible. Thus, $R_H(290°\text{K})=5.2$.

For cesium, the only calculated phase shifts which appear to be useful for the present problem are the very recent ones of Stone and Reitz.[17] Values of Δ_0, Δ_1, and Δ_2 obtained from their results are given in Table I. It appears that the first three or four terms of the modified effective range theory expansion are not adequate to represent the results even at moderate values of k. This is not surprising in view of the high

TABLE I. Triplet-singlet phase-shift differences Δ_l for the S, P, and D partial-wave scattering of electrons from cesium.[a] The functions $f_0=(0.78)[1-\exp(-36k)]$ and $f_1=-(0.66k)\times[1-\exp(-300k^2)]$ are chosen to approximate Δ_0 and Δ_1 in the energy range of interest.

k^2	Δ_0	Δ_1	Δ_2	f_0	f_1
0.001	0.55	−0.05	0.00	0.53	−0.05
0.003	0.65	−0.21	0.01	0.67	−0.21
0.005	0.70	−0.37	0.01	0.72	−0.36
0.007	0.74	−0.49	0.00	0.74	−0.48
0.010	0.77	−0.64	0.03	0.76	−0.63
0.013	0.79	−0.75	0.04	0.77	−0.74
0.020	0.83	−0.93	0.15	0.77	−0.93

[a] See Ref. 17.

polarizability of cesium.[18] Instead, we represent Δ_0 and Δ_1 by functions $f_0=(0.78)[1-\exp(-36k)]$ and $f_1=-(0.66)k[1-\exp(-300k^2)]$ which give adequate agreement with Δ_0 and Δ_1 over the range of interest and which have leading terms proportional to k and k^3, respectively, near zero energy. These leading terms agree with the modified effective range theory. If one interprets the coefficient of the leading term in f_0 as a rough approximation to the triplet-singlet scattering-length difference, this gives $\Lambda(1)-\Lambda(0)=28$. Using f_0 and f_1, we find for cesium ${}^3I_0=0.94$, ${}^cI_0=0.61$, ${}^3I_1=-0.03$, and all other contributions are 0.01 or less. Thus, we obtain $R_{Cs}(290°K)\simeq 1.4$. Since the contributions from P and higher partial waves are small for cesium as well as hydrogen, the S-wave approximation is presumably good for the other alkalis also.

A possible difficulty with the interpretation given above appears when one looks at the calculated triplet S-wave phase shifts rather than just the phase-shift differences. The triplet phase shifts decrease fairly slowly, but the first one is 0.37 rad above 3π. Since the zero-energy limit must be a multiple of π, this raises the possibility that the zero-energy value consistent with the finite energy values is 4π. If so, all the values of Δ_0 in Table I should be increased by π. This would change only the way in which one extrapolates from the lowest calculated point to zero energy and would probably not change the value of R by more than 20%.

Actually, a scattering length difference large enough to give such a steep initial slope for Δ_0 as a function of k seems questionable. Some support for this view comes from the fact that the P-wave triplet phase shifts are also slowly decreasing and the lowest energy one is 0.05 rad above 2π. Since a zero-energy limit of anything but 2π seems inconceivable, it appears that the low-energy values for the S-wave phase shifts may also be somewhat offset by the computational procedure used by Stone and Reitz. This makes the uncertainty in Δ_0 appear to be of the order of 0.4 rad or larger and raises the possibility that Δ_0 could approach or go through $(\pi/2)$ at thermal energies and give a very small value for R_{Cs}.

[18] G. E. Chamberlain and J. C. Zorn, Phys. Rev. 129, 677 (1963).

In the case of sodium the main pieces of information available are the triplet and singlet S-wave scattering lengths $\Lambda(1)=9$ and $\Lambda(0)=-12$ calculated by Salmona and Seaton. If the scattering length approximation under which $\delta_0(1)=k\Lambda(1)$, $\delta_0(0)=k\Lambda(0)$ were valid, we would have $\Delta_0=21k$. Including only the S-wave contribution, this gives ${}^3I_0=0.68$, ${}^cI_0=1.28$, $R_{Na}=0.53$, at 410°K while at 290°K ${}^3I_0=0.80$, ${}^cI_0=1.10$, $R_{Na}=0.73$. In the same approximation, defining

$$\bar{Q}_{ex}=\langle(vQ_{ex}(v))\rangle_{av}/(\bar{v}), \tag{31}$$

we find,

$$\bar{Q}_{ex}=\pi a_0^2(\sqrt{\pi}\,{}^cI_0/4k_m^2). \tag{32}$$

At 410°K this gives $\bar{Q}_{ex}=220\pi a_0^2$. Dehmelt's experimental result,[1] adjusted to correspond to $\bar{v}$ instead of v_{rms}, is $Q_{ex}\geq 280\pi a_0^2$. Salmona and Seaton's zero energy cross section is $Q_{ex}=440\pi a_0^2$.

We will next calculate the modified effective range theory expansion for sodium. From Eq. (4.9) of O'Malley, Rosenberg, and Spruch[13] we find

$$\Delta_0=[\Lambda(1)-\Lambda(0)]k+Ak^3\ln k+Bk^3+Ck^4+\cdots. \tag{33}$$

Here,

$$A=\tfrac{4}{3}(\alpha/a_0^3)[\Lambda(1)-\Lambda(0)], \tag{34}$$

$$B=\{A\cdot\ln[1.23(\alpha/a_0^3)^{1/2}]+\tfrac{1}{3}\pi(\alpha/a_0^3)^{1/2}[\Lambda^2(0)-\Lambda^2(1)]-\tfrac{1}{3}[\Lambda^3(1)-\Lambda^3(0)]+\tfrac{1}{2}[\Lambda^2(0)r_{poS}-\Lambda^2(1)r_{poT}]/a_0\}, \tag{35}$$

$$C=\tfrac{2}{3}\pi(\alpha/a_0^3)[\Lambda^2(1)-\Lambda^2(0)], \tag{36}$$

where r_{poT} and r_{poS} are the triplet and singlet modified effective ranges and α is the polarizability. Using[18] $\alpha=21\times10^{-24}$ cm^3, we calculate $A=3970$, $C=-18\,700$, and $B=10\,600+72(r_{poS}/a_0)-40.5(r_{poT}/a_0)$. Transforming to the variable $x=(k/k_m)$

$$\Delta_0(410°K)=1.07x-0.16x^3+[0.0095(r_{poS}/a_0)-0.0054(r_{poT}/a_0)]x^3+0.52x^3\ln x-0.127x^4+\cdots. \tag{37}$$

We do not know the modified effective ranges, but at least one of them must be very large in order to make the coefficient of x^3 approach one. Since the other coefficients of x^3 and higher terms are fairly small, it appears that the modified range theory expansion may be useful for sodium at 410°K. The exchange cross section and the ratio of electron frequency shift to line broadening calculated in the scattering length approximation thus may be fairly accurate.

Another procedure is to approximate the sodium phase-shift differences by the same function of (k/k_{ex}) as was used to fit the cesium results of Stone and Reitz. Here k_{ex}^2 is the excitation energy for the atom in question. The reason for trying this is that the values of Δ_0 for cesium derived from Stone and Reitz are rather similar to those for hydrogen if both are plotted as a function of (k/k_{ex}). At 410°K we obtain ${}^cI_0\simeq 0.94$, ${}^cI_0\simeq 0.60$, $R_{Na}\simeq 1.6$, and $\bar{Q}_{ex}\simeq 100\pi a_0^2$. This procedure

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

gives poor agreement with Dehmelt's quoted lower limit for the experimental exchange cross section. While Dehmelt's number is not actually a lower limit, since no uncertainties are included, it would indicate a definite error in the experiment if the cross section were as low as $100\pi a_0^2$. Thus, the somewhat similar behavior of the presently available phase-shift differences for cesium and hydrogen does not appear to be characteristic of sodium.

One other possible source of information concerning the phase-shift difference for sodium comes from a rough estimate of the sodium polarization in Hobart's experiment based on a trace he gives[6] of the sodium Zeeman resonances at 3.68 G. This trace (Fig. 3.10 of Ref. 6) indicates a ratio of roughly 2.8:1 for the strongest and weakest $F=2$ Zeeman components. Assuming that the sublevel populations are independent of F and that sublevels differing in M_F by 1 have a constant ratio of populations leads to an approximate sodium-electron polarization $P_A=-0.17$. These assumptions correspond to spin-exchange equilibrium between the sodium atoms. Actually, the small amplitude of the $F=1$ resonances indicates that the magnitude of the polarization was probably higher. However, since we do not know precisely what correction to make, we will use the above number. Combining this with the value $R_{\mathrm{Na}}=0.53$ calculated on the scattering length approximation using the scattering lengths of Salmona and Seaton gives a ratio of shift to half-width of 0.09. While the maximum ratio of shift to half-width observed was only 0.05, it is not clear that the trace given by Hobart applies to the same experimental conditions. Thus, little can be said about the agreement of theory and experiment for sodium. However, it would not be surprising if the sodium phase-shift difference curve actually rose somewhat more rapidly than the scattering length approximation curve which we have used.

4. DISCUSSION

We are now ready to discuss the results of Balling, Hanson, and Pipkin.[9] Their experimental value of $R=0.05\pm0.01$ for rubidium at about 290°K is more than an order of magnitude less than the corresponding value for cesium calculated from the phase shifts of Stone and Reitz.[17] If the phase-shift difference curve for rubidium had the same shape as that calculated for cesium, it would have to have more than twice as high a maximum in order to agree with experiment. However, it seems uncertain whether a calculation for rubidium done by a method similar to that of Stone and Reitz for cesium would give this much different a result. Also, it appears doubtful whether the rather high value for the cesium polarizability used by Stone and Reitz can account for the possible discrepancy.

The argument given by Balling, Hanson, and Pipkin that the Rb^- ion is just barely bound and that therefore $\delta_0(0)$ should be about $\pi/2$ appears to be open to question. This argument, which was also used by Dehmelt[1] for Na, is based on the result for a deep square-well potential[19] and is only valid if the binding energy is small compared with the incident electron energy. The modified effective range theory expansion[12,13] shows that the square well is not a good approximation at extremely low energies. Also, the binding energies of alkali negative ions are believed to be much higher than thermal energies.[20] In particular, a calculation by Szasz[21] gives binding energies of 0.43, 0.53, 0.49, 0.43, and 0.42 eV for Li, Na, K, Rb, and Cs. These results are not expected to be very accurate, as indicated by the value for Li of 0.62 eV obtained by Weiss in a much more thorough calculation.[20] However, the relative values may be good and fairly strong binding for Rb^- seems likely.

In view of the possible discrepancy mentioned above, the assumptions made in the frequency-shift calculation were reviewed. The least certain ones appeared to be that the alkali matrix in the F, M_F representation can be taken as diagonal and that direct interactions between the free electrons can be neglected. The first assumption is discussed briefly at the end of the Appendix and appears to hold for the rubidium experiments. The second assumption is more difficult to investigate because of the very long range of the electron-electron interaction. However, if such interactions were important one might expect that normal variations of the experimental conditions would have given erratic results.

Assuming that the experimental results and their interpretation in terms of the scattering phase shifts are correct, we are left with two possible hypotheses. One is that the rubidium S-wave phase-shift difference Δ_0 increases rapidly at very low energies and fortuitously passes through or approaches $(\pi/2)$ at the proper energy to make R small. This seems somewhat unlikely but cannot be ruled out. The other possibility is that Δ_0 for the higher alkalis rises rapidly initially but for some reason flattens out near $(\pi/2)$ at roughly thermal energies. This would require that the low-energy phase-shift differences for cesium taken from Stone and Reitz be off by approximately 1 rad.

5. CONCLUSIONS

In view of the large difference between the experimental ratio of shift to broadening for rubidium and the ratio calculated for cesium using the phase shifts of Stone and Reitz, the present situation appears to be somewhat unsatisfactory. The quickest approach to seeing if there is a real discrepancy between experiment and theory would be an experimental measurement on cesium.[22] However, in view of the difficulty of calcu-

lations on cesium, it also appears to be desirable to repeat the experiments for sodium or for hydrogen.

ACKNOWLEDGMENTS

I would like to acknowledge helpful conversations with T. F. O'Malley on low-energy electron-alkali scattering phase shifts. Thanks are also due to P. A. Franken, P. M. Stone, and F. M. Pipkin for communicating their results prior to publication.

APPENDIX: DERIVATION OF ELECTRON SPIN RESONANCE FREQUENCY SHIFT FOR ARBITRARY NUCLEAR SPIN

We will treat the case of electrons with an arbitrary 2×2 spin-density matrix ρ colliding with alkali atoms having an electron spin of $\frac{1}{2}$ and a nuclear spin I. ρ is taken to be in the M_e representation, where M_e is the free-electron spin component along the axis and the two states are ordered according to decreasing M_e. The alkali spin density matrix u_{F,M_F} in the F, M_F representation is assumed to be diagonal. The alkali sublevels are taken to be listed in order of decreasing M_F and subordered according to decreasing F; i.e., the F, M_F order of listing is $[(I+\frac{1}{2}, I+\frac{1}{2}), (I+\frac{1}{2}, I-\frac{1}{2}), (I-\frac{1}{2}, I-\frac{1}{2}), (I+\frac{1}{2}, I-\frac{3}{2}), \cdots]$. When u_F is transformed to the M_I, M_J representation in which the states are ordered according to decreasing M_I and subordered according to decreasing M_J, the resulting matrix u will have off-diagonal elements connecting only the second and third, the fourth and fifth, etc., states. This is because there can be no off-diagonal elements connecting states with different values of (M_J+M_I). The diagonal elements can be labeled $(A_I, B_I, A_{I-1}, B_{I-1}, \cdots)$, where A corresponds to $M_J=\frac{1}{2}$, B to $M_J=-\frac{1}{2}$, and the subscript to M_I. Note that the expectation value of the electron polarization for the atom is given by

$$P_A=\sum_{M_I=-I}^{I}(A_{M_I}-B_{M_I}). \tag{38}$$

We now form the density matrix σ for the electron-plus-atom system in the (M_e, M_J, M_I) representation by taking the direct product of ρ and of u in the (M_J, M_I) representation. The states of σ are ordered according to decreasing M_I, first subordered according to decreasing M_J, and second subordered according to decreasing M_e. σ can be thought of as made up of $(2I+1)^2$ 4×4 submatrices. The 4×4 submatrices σ_{M_I} along the diagonal of σ which correspond to different M_I are of the form given in Eq. (11) except that A and B are replaced by A_{M_I} and B_{M_I}.

The transformation of σ to the representation with the electron spins coupled and the states ordered by decreasing M_I, first subordered by decreasing values of the total electron spin S, and second subordered by decreasing values of M_J is given by the following transformation:

$$^c\sigma=\Gamma_I\sigma\Gamma_I'. \tag{39}$$

Γ_I is made up of $2I+1$ identical 4×4 submatrices Γ along its diagonal, with Γ given by Eq. (13). We find then that the $2I+1$ 4×4 submatrices along the diagonal of σ^c are given by

$$^c\sigma_{M_I}=\Gamma\sigma_{M_I}\Gamma'. \tag{40}$$

We can now make use of the results for the case of zero nuclear spin. When we find $(d\sigma/dt)_{\text{Col.}}$ we will contract it to obtain $(d\rho/dt)_{\text{Col.}}$ as was done in Sec. 2. The only parts of $(d\sigma/dt)_{\text{Col.}}$ which we will need are the 4×4 submatrices $(d\sigma_{M_I}/dt)_{\text{Col.}}$. However, since

$$(d\sigma_{M_I}/dt)_{\text{Col.}}=\Gamma'(d^c\sigma_{M_I}/dt)_{\text{Col.}}\Gamma \tag{41}$$

and since $(d^c\sigma_{M_I}/dt)_{\text{Col.}}$ is obtained from $^c\sigma_{M_I}$ in the same way that $(d^c\sigma/dt)_{\text{Col.}}$ was obtained from $^c\sigma$ in Sec. 2, the contribution to $(d\rho/dt)_{\text{Col.}}$ from each σ_{M_I} is identical to that given in Eq. (18) except with A and B replaced by A_{M_I} and B_{M_I}. Thus, $(d\rho/dt)_{\text{Col.}}$ is the same as for the case of zero nuclear spin except that $A\rightarrow\sum_{M_I}A_{M_I}$ and $B\rightarrow\sum_{M_I}B_{M_I}$. In particular, $w'=\frac{1}{2}w$ and $d'=\frac{1}{2}dP_A$, which are identical to Eqs. (19) and (20) for the case of zero nuclear spin.

In this calculation it was assumed that u_{F,M_F} was diagonal. However, u_{F,M_F} does have two off-diagonal elements which have approximately the same time dependence as the off-diagonal elements of ρ. While the rf field at the electron spin resonance frequency cannot directly produce finite values for these elements because the corresponding transition would require $\Delta M_I=2I+1$, these elements can still be produced by the electron-alkali collisions. Thus, in order to be sure that off-diagonal elements of u_{F,M_F} do not change the electron frequency shift and line broadening, we must show that these elements are much smaller than the off-diagonal elements of ρ.

A direct calculation for arbitrary nuclear spin appears to be difficult. However, the calculation can be carried through for zero nuclear spin with the special condition that the rf field does not affect the alkali atom directly. In this case, it is found that the condition for the off-diagonal elements of u to be much smaller than those of ρ is as follows: The ratio of alkali density to electron density must be large compared with the ratio of the width of the electron spin resonance due to alkali collisions compared with the reciprocal of the decay time for the alkali off-diagonal elements. If the decay times for the off-diagonal elements of both ρ and u were determined by electron-alkali exchange collisions, this condition would not hold. However, as long as the decay time for the alkali off-diagonal elements is determined mainly by some other cause such as light absorption rather than by electron-alkali exchange collisions, then the assumption that u is diagonal should be quite good. This condition was apparently satisfied in the experiments of Balling, Hanson, and Pipkin, and of Hobart and Franken.

PHYSICAL REVIEW VOLUME 134, NUMBER 5A 1 JUNE 1964

Fine Structure of Helium*†

CHARLES SCHWARTZ
Department of Physics, University of California, Berkeley, California
(Received 6 January 1964)

Under the expectation that experiments will soon give values for the fine structure intervals of the 2^3P state of helium to an accuracy of $1/10^6$, we have undertaken a program of calculations which, it is hoped, will lead to a new determination of the fine-structure constant α. This paper gives a brief survey of the over-all program, and a detailed report of the successful completion of the first task: The construction of approximate solutions to the Schrödinger equation which lead to average values of the leading fine structure operators accurate to about one part per million.

I. INTRODUCTION

THE early studies of the fine structure of the helium atom by Breit[1] provided very important confirmation of the newly developing theory of the quantum interactions of electrons and the electromagnetic field. Over the intervening years there have been several efforts to increase the accuracy of this analysis, chiefly by the construction of successively more complicated approximations to the nonrelativistic 2-electron wave function. Breit,[1] with a 2-term trial function got values of the fine-structure intervals ν (see Fig. 1) accurate to several percent. Araki[2] and co-workers with 8 terms came within about 1%, and also considered two small corrections to the first-order theory. Traub and Foley,[3] with an 18-parameter function reduced the error to about one part in 10^3; and most recently Pekeris, Schiff, and Lifson,[4] with up to 220 terms in the trial function, came within one part in 10^4 of the final results we have attained. (These numbers refer to the larger interval ν_{01}. In the calculation of the small interval ν_{12} there is a cancellation between separate terms amounting to a full order of magnitude, and a corresponding loss of accuracy results.)

While these studies have been chiefly aimed at checking the theory, we here take another position: Assuming the current theory of quantum electrodynamics, one can combine the calculated and measured fine-structure intervals of helium in order to determine the value of the fine-structure constant α. At present, the best value of α comes from the work of Dayhoff, Triebwasser, and Lamb[5] on the fine structure $(2P_{1/2}-2P_{3/2})$ of hydrogen. That value is uncertain to about one part in 10^5, due essentially to the short lifetime of the $2p$ state, and it has not appeared feasible to improve on those measurements. However, the lifetime of the ^3P state of helium is about 2 orders of magnitude longer, and it is expected[6] that these fine structure intervals can be measured to an accuracy of one part in 10^6 or perhaps better.[7] It then becomes necessary to calculate theoretical values for the helium fine structure to $1/10^6$, and this is the task we here commence. It may be remarked that in the case of the hydrogen fine structure the theoretical formula[8] is very simple; this is not the case for helium. However, we believe that those circumstances which made the hydrogen problem simple, will have the effect of reducing the helium calculation from "impossibly difficult" to merely "difficult."

We should add that there is at present a specific need for a better value of α. Analysis[9] of the hyperfine structure of hydrogen reveals effects due to the electro-

magnetic structure of the proton, but a clear interpretation of those results is spoiled by the present uncertainty in the value of α.

II. PLAN OF THE CALCULATIONS

We will now outline the several parts of the task of calculating the fine structure intervals in helium to an accuracy of about one part in 10^6. The zeroth-order problem is the nonrelativistic two-electron Hamiltonian in a fixed Coulomb field:

$$H_0=\frac{p_1^2}{2m}+\frac{p_2^2}{2m}-\frac{Ze^2}{r_1}-\frac{Ze^2}{r_2}+\frac{e^2}{r_{12}}. \tag{1}$$

The next terms in a nonrelativistic expansion are the well-known[10] fine-structure terms which we shall denote as α^2H_2. [Our reference for energy is $e^2/a_0=\alpha^2mc^2$, and we shall not note factors of Z $(=2)$ as being pertinent to the classification of the expansion terms.] We thus expect an energy level formula something like

$$E_J-E_0=\alpha^2\langle H_2\rangle_J+\alpha^4\left[\langle H_4\rangle_J+\left\langle H_2\frac{1}{E_0-H_0}H_2\right\rangle_J\right]$$
$$+(\text{terms of order }\alpha^5\text{ and smaller which we shall ignore}), \tag{2}$$

where H_4 is some higher order operator which has not yet been worked out.

There are still many terms not represented in this formula (2). The most apparent is the correction for the anomalous magnetic moment of the electron, of order α^3. This is quite simple and has already been included by some authors.[2,4] The reduced mass must be put in properly, and there is also the operator $\mathbf{p}_1\cdot\mathbf{p}_2/M$ correcting for the motion of the nucleus; this is itself spin-independent but will contribute in a second-order calculation mixed with H_2. There are then very many diagrams one could write down describing radiative corrections of many higher orders.

The most extensive work on the fine structure and Lamb shift in hydrogen has produced terms up to, but not including, the order α^7mc^2,[11] which is just to the same order that we now need. But the two-electron atom seems so much more complicated than the one-electron atom that our project might appear too difficult to attempt. A thorough relativistic theory of the two-electron atom has thus far been analyzed[12] only as far as the leading Lamb-shift terms, $\alpha^5mc^2\times(\ln\alpha+\text{const})$, and our goal is well beyond this. What encourages us to proceed is the expectation that most of the difficult terms at these higher orders are spin-independent, and thus, while affecting the absolute energy level, do not contribute to the fine structure.

As an example, consider the effect on the fine structure of some deviation from pure Coulomb potentials occurring at some small distance R. The integrals which occur are of the general form of the familiar $\langle(1/r)\times(\partial V/\partial r)\rangle\sim\langle 1/r^3\rangle$, and are taken over radial wave functions for $l>0$ orbitals. Thus the relative correction would appear to be of the order

$$\int_0^R r^2dr r^{2l-3}\Big/\int_0^a r^2dr r^{2l-3}\approx(R/a)^{2l}\leqq(R/a)^2.$$

Thus the effect of finite nuclear size would seem to be completely negligible, and the effect of vacuum polarization would appear to be of order $\alpha(\alpha)^2=\alpha^3$ on the fine structure intervals, again negligible.

The entire project may be divided into three rather well-separated parts. First, is the task of constructing a sufficiently accurate eigenfunction of H_0 so that the leading term in Eq. (2) can be determined to about $1/10^6$; this is mostly a computer problem. Second, is the task of carrying out a proper relativistic analysis and determining the operator H_4 and whatever else may appear to the required order; this will be a matter needing both formal technique and enlightened short-cutting. The third job will be the evaluation of these smaller corrections to the fine structure, and this will require a combination of modest computer effort and much algebraic detail.

The rest of this paper is concerned with the first of these tasks.

III. THE SCHRÖDINGER WAVE FUNCTION: FIRST ATTEMPT

We wish to construct a good approximation to the lowest ^3P eigenfunction of the equation

$$H_0\psi=E_0\psi. \tag{3}$$

This will be done by setting up a sequence of trial functions ψ, using the variational principle

$$\delta\langle\psi|H_0-E_0|\psi\rangle=0 \tag{4}$$

and seeing how results of interest converge as we make the trial functions larger and larger.

We started with the functions

$$\psi=\left(\frac{1-P_{12}}{4\pi\sqrt{2}}\right)\sum_{l,m,n=0}^{l+m+n\leqq\omega}C_{lmn}\mathbf{r}_1r_1^mr_2^nr_{12}^l\times e^{-(\kappa\sigma/2)r_1}e^{-(\kappa/2)r_2}, \tag{5}$$

where P_{12} exchanges coordinated r_1 and r_2, and the P-state character is represented by the vector sign. The unit of length is $a_0=\hbar^2/me^2$; and the scale parameters κ and σ were taken, by extrapolation from the results of

[10] See Ref. 8, p. 181.

[11] A. J. Layzer, J. Math. Phys. 2, 308 (1961), has calculated terms of order $mc^2\alpha^7\ln^2\alpha$ and $mc^2\alpha^7\ln\alpha$. Only the latter contributes to the fine structure, and we hope it will not be difficult to include the term of this order in our problem.

Traub and Foley,[3] to be 4.62 and 0.29,[13] respectively, and were not varied. The variation of the linear parameters C_{lmn} leaves us then with the numerical problem of finding the eigenvalue and eigenvector of a symmetric matrix of degree

$$N(\omega)=\tfrac{1}{6}(\omega+1)(\omega+2)(\omega+3). \tag{6}$$

Some of the details of the construction of the matrix elements and the numerical methods used will be found in the Appendix. We give in Table I the resulting eigenvalues for the series of trial functions of degree $\omega=2,\ 3,\ \cdots,\ 10$. This was done with 16-decimal arithmetic on an IBM-704 and consumed a total of some 20 h of machine time.

This work very closely parallels that of Pekeris, Schiff, and Lifson,[4] differing only in the specification of the exponential parameters, κ and σ. This makes a non-negligible difference: At 220 terms our eigenvalue is an order of magnitude better converged than theirs.[14]

Our chief interest anyway is not the energy eigenvalue, but the eigenvector, or more properly the average values of the two spin-dependent parts of H_2. These are the well-known[10] spin-orbit terms

$$H(\text{s.o.})=\left(\frac{e\hbar}{2mc}\right)^2\left(\frac{\boldsymbol{\sigma}_1+\boldsymbol{\sigma}_2}{2}\right)\cdot\left[Z\left(\frac{\mathbf{r}_1\times\mathbf{p}_1}{r_1^3}+\frac{\mathbf{r}_2\times\mathbf{p}_2}{r_2^3}\right)-\frac{3(\mathbf{r}_1-\mathbf{r}_2)\times(\mathbf{p}_1-\mathbf{p}_2)}{r_{12}^3}\right], \tag{7a}$$

and the spin-spin term

$$H(\text{s.s.})=\left(\frac{e\hbar}{2mc}\right)^2\frac{1}{r_{12}^3}\left(\boldsymbol{\sigma}_1\cdot\boldsymbol{\sigma}_2-\frac{3\boldsymbol{\sigma}_1\cdot\mathbf{r}_{12}\boldsymbol{\sigma}_2\cdot\mathbf{r}_{12}}{r_{12}^2}\right). \tag{7b}$$

[We have dropped here a term in H(s.o.) which has only off-diagonal matrix elements.] The first-order fine-structure levels are customarily given in terms of two constants C (from s.o.) and D (from s.s.):

$$\begin{aligned}\langle H_2\rangle_{J=0}&=\text{const}-2C-(10/3)D,\\ \langle H_2\rangle_{J=1}&=\text{const}-C+(5/3)D,\\ \langle H_2\rangle_{J=2}&=\text{const}+C-(1/3)D.\end{aligned} \tag{8}$$

[These values will subsequently be given in units of $(e\hbar/2mc)^2a_0^{-3}=(\alpha^2/4)(e^2/a_0)=\frac{1}{2}\alpha^2$ Ry]. These results are also shown in Table I. The accuracy of our C and D values here is hardly better than that of Pekeris *et al.*[4] (about $1/10^4$) and far short of the desired $1/10^6$. At the time when these results were obtained we attempted to extrapolate the apparent rate of convergence of the output numbers, and thus estimated that something approaching 2000 terms of the series (5) would be needed to obtain the required accuracy in C and D. It seemed that, at best, this would be an extremely expensive venture; and we thus decided that this attack had failed.

Two possible paths were then considered. We might start with the wave functions already constructed, and, by use of auxiliary variational calculations of modest size, attempt to increase the accuracy of the C and D integrals to something approaching that which is obtained directly for the energy eigenvalue.[15] However, it appeared that, due to the rather singular nature of the operators H_2, the auxiliary functions needed for this method would be of a complicated analytical nature; and so we did not make a serious attempt in this direction.

Alternatively, we could seek a better set of basis functions for the calculation of ψ. The most likely cause for the slow convergence noted above appeared to be the weak logarithmic singularity in the two-electron wave function studied by Fock.[16,17] It appeared, however, that putting into ψ the explicit logarithm term given by Fock would be a very messy job. Furthermore, it was felt that the reward would be rather slight if only the first term were accounted for; and the higher terms of Fock's expansion appear to be complicated beyond our ability to manage. We then sought, in a much more *ad hoc* manner to introduce just any covenient terms which would add flexibility to ψ especially in the region ($r_1\to 0$ and $r_2\to 0$). We thus chose to try the addition of the simple factor $(r_1+r_2)^{1/2}$ to the series (5).[18] The efficacy of this extension of the basis functions was first tested on the relatively simple calculation of the

[13] The precise values of κ and σ used were about 10^{-8} smaller than the figures given here, due to the decimal-to-binary conversion operation of the machine.

helium ground state (1^1S), and those very successful results have already been presented.[19]

The calculations reported in this section are not a total loss, since we can expect to use these medium-accuracy wave functions for the later calculation of the small correction terms schematically represented in Eq. (2).

IV. THE WAVE FUNCTION: SECOND ATTEMPT

The expanded basis now looks like the expression (5) with the replacement

$$C_{lmn}\rightarrow C_{lmn}+D_{lmn}(r_1+r_2)^{1/2}; \tag{9}$$

and the single term D_{000} is omitted. The scale parameter σ was left fixed as before at 0.29,[13] but after a short search we changed the value of κ to 4.0 (exactly). The matrix elements of H_0 and H_2 are more complicated with the half-power terms, but once we had learned to evaluate the integrals C and D even with the old basis, the new techniques were not very difficult (see Appendix). The results converged much more rapidly, than before, but it was found, as might be expected that as one approached more closely to the exact fitting of the function numerical accuracy became more and more critical at an alarming rate. We found it necessary to construct special programs to do all our arithmetic to an accuracy of 30, and then 52 decimals; the resulting cost in machine time was very great. The total labor took some 30 h on an IBM-7090.

In Table II are presented our results with the half-power functions up to the ninth order. We show here separately the contributions from the two parts of (7a):

$$C=C_Z+C_e. \tag{10}$$

V. RESULTS

From the numbers in Table II we now must give our best values for the fine-structure intervals along with an estimate of their probable uncertainty. This we do by attempting to extrapolate the results shown to $\omega\rightarrow\infty$; the smoothness of the sequence of computed numbers will be used to indicate the reliability we may place on this extrapolation.

[19] C. Schwartz, Phys. Rev. 128, 1146 (1962).

TABLE III. Extrapolation of the calculated interval ν_{12} (in units of $\frac{1}{2}\alpha^2$ Ry).

Number of terms	Calculated $2D-2C$	Successive differences	Ratios of successive differences
7	0.0343768105		
		−0.008279	
19	0.0260979112		0.022
		−0.00018529	
39	0.0259126200		−0.800
		0.0001483866	
69	0.0260610066		1.962
		0.0002911883	
111	0.0263521949		0.257
		0.0000747812	
167	0.0264269761		0.306
		0.0000228957	
239	0.0264498718		0.151
		0.0000034446	
329	0.0264533164		0.127
		0.0000004379	
439	0.0264537543		
	Projected increment = 0.000000064 ±21		
	Extrapolation = 0.026453818 ±21		

Table III shows the details of such an extrapolation for the small interval

$$\nu_{12}=\tfrac{1}{2}\alpha^2\ \text{Ry}\cdot(2D-2C). \tag{11}$$

(It does make a helpful difference on the final error estimates that we extrapolate the combined integrals, rather than combine the extrapolated integrals.) The table shows values, differences, and ratios of successive differences; attempts to extrapolate must be based on the behavior of these ratios, especially at the bottom of the sequence. It is clear from Table III that these ratios cannot be very well described in any simple analytical terms; but it is to our advantage that they are very small.[20] After some playing with these numbers, attempting various analytical and graphical fits, it was decided that a reasonable procedure would be simply to extrapolate from the last step as if we had a geometric series, and assign as our uncertainty $\frac{1}{3}$ of the added increment. That is, if Δ' is the last difference recorded and R' is the last ratio, our final answer is gotten by adding to the last computed value the quantity

$$\Delta''=\Delta'\left(\frac{R'}{1-R'}\right)(1\pm\tfrac{1}{3}). \tag{12}$$

[20] By way of contrast one may note that the corresponding ratios in the work of Pekeris *et al.* (Ref. 4) are much smoother, but also quite a bit larger. One may also notice that while their value for ν_{01} calculated with 220 terms is 0.011% larger than our final result, their extrapolated value is 0.009% too small. Their extrapolation here was thus in error by about 45%. (For ν_{12} their extrapolation erred by only about 16%) We point these numbers out intending not to chasten others, but to emphasize the need for a critical attitude toward any attempts at numerical extrapolation, and in particular our own.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

We thus arrive at the following results for the intervals of the 2^3P state of helium, bare of any higher order corrections whatsoever.

$$\nu_{01}=\tfrac{1}{2}\alpha^2\ \mathrm{Ry}[0.33751721(7)]$$
$$R'=0.210 \tag{13a}$$

$$\nu_{12}=\tfrac{1}{2}\alpha^2\ \mathrm{Ry}[0.02645382(2)]$$
$$R'=0.127 \tag{13b}$$

$$\nu_{02}=\tfrac{1}{2}\alpha^2\ \mathrm{Ry}[0.36397101(9)]$$
$$R'=0.172. \tag{13c}$$

The number in the inner parenthesis gives the uncertainty in the last figure quoted, arrived at according to (12). If our extrapolations are accepted, then we have achieved the desired goal of $1/10^6$ accuracy. If it becomes necessary, we could, without too much expense, carry the numerical work one order further and thus increase the certainty of these numbers by about a factor of 5; but at present we feel this part of the program can rest, and wait for the experimental work and the analysis of higher-order corrections to catch up.

VI. CONCLUSION

The first major goal of the plan outlined in Sec. II has now apparently been achieved, and this encourages us to proceed with the other parts of the over-all program for the redetermination of α. There are two rather apparent cautions which we wish to make. First, regarding the extrapolation and error estimation, we have tried to be both clever and objective in our analysis, but each reader will have to find his own measure of skepticism regarding the precise accuracy of our results. Secondly, while we have endeavored to check and recheck all our algebra and computer programs, the considerable complexity of the work reported here must leave open the possibility of some undiscovered error of importance. To this point we report the following experience.

Six months after we had completed the last of our computations, there was discovered an error in our computer program for multiple precision division. It turned out that the last ten decimals were sometimes treated incorrectly; but some conditions under which this error would not arise could also be precisely identified. A detailed scrutiny of all our programs then revealed the astonishing fact that this mistake did not have any effect at all on any of the matrix element computations. The error could work only in the process of solving for the eigenvectors of the matrices; but our method was, at the end, an iterative process, so that we suffered only a slower convergence (paid more dollars) as a result of the mistake, and all our final answers were unaffected.

We hope that someone, working independently of us, will repeat and check all this work; this is the best insurance we can imagine for the reliability of these important results.

One can ask for a comparison of the present best experimental and theoretical values for the fine-structure intervals. Adding to our results (13) the simple correction for the anomalous magnetic moment of the electron[2] (the only correction of relative order α) and using the value of the Rydberg for helium,

$$\tfrac{1}{2}\alpha^2\ \mathrm{Ry}=2.921374\ \mathrm{cm}^{-1}, \tag{14}$$

we get

$$\nu_{01}=0.987837\ \mathrm{cm}^{-1},$$
$$\nu_{12}=0.0765302\ \mathrm{cm}^{-1}, \tag{15}$$
$$\nu_{02}=1.064367\ \mathrm{cm}^{-1}.$$

These may be compared with the experimental values

$$\nu_{01}=0.98791(4)\ \mathrm{cm}^{-1},$$
$$\nu_{12}=0.076423(3)\ \mathrm{cm}^{-1},$$
$$\nu_{02}=1.06434(3)\ \mathrm{cm}^{-1}.$$

[*Note added in proof.* The numbers quoted here have been corrected, relative to those published (Ref. 7), according to private communication from Dr. R. H. Sands. See also F. M. J. Pichanick, R. D. Swift, and V. W. Hughes, Bull. Am. Phys. Soc. 9, 90 (1964).] The differences are about 0.0001 cm^{-1}, which is roughly what one would expect due to the neglected terms of relative order α^2. Araki[2] has considered one such higher-order term, the mixing with the nearby 2^1P state; Perkeris *et al.*[4] give for this effect a resulting downward shift of 0.000158 cm^{-1} to the $J=1$ level. The addition of this correction appears to do little more than change the signs of the discrepancies for the 0–1 and 1–2 intervals; and this indicated that all the higher order terms of Eq. (2) will have to be treated together.

ACKNOWLEDGMENTS

The author was assisted in some of the early programming by A. Miller. He also wishes to thank many staff members of the University of California Computer Center for the advice and service they have generously given him.

APPENDIX: NUMERICAL METHODS

The many matrix elements of the operators H_0 and H_2 in the basis used were evaluated in terms of pretabulated integrals of the following general type:

$$A_\Lambda(L,M,N)=\left(\frac{1+\sigma}{2\sigma}\right)^{L+M+N+(\Lambda/2)}\int\frac{dv_1}{4\pi}\int\frac{dv_2}{4\pi}e^{-r_1}e^{-r_2/\sigma}$$
$$\times r_1^{M-2}r_2^{N-2}r_{12}^{L-2}f_\Lambda(r_1,r_2), \tag{A1}$$

$B_\Lambda(L,M,N)$ = same as (A1) but with a factor

$$\cos\theta_{12}\ \text{under the integral.} \tag{A2}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

L, M, N are integers greater than zero; $\sigma(0<\sigma<1)$ is a general parameter which is put $=0.29$ for the direct integrals and $=1$ for the exchange integrals; and f_Λ is a homogeneous function of degree $\frac{1}{2}\Lambda$ in the two lengths r_1 and r_2.

By use of the following identity referring to integration over the angle θ_{12} (signified by the angular brackets)

$$\langle \sin^2\theta_{12} r_{12}{}^L\rangle = \frac{-2}{(L+2)}\left\langle \cos\theta_{12}\frac{r_{12}{}^{L+2}}{r_1 r_2}\right\rangle, \qquad \text{(A3)}$$

one can easily establish the following recursion formulas:

$$\begin{aligned} A(L,M,N) &= A(L-2,M+2,N)+A(L-2,M,N+2) \\ &\quad -2B(L-2,M+1,N+1), \\ B(L,M,N) &= [(L-2)/(L+2)][B(L-2,M+2,N) \\ &\quad +B(L-2,M,N+2) \\ &\quad -2A(L-2,M+1,N+1)]. \end{aligned} \qquad \text{(A4)}$$

Our general method for building tables of integrals is by the use of such recursion formulas; but one must be careful that the particular recursive scheme chosen does not build by taking differences of nearly equal numbers (most obvious recursion schemes do suffer from this serious drawback.) For the above integrals—for large values of L, M, N in particular—the main contribution comes from large values of r_{12}; thus $\cos\theta_{12}$ is mostly negative, the integrals A and B have opposite signs, and the recursion schemes (A4) are safe.

In order to start the recursion sequence we need to evaluate A and B for $L=1$ and 2. The angular integrals are simple and we can express the results in terms of two families of two-dimensional integrals. (The subscript Λ is understood in what follows.)

$$\begin{aligned} &B(2,M,N)=0, \\ &A(2,M,N)=F(M+1,N+1)+G(N+1,M+1), \\ &B(1,M,N)=\tfrac{1}{3}F(M+2,N-1)+\tfrac{1}{3}G(N+2,M-1), \\ &A(1,M,N)=F(M+1,N)+G(N+1,M), \end{aligned} \qquad \text{(A5)}$$

where

$$\begin{aligned} F(M,N) &= [(1+\sigma)/2\sigma]^{M+N+(\Lambda/2)}\int_0^\infty dr e^{-r} r^{M-1} \\ &\quad \times\int_r^\infty ds e^{-s/\sigma} s^{N-1} f_\Lambda(r,s) \\ &= \left(\frac{1+\sigma}{2\sigma}\right)^{M+N+(\Lambda/2)}\Gamma\left(M+N+\frac{\Lambda}{2}\right) \\ &\quad \times\int_0^1 dx \frac{x^{M-1} f_\Lambda(x,1)}{[(1/\sigma)+x]^{M+N+(\Lambda/2)}}, \end{aligned} \qquad \text{(A6)}$$

and

$$\begin{aligned} G(M,N) &= \left(\frac{1+\sigma}{2\sigma}\right)^{M+N+(\Lambda/2)}\int_0^\infty dr e^{-r/\sigma} r^{M-1} \\ &\quad \times\int_r^\infty ds e^{-s} s^{N-1} f_\Lambda(s,r) \\ &= \left(\frac{1+\sigma}{2\sigma}\right)^{M+N+(\Lambda/2)}\Gamma\left(M+N+\frac{\Lambda}{2}\right) \\ &\quad \times\int_0^1 dx \frac{x^{M-1} f_\Lambda(1,x)}{[1+(x/\sigma)]^{M+N+(\Lambda/2)}}. \end{aligned}$$

We shall again tabulate these two dimensional arrays, F and G, by recursion; but all the obvious formulas we have looked at (proceeding from small to large values of M and N) are badly behaved regarding loss of accuracy from subtractions. We thus use the backward iteration formulas

$$\begin{aligned} F(M,N) &= \frac{2/(1+\sigma)}{(M+N+\frac{1}{2}\Lambda)}[\sigma F(M+1,N)+F(M,N+1)] \\ G(M,N) &= \frac{2/(1+\sigma)}{(M+N+\frac{1}{2}\Lambda)}[G(M+1,N)+\sigma G(M,N+1)]. \end{aligned} \qquad \text{(A7)}$$

These recursions start from the values of F and G along the line $M+N=$ constant (about 30 in our work). We have found the following devious, but numerically safe, procedure for these evaluations. After Eq. (A6) make the change of variables

$$x=\frac{1-u}{1+u}, \qquad \text{(A8)}$$

implying

$$\begin{aligned} f_\Lambda(x,1) &= (1+u)^{-(\Lambda/2)} f_\Lambda(1-u,1+u), \\ f_\Lambda(1,x) &= (1+u)^{-(\Lambda/2)} f_\Lambda(1+u,1-u); \end{aligned} \qquad \text{(A8)}$$

then expand the resulting denominator of F in an infinite power series in

$$[\tfrac{1}{2}(1-\sigma)(1-u)],$$

and the denominator of G in terms of $\{[(1-\sigma)/(1+\sigma)]\times u\}$. Also make the binomial expansion of the resulting numerator factor $(1+u)^{N-1}$ according to the separation

$$(1+u)=2u+(1-u).$$

The resulting expressions are

$$\begin{Bmatrix} F(M,N) \\ G(M,N) \end{Bmatrix} = \sum_{J=1}^{N} \frac{(N-1)!2^{J-1}(M+N-J-1)!}{(N-J)!2^{M+N+(\Lambda/2)-1}} \times \begin{Bmatrix} \tilde{F}_J(M+N) \\ \tilde{G}_J(M+N) \end{Bmatrix}, \qquad \text{(A9)}$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

where

$$\tilde{F}_J(K)=[\tfrac{1}{2}(1+\sigma)]^{K+(\Lambda/2)}\sum_{k=0}^{\infty}\left(\frac{1-\sigma}{2}\right)^k \times\frac{(K+\frac{1}{2}\Lambda-1+k)!}{k!(J-1)!(K-1-J)!}\tilde{F}_J'(k,K), \tag{A10}$$

$$\tilde{G}_J(K)=\sum_{k=0}^{\infty}\left(\frac{1-\sigma}{1+\sigma}\right)^k\frac{(K+\frac{1}{2}\Lambda-1+k)!}{k!(J-1)!(K-1-J)!}\tilde{G}_J'(k,K),$$

and

$$\tilde{F}_J'(k,K)=\int_0^1 du f_\Lambda(1-u,1+u)u^{J-1}(1-u)^{K-1-J+k}, \tag{A11}$$

$$\tilde{G}_J'(k,K)=\int_0^1 du f_\Lambda(1+u,1-u)u^{J-1+k}(1-u)^{K-1-J}.$$

For most of the integrals of interest the function $f_\Lambda(r_1,r_2)$ is $(r_1+r_2)^{\Lambda/2}$ ($\Lambda=0$, ±1, or 2); and so in the final expressions (A11) the function f_Λ is merely a constant and these integrals are trivial. However in treating H_2 we also run into the spectral case of Eq. (A3) for $L=-2$, and this leaves us with

$$f_\Lambda(r_1,r_2)=\ln\left|\frac{r_1-r_2}{r_1+r_2}\right|\cdot(r_1+r_2)^{\Lambda/2} \tag{A12}$$

in Eq. (A6); but this reduces to $2^{\Lambda/2}\ln u$ in Eq. (A11), and these final integrals are again easy.

The infinite sums in Eq. (A10) are rapidly converging for our values of σ; and the entire procedure worked very well.

Matrices of dimension 440 in sextuple precision require over half a million words of machine storage space (an order of magnitude more than what is available in the core) and so we made extensive use of magnetic tapes. The most time-consuming operation was the matrix inversion carried out at the start of the eigenvector calculation. For the largest, dimension 438, this took 10 h of 7090 time—equivalent to about one billion simple 8-figure multiplications on this machine.

We will now describe the method used for finding the eigenvector. Given two symmetric matrices H and N ($N>0$) of order n, we separate the problem

$$\sum_{j=1}^{n}(H_{ij}-\lambda N_{ij})x_j=0,\quad i=1,2,\cdots,n \tag{A13}$$

as follows: Set $x_1=1$, and solve for x_i from

$$\sum_{j=2}^{n}(H_{ij}-\lambda N_{ij})x_j=-(H_{i1}-\lambda N_{i1}),\ i=2,3,\cdots,n \tag{A14}$$

once λ is known; but we can get a stationary estimation for λ, once an approximate vector x is known, from the Rayleigh quotient,

$$\lambda=(x,Hx)/(x,Nx). \tag{A15}$$

In this work we always have a very good guess for λ to start with, and the alternating iteration (A14), (A15) is very rapidly convergent. Most of the time goes into solving (A14); the process of solving n simultaneous linear equations

$$Ax=b \tag{A16}$$

by the direct method of elimination takes $\frac{1}{6}n^3$ operations (for a symmetric matrix A). On the other hand, iterative attacks on the solution of (A16) require only of the order of n^2 operations per cycle, but many iteration schemes do not converge at all well. The general criterion is that one have some "good" approximation to the inverse of the matrix A; then

$$x^{(l+1)}=x^{(l)}+\tilde{A}\cdot(b-Ax^{(l)}), \tag{A17}$$

where $\tilde{A}$ approximates A^{-1}, can be expected to converge "rapidly." For our problem the matrix to be inverted (A14) changes only very slightly, as our value of λ is improved, so that it is necessary to calculate *only once* an inverse matrix (by the direct method[21]), and then we use this as the kernel of the iterations (A17), until both eigenvalue and eigenvector are converged.

This process works well, but as one goes to larger and larger matrices, loss of numerical accuracy becomes a serious problem at a rate much beyond any that could be attributed to statistical phenomena. Obviously, the full matrix $(H-\lambda N)$ in Eq. (A13) is singular—for the correct λ—but one would think that the remnant matrix in Eq. (A14) is far from singular since the most important element of the basis has been removed. In actuality, however, the removal of a single trial function does not prevent the convergence of the variational sequence, it may merely slow it. Thus, as we go to larger and larger bases, the matrix in Eq. (A14) does come closer and closer to being singular, and at a painfully fast rate. We handled this problem by the brute force method of using higher precision arithmetic, but the cost was quite great. (It may be that the problem would not have been quite as bad as it did appear to us, had we caught earlier the error mentioned in Sec. VI.)

[21] After completion of this work the following, possibly more efficient, method occurred to us. The new terms one is adding to the basis at each step in the sequence of variational calculations must be numerically of decreasing importance (if the entire process is converging at all well). Then it may be sufficient to get $(\tilde{A})$ by carrying out the direct calculation on only a small submatrix representing the dominant terms, and simply using the diagonal elements for the higher parts of the matrix.

Low-Energy Expansion of the Scattering Amplitude for Long-Range Quadrupole Potentials*

THOMAS F. O'MALLEY†
Joint Institute for Laboratory Astrophysics, Boulder, Colorado

(Received 20 January 1964)

For static potentials which are proportional asymptotically to $qP_2(\cos\theta)/r^3$, the low-energy expansion of the scattering amplitude is found through terms of $O(k)$, using a modification of the method developed by Levy and Keller for central potentials. The resulting expansion to lowest order in k is found to be $f(\theta,\phi)\sim -A + (q/3)P_2(\cos\theta_K)+O(k)$, where A is the scattering length and θ_K is the coordinate of the momentum transfer vector. Applications are attempted first to electron-atom elastic scattering where results are somewhat more complicated than for the potentials above, secondly to transitions between magnetic quantum states of atoms caused by slow electrons.

1. INTRODUCTION

EFFECTIVE range expansions developed originally for short-ranged potentials[1] have been extended in recent years first to spherical potentials with r^{-4} tails[2] and finally to potentials with arbitrary r^{-n} radial dependence asymptotically.[3] This has enabled the usefulness of the low-energy expansion to be extended to electron-atom collisions,[4] and to any scattering problem where long-range Van der Waals forces are operative. However there are physical problems, exemplified by the scattering of electrons from atomic oxygen or other nonsymmetric atoms, for which the asymptotic form of the interaction is not the r^{-4} polarization potential but rather the quadrupole interaction proportional to $r^{-3}P_2(\cos\theta)$; in particular:

$$(2m/\hbar^2)V(\mathbf{r})\sim qP_2(\cos\theta)/r^3-r^{-4}[p+p'P_2(\cos\theta)] +O(r^{-5}). \quad (1.1)$$

Since such a potential is not spherically symmetric, the usual phase-shift analysis is not applicable for one has a coupling of different angular momentum states. Hence the expansions of Levy and Keller[3] for the phase shifts are not applicable. But while phase shifts for this problem are not well defined, the scattering amplitude, $f(\theta,\phi)$, is. In this paper we will look for an energy expansion for $f(\theta,\phi)$,[5] adapting to this purpose the approach which was used by Levy and Keller[3] (LK) to expand $\tan\eta$ for symmetric potentials.

In Sec. 2, we shall briefly review the LK method, modifying it to a more heuristic form which we find easier to apply to the present purpose. In Sec. 3, the method is then applied to expanding the amplitude, $f(\theta,\phi)$, for potentials with the asymptotic form (1.1). The dipole potential is also briefly considered. Section 4 is devoted to considering the relation of the results of the previous section to the electron-atom scattering problem. In particular, the derivation of the form (1.1) of the potential is indicated and the relation of q to the atom's quadrupole moment is discussed. It is seen that that electron-atom problem is somewhat more complicated, due to the possibility of atomic transitions from one magnetic quantum state to another. The amplitude for these transitions is obtained to lowest order in the energy.

2. MODIFIED LEVY–KELLER METHOD

To introduce the method which will be applied in Sec. 3, consider the $L=0$ scattering of a particle by a long-range central potential, $U(r)$, proportional to r^{-n} asymptotically. Levy and Keller's starting point in attacking this problem was the first-order nonlinear equation[6] for the phase shift

$$d/dr\,\tan\eta(r)=-k^{-1}U(r) \times[\sin(kr)+\tan\eta(r)\cos(kr)]^2 \quad (2.1)$$

with boundary condition $\eta(0)=0$. $\eta(\infty)$ is the desired phase shift. They then represented $\tan\eta$ as a series in odd powers of k

$$\tan\eta(r)=k\sum_{j=0}^{\infty}k^{2j}i_j(r). \quad (2.2)$$

Equation (2.2) is substituted into (2.1) and equating like powers of k gives the equations for each of the

[5] An alternate approach might be to look for an expansion of the elements of the reactance matrix connecting states of different angular momentum. If one is interested in the scattering amplitude only, this approach is more complicated. But as other information in addition to the scattering amplitude can be found this way, work along this line is being done.

$l_j(r)$. $l_0(\infty)$ is the negative of the scattering length, A. Its equation is found to be

$$dA/dr = U(r)[r - A(r)]^2, \tag{2.3}$$

where we have changed the symbol l_0 to $-A$. The equations for l_1, etc., are similarly found.[3] If the potential were of short range, the problem would be finished, with the $l_j(\infty)$ furnishing the desired expansion of $\tan\eta$. However for long-range potentials, which are proportional asymptotically to r^{-n}, it is found that at most the first few of the l_j tend to a finite limit as $r \to \infty$. For example, if $n=4$, only $l_0(\infty)$ exists. [It should be pointed out for later reference that all the quantities $l_j(r)$ are still well defined for any finite r, and the expansion, Eq. (2.2) is still meaningful. One is merely prevented from going to the limit.]

Levy and Keller's procedure at this point was to consider the difference,

$$\tan\eta(r) - k\sum_{j=0}^{m} k^{2j} l_j(r) = k\beta(r,k),$$

where l_m is the last one whose limit is finite. Upon substituting this into (2.1), an equation for the function β was derived. This equation was then solved by an iteration or perturbation approach. It was found that, to lowest order in k, β was determined by the asymptotic region $r \to \infty$. In this region, the usefulness of the iteration method arises from the fact that successive iterations produce successively higher powers of k, so that a series in powers of k tends to fall out immediately.

For the purposes of this paper, a somewhat heuristic version of this method will be employed. We shall use the perturbation approach from the very beginning, and work directly with $\tan\eta$, rather than introduce the difference function, $\beta(r)$. The result of this is a greater directness and brevity, and a more intuitive approach. This will be done at the expense of introducing certain anomalous terms into the results, which however we shall see to have a clear interpretation.

To begin, let us rewrite Eq. (2.1) in integral form

$$\tan\eta(r) = \tan\eta(R) - k^{-1} \times \int_R^r U(r)[\sin(kr) + \tan\eta(r)\cos(kr)]^2. \tag{2.4}$$

R will be taken to be any very large but fixed distance (independent of k) and we vary k so that $kR \to 0$. The region $r < R$ is described by Eq. (2.2), as already pointed out. Now since R may be taken to be arbitrarily large, the integral may be considered to be a very small quantity for any allowable potential. (It is shown below that this imposes the mild restriction that r^2U approach zero.) Thus the aptness of a perturbation approach to Eq. (2.4) for $r > R$ is clear.

Since R is arbitrarily large, we substitute for $U(r)$ its asymptotic expansion,

$$U(r) \sim \sum_n U_n r^{-n}.$$

We further introduce the new variable $kr = x$. Equation (2.4) then becomes

$$\tan\eta(r) = \tan\eta(R) - \sum_n k^{n-2} U_n \times \int_{kR}^{kr} dx\, x^{-n}[\sin(x) + \tan\eta\cos(x)]^2. \tag{2.5}$$

If we temporarily ignore the k dependence of the lower limit of integration, the way in which the various terms in the asymptotic expansion of U contribute to the energy expansion of $\tan\eta$ follows by inspection from Eq. (2.5). In applying perturbation theory, one first takes $\tan(R)$ as the zeroth-order quantity and substitutes this for $\tan\eta$ on the right-hand side of Eq. (2.5). From Eq. (2.2), we see that this quantity is $O(k)$. In first-order perturbation theory then, each r^{-n} term in U contributes a k^{n-2} term to $\tan\eta$ plus terms of higher order. Now when these first-order terms are substituted back into the integral on the right-hand side, they produce in second order an additional factor k^{n-2}; and so provided the lowest n, n_0, is greater than 2, the leading term in second-order perturbation theory is $O[k^{2(n_0-2)}]$, and so on, just as found in LK. It is in this property that the power of the method lies. However, because of the k dependence of the lower limit of integration, there will be additional lower order terms in the total result.

We now proceed to study these terms and illustrate the method at the same time by solving for $\tan\eta(\infty)$ in first order, for a potential with $n_0=4$, the case which LK treated in detail. We assume for convenience that there are no other terms in the asymptotic expansion, and look for terms of order less than k^3. It will be seen that all the terms found by LK are reproduced very simply. In the zeroth order, we set for $r \geq R$

$$\tan\eta^{(0)}(r) = \tan\eta(R) = -A(R)k + O(k^3), \tag{2.6}$$

where the second equality follows from Eq. (2.2) with the notation $A = -l_0$. (This equation, as mentioned above, is valid up to any R which is fixed and finite.) Substituting this in the approriate places on the right-hand side of Eq. (2.5) gives for the first-order result

$$\begin{aligned}\tan\eta^{(1)}(\infty) = &-A(R)k - U_4k^2 \\ &\times \int_{kR}^{\infty} [\sin x - A(R)k\cos x]^2 \\ &\times x^{-4}dx + O(k^3) \\ = &-\left[A(R) + \frac{U_4}{R} - \frac{U_4A(R)}{R^2} \right. \\ &\left. + \frac{U_4A^2(R)}{3R^3}\right]k + \tfrac{1}{3}\pi U_4k^2 \\ &+ \tfrac{4}{3}U_4A(R)k^3\ln k + O(k^3). \end{aligned} \tag{2.7}$$

The integrals, which are elementary, are simplified if one notices that with the exception of the k^2 term all other terms come from the singularities at the lower limit of integration. [In all this analysis, since R is fixed, the quantity kR is considered an infinitesimal.] If one compares the result, Eq. (2.7), with the corresponding result Eq. (35) of LK[3] which is likewise first order, one sees that they are essentially the same. The only difference is that their η_0 (the negative of the scattering length) is replaced by the bracket term in the present result. A moment's reflection shows in what sense they are the same, namely the bracket represents the beginning of a perturbation expansion of A, starting with $A^{(0)}=A(R)$ in Eq. (2.3). This was to be expected since we are using a perturbation method throughout. It can be verified explicitly if one looks for the solution of Eq. (2.3) in first-order perturbation theory with the present potential. This is given by

$$A^{(1)}(\infty)=A(R)+U_4\int_R^\infty [r-A(R)]^2 r^{-4}dr$$

which when evaluated is exactly equal to the bracketed quantity in Eq. (2.7). These perturbation corrections to $A(R)$ are easily recognized in a calculation like Eq. (2.7) first by their k dependence and secondly by their explicit dependence on R. What they amount to is a renormalization of our zeroth-order scattering length. [If we had kept higher powers of k, there would have been renormalizations of the effective range as well.] The other terms in Eq. (2.7), the k^2 and $k^3 \ln k$ terms, are quite independent of the choice of R. Our practice in applying the method hereafter will be to replace, in all final results, both terms like the bracket term in Eq. (2.7) and quantities like $A(R)$ in the log term by the fully renormalized quantity $A=A(\infty)$, to which they tend as either $R\to\infty$ or the order of perturbation theory is increased.

Since the method just described is to be used in the following section to find the expansion of the scattering amplitude, a brief review of the procedure may be in order. One first finds the exact first-order nonlinear equation for the quantity f of interest corresponding to Eq. (2.1) above and writes it in integral form as in Eq. (2.4). One then considers the region r less than some large but fixed R, and makes the expansion corresponding to Eq. (2.2) for $f(R)$. Since this is the same whether the potential is short or long ranged, the form of the expansion will usually be known already. However, it is very simply derived by substituting an assumed expansion such as Eq. (2.2) into the exact equation and equating powers of k. Having done this, one is ready to study the contribution from $r>R$ by the perturbation or iteration method. R is assumed very large, the asumptotic expansion of $U(r)$ is substituted into the equation, and the new variable $x=kr$ is introduced. With $f(R)$ taken as the zero-order quantity, the iteration is begun. One then notices that the leading power of k introduced by each succeeding order of perturbation theory is of higher order in k than the last (apart from the renormalizations already discussed), and uses this to decide at which order to stop. Finally, one replaces partially renormalized quantities like the bracket and $A(R)$ in Eq. (2.7) by the fully renormalized quantity, such as A.

3. EXPANSION OF THE SCATTERING AMPLITUDE, $f(\theta,\phi)$

In this section we are interested in the solution of the Schrödinger equation

$$[\nabla^2+k^2-U(\mathbf{r})]\psi(\mathbf{r})=0$$

with the asymptotic form

$$\psi\sim\exp(i\mathbf{k}_i\cdot\mathbf{r})+f(\theta,\phi)\exp(ikr)/r,$$

where the vector $\mathbf{k}_i$ is in the direction of the incident plane wave. The noncentral potential $U(\mathbf{r})$ may be represented by a Legendre expansion relative to some z axis

$$U(\mathbf{r})=\sum_{L\text{ even}} U_L(r)P_L(\cos\theta), \tag{3.1}$$

where the U_L are assumed to have the following asymptotic dependence as $r\to\infty$:

$$\begin{aligned} U_2&\sim q/r^3-p'/r^4+O(r^{-5}),\\ U_0&\sim -p/r^4+O(r^{-5}), \end{aligned} \tag{3.2}$$

and higher U_L, if they exist, are $O(r^{-5})$. The reason for the particular asymptotic dependence assumed for the potentials by Eq. (3.2) is that this is the asymptotic form which one finds for the electrostatic interaction of a charged particle with a neutral quantum mechanical system, for example an electron and an atom. In this case the asymptotic form of U_2 will be proportional to the electric quadrupole moment of the target system, and this will be the dominant long-range interaction if it exists. The r^{-4} term in U_0 will be proportional to the target's electrical polarizability. The derivation of the known asymptotic forms Eq. (3.2) for an electron-atom system is indicated in Sec. 4. The restriction of the sum to even terms only is also dictated by the application. Physically this follows from the target system's having a well-defined parity.[7] In addition to being noncentral, we may allow the potential $U(\mathbf{r})$ to be nonlocal and energy dependent, provided that the nonlocality is of short range and the energy dependence can be represented by an expansion in k^2 near $k=0$. (These points will not be explicitly discussed further.)

In order to apply the method discussed in the preceding section, the Schrödinger equation must first be

[7] The only exception to this is the excited states of the H atom, where there is degeneracy between states of different angular momentum.

replaced by the appropriate first-order nonlinear equation for the quantity of interest, in this case the scattering amplitude, $f(\theta,\phi)$. This equation was found by Spruch[8] to be

$$f_r(\mathbf{k}_i\to\mathbf{k}_f)=f_{r_0}(\mathbf{k}_i\to\mathbf{k}_f)-(1/4\pi)\int_{r_0}^{r}r'^2dr'$$
$$\times\int d\Omega[e^{i(\mathbf{k}_i\cdot\mathbf{r}')}+f_{r'}(\mathbf{k}_i\to\mathbf{k}')e^{ikr'}/r']U(\mathbf{r}')$$
$$\times[e^{-i(\mathbf{k}_f\cdot\mathbf{r}')}+f_{r'}(-\mathbf{k}_f\to\mathbf{k}')e^{ikr'}/r'], \quad (3.3)$$

where the argument r is now written as a subscript. The vector $\mathbf{k}_i$ is again in the direction of the incident plane wave and $\mathbf{k}_f$ is a vector in the final direction, or the direction of observation. The vector $\mathbf{k}'$ has as its angles the variables θ and ϕ of integration. The lower limit of integration, r_0 is arbitrary.

Before looking for the contribution to f from the asymptotic region of the potential, let us first, as in the last section, consider the expansion of f_r for r less than some finite and fixed, though possibly large, R. It is easily verified that the appropriate expansion which takes the place of Eq. (2.2) of the last section is one in powers of ik, namely

$$f=\sum_{n=0}^{\infty}(ik)^n f_n \quad (3.4)$$

for $r<R$ fixed. Substituting this in Eq. (3.3) and equating like powers of ik one finds the equations for the individual functions, f_n. In particular the equation for f_0 is

$$f_0(r)=-(1/4\pi)\int_0^r r'^2dr'[1+f_0/r]^2\int d\Omega U(\mathbf{r}), \quad (3.5)$$

where for the present purpose we have set $r_0=0$. Since the angular integral over the potential simply gives $4\pi U_0$, we see that Eq. (3.5) is identical with Eq. (2.3) for the scattering length (rather for $-A$), with the potential given by the spherically symmetric component U_0. Therefore we shall refer to the quantity $-f_0$ as the scattering length and use the notation $-f_0=A$. An important property of A is that it is entirely independent of the $L>0$ (the nonspherically symmetric) terms in the potential.

The equation for the next function, f_1, in Eq. (3.4) may similarly be found. It is more complicated but simplifies when we use the fact that the potential $U(\mathbf{r})$ contains only even angular terms. We shall not write the equation for f_1, but it is exactly satisfied by the function

$$f_1(r)=f_0^2(r). \quad (3.6)$$

If we temporarily imagine that the potentials are of short range so that we may go to the limit $r=\infty$, Eq. (3.6) gives the optical theorem in the zero-energy limit. Again we note that Eq. (3.6) explicitly assumes that the potential has no component proportional to $P_1(\cos\theta)$.

We may now sum up the result of Eqs. (3.4) through (3.6) to write the expansion of the amplitude, f_R for any finite though possibly very large R, as $kR\to 0$. It is

$$f_R=-A(R)+ikA^2(R)+O(k^2). \quad (3.7)$$

Equation (3.7) might have been simply written down immediately as the known contribution to the scattering amplitude due to a potential in the region r less than some finite R. However, it seems more consistent to rederive it in the context of the present method.

We now proceed to our main purpose, namely to seek the contribution to the amplitude f from the region $r>R$, using Eq. (3.3) and writing $r_0=R$. As in the last section, the arbitrary distance R will be considered to be very large so that the asymptotic expansion (3.2) of the potential may be used. Accordingly we substitute the potential from (3.1) and (3.2) into Eq. (3.3) and multiply out the two brackets. We again introduce new variables

$$x=kr',$$
$$y=Kr'=(K/k)x, \quad (3.8)$$

where K is the magnitude of the momentum transfer vector, $\mathbf{K}=\mathbf{k}_i-\mathbf{k}_f$. It is related to k by $K=2k\sin(\theta_{if}/2)$ (see Fig. 1). The equation becomes

$$f_r(\mathbf{k}_i\to\mathbf{k}_f)=f_R(\mathbf{k}_i\to\mathbf{k}_f)-(1/4\pi)\int_{kR}^{kr}x^2dx$$
$$\times\int d\Omega\{qP_2(\cos\theta)x^{-3}-kx^{-4}[p+p'P_2(\cos\theta)]+\cdots\}$$
$$\times\{e^{iy\cos(\theta,\theta_K)}+(k/x)f_{r'}(\mathbf{k}_i\to\mathbf{k}')e^{ix[1-\cos(\theta_f,\theta)]}$$
$$+(k/x)f_{r'}(-\mathbf{k}_f\to\mathbf{k}')e^{ix[1+\cos(\theta,\theta_i)]}$$
$$+(k^2/x^2)f_{r'}(\mathbf{k}_i\to\mathbf{k}')f_{r'}(-\mathbf{k}_f\to\mathbf{k}')e^{2ix}\}, \quad (3.9)$$

where the notation $\cos(\theta_1,\theta_2)$ is used here and throughout the paper to denote the cosine of the angle, θ_{12}, between the vectors $\mathbf{k}_1$ and $\mathbf{k}_2$. $\cos(\theta_1,\theta_2)$ is given by the relation

$$\cos(\theta_1,\theta_2)=\cos\theta_1\cos\theta_2+\sin\theta_1\sin\theta_2\cos(\phi_1-\phi_2). \quad (3.10)$$

There remains nothing now but to go ahead and evaluate the integrals in Eq. (3.9) by the iteration or perturbation method, beginning with

$$f_r^{(0)}=f_R=-A(R)+ikA^2(R)+O(k^2), \quad (3.11)$$

where the superscript henceforth denotes the order of perturbation theory. We proceed to sufficiently high order in perturbation theory to obtain all the powers of k which are desired. As implied in Eq. (3.11) only

[8] Reference 6, p. 209.

terms through $O(k)$ will be sought here. (These will be seen to provide more than sufficient difficulty in evaluating while at the same time furnishing a great deal of detail in the results.)

By inspection of Eq. (3.9) it may be seen directly to what order in perturbation theory we must go in order to find all terms through $O(k)$, by taking the heuristic point of view explained in the last section of neglecting temporarily the k dependence of the lower limit of integration. Of the four exponential terms in the last bracket, the first term is $O(1)$. This will be called the Born term since it appears also in the Born approximation. Since it is not multiplied by any factor f as are the subsequent terms, it makes its contribution once and for all in first order. It contributes to f a q term of $O(1)$ and p and p' terms of $O(k)$. Higher terms in the potential would give contributions of $O(k^2)$ which is why they have not been written explicitly. Skipping ahead to the last exponential term in the bracket, it is seen that this already contains a factor k^2 which makes it higher order from the very beginning, and so it makes no contribution. Finally the two linear f terms in the bracket behave alike. They have a factor of k to start with. Since the lowest order terms in $f^{(0)}$ and $f^{(1)}$ are $O(1)$, the p and p' terms produced by these will always be $O(k^2)$. In first order, these linear f terms will produce q terms of $O(k)$ proportional to $f^{(0)}$. When we set these f's equal to $f^{(1)}$ to obtain the second-order result, we see that the Born term proportional to q will result in a q^2k term in this order. If the iteration process is continued further, it is seen that only terms of $O(k^2)$ are produced and so second order suffices.

We now proceed to evaluate the first-order contribution, $f^{(1)}$ to the amplitude. First, the zero-order quantity, $f^{(0)}$, given by Eq. (3.11) is substituted for f on the right-hand side of Eq. (3.9). The angular integrations are easily performed using the relation

$$\int d\Omega P_L(\cos\theta)e^{ix\cos(\theta,\theta_k)}=4\pi i^L j_L(x)P_L(\cos\theta_k). \quad (3.12)$$

This reduces Eq. (3.9) to

$$\begin{aligned} f_r^{(1)}(\mathbf{k}_i\to\mathbf{k}_f)&-[-A(R)+ikA^2(R)] \\ &=P_2(\cos\theta_K)q\int_0^{kr} dx x^{-1}j_2(y)+pk\int_{kR}^{kr} dx x^{-2}j_0(y) \\ &\quad -p'kP_2(\cos\theta_K)\int_0^{kr} dx x^{-2}j_2(y) \\ &\quad -qkA(R)[P_2(\cos\theta_f)+P_2(\cos\theta_i)] \\ &\quad \times\int_0^{kr} dx x^{-2}e^{ix}j_2(x)+O(k^2). \quad (3.13) \end{aligned}$$

The lower limit of integration has been extended to zero whenever the error introduced into f thereby was $O(k^2)$. The first three terms, resulting from the Born term in Eq. (3.9) are complicated by the presence of two different variables, x and y. It is easiest to eliminate the variable x in favor of y by use of Eq. (3.8). In the first integral, this merely changes the limits ($kr\to Kr$). In the second and third it also replaces the initial factor k by K.

Before proceeding to second order, let us look at the physical amplitude, $f_\infty^{(1)}$ in this order. Letting $r\to\infty$, we have

$$\begin{aligned} f_\infty^{(1)}(\mathbf{k}_i\to\mathbf{k}_f)&=-[A(R)-p/R]+\tfrac{1}{3}qP_2(\cos\theta_K) \\ &\quad -\tfrac{1}{4}\pi pK-(\pi/16)p'KP_2(\cos\theta_K)+ik\{A^2(R) \\ &\quad -\tfrac{1}{12}A(R)q[P_2(\cos\theta_f)+P_2(\cos\theta_i)]\}+O(k^2). \quad (3.14) \end{aligned}$$

The first term on the right is of course the scattering length, partially renormalized in first order. The second term represents the principle new result of the paper, a term generated by the quadrupole potential which is $O(1)$ but with angular dependence. As in previous work, this leading term is given by the Born integral. The angular factor $P_2(\cos\theta_K)$ requires some explanation. The angle θ_K is not the scattering angle. It is the angle made with the z axis by the momentum transfer vector $\mathbf{K}=\mathbf{k}_i-\mathbf{k}_f$ (the magnitude, K, of this vector appears in the following term). The vector $\mathbf{K}$ is represented in Fig. 1. The magnitude K is given (since $|\mathbf{k}_i|=|\mathbf{k}_f|=k$) by the familiar relation

$$K=2k\sin(\theta_{if}/2)=k\sqrt{2}[1-\cos(\theta_i,\theta_f)]^{1/2}.$$

The quantity $\cos\theta_K$ can be found from the relation

$$\cos(\theta_K)=\frac{K_z}{K}=\frac{\cos\theta_i-\cos\theta_f}{\sqrt{2}[1-\cos(\theta_i,\theta_f)]^{1/2}}. \quad (3.15)$$

The denominator might in turn be eliminated in favor of the angles θ_i, θ_f and $\phi_i-\phi_f$ by the relation

$$\cos(\theta_i,\theta_f)=\cos\theta_i\cos\theta_f+\sin\theta_i\sin\theta_f\cos(\phi_i-\phi_f).$$

So if the initial angle θ_i is arbitrary relative to the z axis from which the quadrupole potential is measured, the amplitude will depend on ϕ as well as θ. Now for the special case $\theta_i=0$, Eq. (3.15) reduces to

$$\cos\theta_K=\sin(\theta/2)\quad(\theta_i=0),$$

where we have written $\theta_f=\theta$. $P_2(\cos\theta_K)$ is then given by

$$P_2(\cos\theta_K)=P_2[\sin(\theta/2)]=\tfrac{1}{4}(1-3\cos\theta)\quad(\theta_i=0). \quad (3.16)$$

The third term in Eq. (3.14) is the known term[4] giving the lowest order effect of the r^{-4} potential. As a consistency check, if one considers the case $\theta_i=0$, the imaginary terms for $\theta_f=0$ may be deduced from the two leading (real) terms by means of the optical theorem[9] and they agree with those in Eq. (3.14).

Digitized by Arya Samaj Foundation Chennai and eGangotri

Now, to proceed to second order, we substitute $f_r^{(1)}$ from Eq. (3.13) with the required changes of angles back into the right-hand side of Eq. (3.9). The leading term in $f_r^{(1)}-f^{(0)}$ is the first q term in (3.13) which is $O(1)$. This term multiplied with the q term in the potential will given a q^2k term as mentioned above. All other terms are $O(k^2)$ and hence higher order (except for second-order corrections to the scattering length arising from the p terms). Since further iterations may be seen to produce only higher order terms, $f^{(2)}$ is as high in perturbation theory as we shall go, and so, letting $r\to\infty$, we find

$$f_\infty^{(2)}(\mathbf{k}_i\to\mathbf{k}_f)-f_\infty^{(1)}=-(1/4\pi)\int_{kR}^{\infty}x^2dx \times\int d\Omega(q/x^3)P_2(\cos\theta)(k/x)qP_2(\cos\theta_{K'}) \times[\tfrac{1}{3}-j_1(K'r')/K'r']e^{ix[1-\cos(\theta_f,\theta)]} +(\mathbf{k}_i\leftrightarrow-\mathbf{k}_f)+O(k^2), \quad (3.17)$$

where, according to the requirements of Eq. (3.9), $\theta_{K'}$ is defined as the angle made with the z axis by the vector $\mathbf{K}'=\mathbf{k}_i-\mathbf{k}'$. An analysis like that leading to Eq. (3.15) for θ_K gives

$$\cos\theta_{K'}=\frac{\cos\theta_i-\cos\theta}{\sqrt{2}[1-\cos(\theta_i,\theta)]^{1/2}}, \quad (3.18)$$

while the magnitude K' is equal to $k\sqrt{2}[1-\cos(\theta_i,\theta)]^{1/2}$. The corresponding quantities for $(\mathbf{k}_i\leftrightarrow-\mathbf{k}_f)$ should be clear. The r' should be eliminated by the relation $K'r'=(K'/k)x$. At this point it does not seem that the integrations in Eq. (3.17) can be carried out analytically, so we will simply write

$$f_\infty^{(2)}-f_\infty^{(1)}=q^2kI(\theta,\phi)+O(k^2), \quad (3.19)$$

where

$$I(\theta,\phi)=-(1/4\pi)\int_0^\infty dx x^{-2}e^{ix} \times\int d\Omega P_2(\cos\theta)P_2(\cos\theta_{K'}) \times[\tfrac{1}{3}-j_1(K'r)/K'r]e^{ix\cos(\theta_f,\theta)} +(k_i\leftrightarrow-k_f)$$

$$=(4\pi)^{-2}\int d\tau_x x^{-4}e^{ix}e^{-ix\cos(\theta_f,\theta)}P_2(\cos\theta) \times\int_0^x x'^2dx'\int d\Omega' x'^{-3}P_2(\cos\theta') \times e^{ix'\cos(\theta',\theta_{K''})}+(\mathbf{k}_i\leftrightarrow-\mathbf{k}_f). \quad (3.20)$$

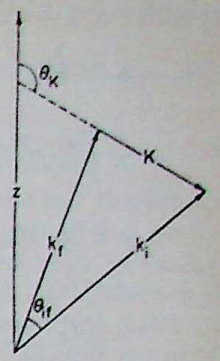

FIG. 1. Shows schematically the meaning of the angle θ_K.

$I(\theta,\phi)$ has been written in the alternate form of a double integral from which it arose, since it might prove more amenable to solution in this form. At any event it should be possible to evaluate the integrals numerically for various values of θ_f and ϕ_f if it is ever needed. The angle $\theta_{K''}$ represents the vector $\mathbf{K}''$ which is the difference between the vectors $\mathbf{k}_i$ and $\mathbf{k}'$, the latter having the angles θ' and ϕ' of integration. $I(\theta,\phi)$ should of course have both a real and an imaginary part.

As mentioned earlier, an evaluation of $f^{(3)}$ leads only to terms of $O(k^2)$ aside from further renormalizations of the scattering length, A. The final result then may be written, combining Eqs. (3.19) and (3.14),

$$f(\mathbf{k}_i\to\mathbf{k}_f)=-A+\tfrac{1}{3}qP_2(\cos\theta_K) -\tfrac{1}{4}\pi pK+q^2k\,\mathrm{Re}I(\theta,\phi)-(\pi/16)p'KP_2(\cos\theta_K) +ik[A^2-\tfrac{1}{12}qA(P_2(\cos\theta_i)+P_2(\cos\theta_f)) +q^2\,\mathrm{Im}I(\theta,\phi)]+O(k^2), \quad (3.21)$$

where the renormalized quantity, $A=A(\infty)$ has been substituted throughout, and θ_K may be found from Eq. (3.15), ff. Eq. (3.21), the final result of this section represents the expansion of the scattering amplitude through terms linear in k for the potential of Eqs. (3.1) and (3.2). An attempt will be made in Sec. 4 to apply this result to low-energy electron-atom scattering.

Dipole Potential

As a digression, let us attempt to apply the above method to a potential whose asymptotic form contains a leading dipole term

$$U(\mathbf{r})\sim D\cos(\theta)/r^2. \quad (3.22)$$

(This kind of potential arises in connection with the scattering of electrons from the excited states of the H atom, because of the accidental degeneracy between states of different angular momentum.) We substitute this asymptotic form into Eq. (3.3), neglecting any higher order terms in U since we shall only look for the leading k term in $f(\theta)$. In addition, we again substitute the new variables $kr'=x$ and $Kr'=y$, and multiply through by a factor k. We find in place of

Eq. (3.9)

$$kf_r(\mathbf{k}_i \to \mathbf{k}_f) = kf_R - (1/4\pi)\int_{kR}^{kr} x^2 dx \times \int d\Omega D\cos(\theta) x^{-2}\left[e^{iy\cos(\theta,\theta_K)} + x^{-1}kf_x(\mathbf{k}_i \to \mathbf{k}')e^{ix}e^{-ix\cos(\theta,\theta_f)} + x^{-1}kf_x(-\mathbf{k}_f \to \mathbf{k}')e^{ix}e^{ix\cos(\theta,\theta_i)} + x^{-2}kf_x(\mathbf{k}_i \to \mathbf{k}')kf_x(-\mathbf{k}_f \to \mathbf{k}')e^{2ix}\right]. \quad (3.23)$$

Now by Eq. (3.11) f_R is $O(1)$. (As mentioned before the ik term would be different for a dipole potential, but this is a higher order term anyway.) So kf_R is $O(k)$. Let us neglect terms of $O(k)$ as higher order and look only for terms of lower order than this. We then have $kf^{(0)} = O(k)$. Using this on the right-hand side we find for $f^{(1)}$

$$kf^{(1)}(\mathbf{k}_i \to \mathbf{k}_f) = -\left(\frac{D}{4\pi}\right)\int_{kR}^{kr} dx \times \int d\Omega \cos\theta e^{iy\cos(\theta,\theta_K)} + O(k) = -iD(k/K)\cos\theta_K[1 - j_0(y)] + O(k). \quad (3.24)$$

Thus, in first order, kf is $O(1)$ as we could see by inspection of (3.23). If we now proceed to substitute $kf^{(1)}$ on the right-hand side in order to find $kf^{(2)}$, we see immediately that the new terms are also $O(1)$ and so to all higher orders of perturbation theory. So that the situation here is very different from that for an r^{-3} or r^{-4} potential, where the new terms in higher orders of perturbation theory represented successively higher powers of k. With the dipole potential, all orders of perturbation theory give the same power of k, namely $f \propto k^{-1}$. Thus for the dipole potential, Eq. (3.24) (for $y = \infty$) gives only the first Born approximation to the k^{-1} term in $f(\theta)$, and so will only be of use if D happens to be very small. For moderate D higher order perturbation terms would be needed, while for still higher D the expansion will very likely not converge at all.

So we see that unfortunately the present method breaks down for a potential which falls off as slowly as r^{-2}. From Eq. (3.24) we may at least salvage the qualitative result that the amplitude diverges as k^{-1} in agreement with the classical result,[10] and also with that of Seaton[11] who considered the electron-hydrogen problem for a fixed value of the total angular momentum L, and with Gailitis and Damburg[12] who carried this result somewhat farther. If one wishes to go beyond the Born approximation or the contribution to the amplitude from single angular momentum states, what seems to be needed is an exact solution of the wave equation with the dipole potential (3.22).

4. ELECTRON-ATOM SCATTERING

The particular asymptotic form of the potential $U(r)$ given by Eq. (1.1) was chosen because it corresponds to the long-range interaction between a neutral atom (or molecule) in a particular state and a charged particle (electron).

The potential between an atom and an electron is taken (neglecting spin-dependent forces) to be the sum of all Coulomb forces between particles (electrons and nucleus). When the separation r is very large, the interaction assumes the asymptotic form

$$V(\mathbf{r},\mathbf{r}_j) \sim \sum_{L=1}^{\infty} e^2/r^{(L+1)} \sum_{j=1}^{Z} r_j{}^L P_L[\cos(\theta,\theta_j)], \quad (4.1)$$
